(3) Immediate serum reactions of a dangerous nature were rarely seen in the present series of cases, except that one or two batches of a particular concentrated mixed serum did cause rigors and collapse at both the centres where they were used. There were no unpleasant late anaphylactic results with the concentrated serum. On the whole a good serum seemed to be devoid of disturbing effects on the patient, and on these grounds there need be no hesitation in the use of the treatment.

(4) The benefits from serum are not so emphatic as to make it desirable that all severe cases of lobar pneumonia, irrespective of the type of the infecting pneumococcus, should be treated with type I and type II antiserum on the chance that they might

belong to a type which is favourably influenced. Moreover, the special technique required for repeated intravenous injections, and the cost of the serum make the treatment unsuitable for universal application.

Each case must be typed as soon as possible, so that the appropriate serum may be used in the optimum dose; the use of the serum is not recommended except under conditions where typing of the pneumococcus can be obtained.

(5) If accurate typing of the sputum can be done in five or six hours, serum should be withheld until the type is known, and then a dose of 20,000 Felton units of the specific serum given. But if more time is required for the typing, then a preliminary dose of 20,000 Felton units type I, together with 20,000 units type II, should be given; and the specific type serum, either I or II alone, continued when the nature of the infection is known.

Treatment is continued by injection of 20,000 units at a time, twice a day with approximately an eight-hour interval. Usually a total dosage of 80,000 units, with variation from 50,000 to 120,000 units, of the single specific serum is required, type II cases on the whole needing a larger dosage than type I. If no obvious clinical improvement occurs in the first 48 hours of serum treatment, it is probably useless to continue with it.

(6) The serum should be given intravenously. There is no satisfactory preliminary test for any peculiar sensitiveness of the patient to horse serum. The first injection should therefore be made cautiously and slowly, 1.0 c.cm. being introduced into the vein in a minute or two and the total being injected in 10 or 15 minutes. Adrenaline solution 1/1000 must be ready beforehand, and 0.5 or 1.0 c.cm. of this should at once be injected *subcutaneously*, if the patient reacts unfavourably with collapse and failure of the pulse or urgent dyspnoea. Second and subsequent injections of serum may be given with less precaution.

In addition to anaphylactic sensitiveness of the individual, there is the chance that the serum supplied by the manufacturer may contain protein substances which are toxic to most individuals, as occurred in a few batches used in the present inquiry. To safeguard against this, 1.0 c.cm. of the serum may be injected intravenously, and the remainder of the dose slowly injected half an hour later, provided that no untoward symptoms have occurred. This precaution is unnecessary if the batch of serum is known to be harmless, either from other experience, or because the manufacturers state that it has already been tested from this point of view.

(7) No data were collected in this inquiry with regard to the use of the serum in children, or in patients over the age of 60, or in cases of broncho-pneumonia.

Blood Transfusion

By NORMAN HILL, M.D., M.R.C.P.

(From the *Medical Press and Circular Supplement*, 24th January, 1934, p. 14)

COMPARATIVELY few years ago a blood transfusion was regarded as a procedure only to be undertaken by a specialist in that particular branch of medicine, but at the present time transfusions are being given daily by house physicians and house surgeons throughout the country. As the resident medical officers of to-day are the practitioners of to-morrow, it follows that transfusions have passed out of the hands of the specialist, and can be undertaken by any practitioner familiar with the technique. The methods here described do not attempt to include all the various ways of giving blood, but they do claim to be both simple and efficient.

BLOOD GROUPS

It has been found that blood indiscriminately transferred from donor to recipient may produce in the

latter dangerous and even fatal symptoms, so that the suitability of the donor's blood must always be ascertained before commencing a transfusion. These symptoms, which include precordial pain, urticaria, collapse, and sometimes death, are due to the fact that in some cases the corpuscles of the donor are agglutinated by the serum of the recipient, and if this takes place that particular donor should on no account be used.

There are four main blood groups, described as 1, 2, 3, 4. Group 1 is known as the universal recipient, as he can receive blood with safety from his own group, and also from groups 2, 3 and 4. Group 4 is known as the universal donor as he can give blood to his own group and also to groups 1, 2 and 3. All groups may receive blood from similar groups, or from group 4. Group 4 can only receive blood from group 4. The most common groups are 2 and 4. In order to ascertain the group to which any particular individual belongs, it is necessary to procure a small quantity of group 2 and group 3 sera: these are usually supplied ready for use in sealed capillary tubes. The serum is then expressed on to a white porcelain dish—a household plate will serve—previously marked so that the groups will not be confused. A drop of blood of the unknown group is then obtained, and about as much as will fill the eye of a large needle is mixed with the serum. It is a good thing to use two needles using the eye of one for group 2 serum and the eye of the other for group 3, and by this means there is no possibility of mixing even a small quantity of the sera. The dish should be gently agitated so as to mix thoroughly the sera and corpuscles. If agglutination takes place the appearance is that of a sprinkling of cayenne pepper, whilst if there is no agglutination, the two drops remain as they started after the original mixing. A hand lens may be used for observing this, but it is usually unnecessary, agglutination being obvious to the naked eye. If agglutination should occur it will be seen in the first minute or two if fresh active serum is used, and the mixtures need never be watched for longer than five minutes.

It is important to note that if tubes of the known sera be kept for any length of time they should be stored in an ice chest, otherwise they tend to deteriorate, and fallacious readings may result if the tubes have been kept at ordinary room temperature. Reference is then made to the accompanying table and the group determined.

Corpuscles	Serum			
	1	2	3	4
1	—	+	+	+
2	—	—	+	+
3	—	+	—	+
4	—	—	—	—

For example, if there is agglutination in both drops, then the blood is group 1; if there is no agglutination in the group 2 serum, but there is in the group 3, then the blood belongs to group 2.

If no known sera are available, then the patient and donor cannot be grouped, but a direct agglutination test may be carried out in order to discover whether the particular donor is suitable for the patient, even though neither blood group may be known. This is performed by taking a little blood from the patient and obtaining the serum from it. This may be done either by withdrawing about 1 c.cm. of blood and placing it in a narrow tube, when the serum will gradually separate; or by filling a capillary tube with blood, and after coagulation a string clot can be pulled out, leaving sufficient serum for the test.

The test is carried out in exactly the same manner as described under grouping, the drop of the patient's serum being mixed with the blood of the donor. If no agglutination takes place, then that donor is suitable for the patient.

When giving a transfusion to a patient with one of the 'blood diseases' (pernicious anaemia, etc.) it is

always safer, even though the groups of both donor and recipient are known, to do a direct agglutination in addition, as in practice these 'anæmic' bloods do not always behave as in theory they should do, and agglutination occasionally occurs in groups which should be quite compatible.

THE TRANSFUSION (CITRATE METHOD)

The most simple method of all is to administer the blood in exactly the same manner as an intravenous saline is given, and with this method a minimum of apparatus is required.

The essentials are: a flask graduated up to 1,000 c.cm., a funnel, some rubber tubing, glass connections, a clip, and needles. In order that the blood may not coagulate, it must be received direct into an anticoagulant, and the flask, sterilized either in the autoclave or by boiling, must be prepared in advance. Into the flask is introduced 50-100 c.cm. of sterile normal saline at about 100°F., to which is added the necessary quantity of sodium citrate. This quantity naturally varies with the amount of blood it is proposed to take: 1 gm. of citrate should be sufficient for 400 c.cm. of blood, though it is probably safer to add rather more than this. The citrate can be obtained from many chemists made up in solution, a sterile ampoule containing 1 gm. of citrate in 3 c.cm. The flask should now be corked, and the first stage of the transfusion may be started.

The donor should preferably be a young healthy male with prominent veins, and only those with no taint of venereal disease, malaria, etc., should be used. He should be lying on a couch or bed with the arm selected on the edge. A tourniquet or better still a sphygmomanometer, should be placed round the arm well above the region of the antecubital fossa, and the armlet inflated until the dial reads about 80 mm. It is of the utmost importance that the arm be not compressed too tightly, or else the blood will not flow, hence the advantage of the sphygmomanometer over the tourniquet. When pressure is put on the arm the veins in the region of the bend of the elbow, the median cephalic, and the median basilic will become prominent, and can be made even more so by the donor clenching his fist.

The needle—and the type known as a French's needle is recommended—is now introduced into the vein in an upward direction, and if this manœuvre is performed successfully, blood will be seen through the glass connector coming down the tube into the flask. The latter should be held low down preferably by an assistant, and gently rotated in order to mix the blood and citrate together. As the blood flows the donor should clench and unclench his fist at intervals, about twelve to fourteen times per minute, and this pumps the blood from his vein into the flask. The assistant should be most careful not to put any tension on the tube attached to the flask, as if this occurs the needle may be pulled out of the vein, and the latter rendered useless for that particular transfusion. The blood should flow in a fairly rapid stream, accentuated every time the donor clenches his fist and unless the blood does flow rapidly there is danger of coagulation between the needle and the flask. If blood ceases to flow, or the rate suddenly decreases, a little gentle manipulation of the needle, such as a very slight withdrawal, will usually start the stream flowing again.

In order to prevent coagulation it has been suggested that sterile paraffin should be run through the tubing before taking blood, but I have never found this procedure necessary. As soon as the requisite amount of blood has been obtained the armlet is deflated, the sphygmomanometer removed, the needle withdrawn, a wad of sterile wool placed over the puncture, and the donor made to flex his elbow as far as possible. He should then be given half to one pint of hot coffee, and made to rest for an hour, after which he may go home. During these attentions to the donor the flask

of blood should be placed in a vessel containing warm water, so that the blood will not cool.

Some controversy has taken place as to whether a local anæsthetic should be given to the donor. If the needle is as sharp as it ought to be, this is seldom necessary, and most donors whom I have asked prefer to do without it. One of the objections to a local anæsthetic is that when the vein is not easily seen it may be masked altogether by the injection. Some operators give a small bleb of anæsthetic intradermally, and make a tiny incision in the skin, just large enough to take the needle, and this avoids the force sometimes necessary in introducing the needle through the skin. It should never be necessary to cut down upon the vein of the donor, and most bodies supplying donors, such as the London Blood Transfusion Service, rightly insist that this shall not be done. It cannot be emphasized too strongly that the needle should be sharp, and I have seen more than one transfusion ruined as a result of a blunt needle tearing the vein and causing a hæmatoma, which renders the vein useless for some time.

Everything is now ready for the administration of the blood to the recipient. If one of his veins is visible the blood can be given through a needle inserted into the vein, but if the vein cannot be clearly made out, a condition which obtains in many bloodless subjects, it must be dissected out, and a glass cannula inserted. If the intravenous needle is used, a tourniquet may be applied above the vein in order to render it more distinct; as soon as the needle is inserted the tourniquet should be removed. The funnel and rubber tubing, including the needle, should now be filled with warm sterile normal saline until the latter is visible at the lowest part of the funnel, and a clip applied at the needle-end. The tubing is then gently massaged in order to expel any air bubbles, which will come to the surface of the saline showing in the funnel.

The needle or cannula is now introduced into the vein, and the warmed blood gently poured down the side of the funnel until the latter is full, the clip released, and the funnel elevated about twenty-four to thirty inches, when the blood flows into the vein by gravity. Towards the end of the transfusion the remaining blood may be somewhat 'frothy' and this froth must on no account be introduced into the vein, so that the injection should be stopped by tightening the clip before the froth has left the funnel. An assistant should be always be present, as it is most difficult to carry this out single-handed; it is essential for one to keep the needle in the vein of both donor and recipient as the slightest movement may dislodge it and cause failure.

Within a few hours of transfusion by the citrate method the recipient may have a rigor and high temperature. This is of short duration, and I have never seen harm result, unpleasant though it may be for the patient. It seems to be more common in those cases suffering from a 'blood disease' than in the purely surgical cases.

Flask fitted for giving blood.

Another method of giving citrated blood is by pumping the blood direct from the flask, into which it is received, through an airlock into the vein of the recipient. The apparatus required consists of a stout graduated glass flask with side-piece, rubber corks, air

filter, an airlock, glass tubing and glass connectors, rubber tubing and clip. In addition, a pump, scent spray type, and an evacuator are required.

The blood is taken from the donor in exactly the same way as has already been described. The cork and tubing used during the taking of blood is now removed, and the cork with the bent glass tube, to which is attached the airlock, tubing, and cannula, is inserted in its place.

The tubing is filled with warm sterile saline up to the top of the airlock, and the clip tightened; this can easily be done by attaching the evacuator to the air filter, and gently squeezing the needle meanwhile being dipped in the saline solution. This procedure can be done whilst the apparatus is being prepared, as once the clip has been tightened the cork can be removed from the flask, and none of the saline will escape when it is laid aside. The evacuator is now removed, the pump substituted, and all is ready to start. Once the needle or cannula is in the vein, the clip is loosened, and pumping started. As the blood flows over into the airlock, a certain amount of the saline in the latter is displaced by the air contained in the bent glass tube, but after that the blood level remains about the middle of the airlock until the transfusion is finished. When the last of the blood is going in, this level in the airlock begins to fall, and at that point the clip should be tightened, and the transfusion ended. In the use of this apparatus there are two practical points which are of importance; firstly, the cork should either be tied on to the flask, or held firmly in by an assistant when the blood is being pumped in; and, secondly, it is advisable to secure the rubber tubing to the glass by means of some soft copper wire, as after the tubing has stretched leakage may take place at these joints. The advantages of this method are that it is more easy to work single-handed than the funnel method, and that the blood is never exposed to the air.

Other methods of giving blood usually require more complicated and more expensive apparatus, and are not so suited to the occasional transfusion which may have to be performed by the practitioner. These include the giving of whole blood, and defibrinated blood.

INDICATIONS

The indications for blood transfusion are many and varied, but can be divided roughly into surgical and medical.

Surgical.—The chief indication is hæmorrhage, and transfusion may be done either simply to make up for blood lost accidentally, or to enable the surgeon to operate on a bloodless patient. If given for the latter cause, it may be done before, during or after operation, and in very severe cases may be performed in all three periods. There is no doubt that transfusion has enabled surgeons to operate successfully on many cases in which, without it, operative measures would have proved fatal.

Medical.—Pernicious anæmia. Before the introduction of liver therapy, transfusion was almost a routine during some period of this disease. At the present time it is almost unnecessary except in those cases which are moribund when first seen. Such patients are often unable to take food, and an initial transfusion is the most rapid method of restoring them to normal health. Severe anæmias of the pernicious type which do not respond to liver or hog's stomach may be benefited permanently by a transfusion.

Purpura.—When excessive bleeding has taken place, transfusion may be a life-saving measure. It is almost always necessary before splenectomy in those cases of essential thrombocytopenic purpura hæmorrhagica.

Hæmophilia.—Transfusions every few months are said to benefit these cases. It should always be done prior to any possible operative measures.

Leukæmia.—May be done as symptomatic treatment. It never does any lasting good.

Hæmatemesis and melana from peptic ulcers.—In severe cases transfusion is recommended, even though

no surgical interference is anticipated. The idea that the introduction of fluid into the circulation will raise the blood pressure and restart the bleeding is not borne out in practice.

Ulcerative colitis.—Severe cases are undernourished and anæmic, and a blood transfusion, repeated if necessary, is often the turning point in their illness, and should always be given if they do not respond readily to the usual treatment.

Hæmorrhage in the newly born.—Transfusion often is the only remedy, and should always be done. Blood may be taken (5-10 c.cm.) direct from a parent's vein, and injected intramuscularly into the infant, and repeated in a few hours. If this is done rapidly clotting will not occur. Given thus, the blood need not be grouped.

Marasmus.—Good results have been reported from transfusions in this condition, though, personally, I have never seen them.

Finally, as regards the quantity of blood that should be injected, there is no hard-and-fast rule, and it must be left largely to the discretion of the operator. Five hundred c.cm. is an average amount for an adult to receive. If it is desired to inject very large quantities, it is better to give repeated transfusions than one enormous one.

Treatment of Decubitus with Tannic Acid

By EARL O. LATIMER, M.D.

(From the *Journal of the American Medical Association*, Vol. 102, 10th March, 1934, p. 751)

DECUBITUS, or pressure sore, is the result of local impaired nutrition, frequently in a person whose tissues have a lowered resistance because of age, disease, injury or nerve involvement. Such lesions are initiated by pressure and often aided by some slight injury or by irritation from urine, feces or perspiration. While the lesion often occurs in paralysed parts, it is by no means limited to patients with nerve involvement. The soft tissues over bony prominences are the common location of these ulcers; but with the widespread use of casts, splints and skin traction few parts of the body surface are exempt. Pressure produces a local ischæmia with subsequent thrombosis, death of tissue and ulcer formation.

Prophylaxis is the ideal procedure. Such measures as frequently changing the position of the patient, massage, dusting powders including lead tannate, cleanliness and protection of susceptible parts are of the utmost importance. Air cushions, rubber rings and pads aid in relieving pressure on the skin overlying bony prominences. Too much emphasis cannot be placed on the proper fitting of casts and splints and the careful application of skin traction. The mere removal of pressure from an involved region does not necessarily prevent the continued development or extension of the lesion. Not infrequently decubitus develops in spite of prophylactic measures. This is especially true of patients with cord lesions and bed-ridden, aged, emaciated and diabetic patients.

Once the lesion has developed, the recommended local treatments are numerous. A few therapeutic measures advocated are ointment of zinc oxide, scarlet, red ointment, silver nitrate solution, ultra-violet rays, sunlight, dry heat and excision of the slough. More recently, sulphosalicylic acid and thiocresol have been recommended. The sulphur-containing radical is believed to stimulate epithelial growth. In severe cases and in extremely emaciated patients the continuous water bath has been used. Treatment to improve the general condition of the patient is important.

The gross similarity of decubitus to certain burns suggested the rationale of treating suitable lesions with tannic acid. Bligh treated an abrasion with tannic acid and Maddock used it to treat the surface from which Ollier-Thiersch grafts were removed.

Chapter II deals with sympathectomy for disorders of the circulation. The most interesting feature is the selection of cases suitable for the operation. The various tests for this purpose have been discussed in detail. Some of them require special instruments and appliances.

As regards periarterial sympathectomy the reviewer also is of opinion that though it has been given up nowadays as anatomically and physiologically unsound, it certainly relieves the patients of the severe pain which makes them pass sleepless nights for months together, helps in limiting the spread of gangrene by the formation of a definite line of demarcation, and accelerates healing of chronic ulcers of the leg. But unfortunately its effects do not last for more than three weeks.

A good account of cervical and lumbar ganglionectomy is given and is of great value to surgeons who have some idea of the anatomy of the parts. For cervical ganglionectomy the anterior route is always preferred by the reviewer as it is really a piece of fine dissection without practically any bleeding.

Chapter III deals with sympathectomy for disorders of the visceral motor mechanism. The different views about peristalsis have been discussed and all the recent work on the nerve supply of the intestines has been incorporated. Megacolon and its operative treatment have been dealt with.

The book is well illustrated. Most of the illustrations have been borrowed from different journals, especially the *British Journal of Surgery*. The book will be of immense value as full references are given at the end of each chapter. It is good reading and may be read and re-read with much profit. It is well printed on good paper.

We should like to see another edition of this book in the near future and hope that further work by the authors on this line will be embodied.

D. C. C.

BRIGHT'S DISEASE: A CLINICAL HANDBOOK FOR PRACTITIONERS AND SENIOR STUDENTS.—By J. Norman Crulokshank, M.C., M.D., D.Sc., F.R.F.P.S. (Glas.), M.R.C.P. (Lond.). 1933. E. and S. Livingstone, Edinburgh. Pp. x plus 208. Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 7-14

NOTWITHSTANDING the constant research and much discussion on the subject of nephritis, the classifications of this disease are not always well balanced, and the different schools of thought have, from time to time, put forward arguments in their defence, which are nearly always more eloquent than plausible. From among the mass of literature on the subject the author has tried to provide practitioners and students with a clear view of the nature of Bright's disease, discussed from a clinical point of view.

The book opens with a chapter on general consideration regarding the normal functions of the kidney. With the idea of studying the functional abnormalities on scientific lines, the author has devoted much attention to the consideration of the associated structural changes—an attempt which is rational and helpful for it furnishes the readers with a secure basis for a clear conception of the disease.

In connection with the classification of the types of Bright's disease, the author has followed the German school, particularly the work of Volhard and Fahr, and in the preface he has acknowledged his gratitude to Professor Fahr for giving him access to his collections of histological preparations. From a clinical point of view it is recognized that most cases of Bright's disease have mixed lesions and it is very difficult to lay down a clear-cut line of demarcation between the different types. On a rough basis of the different types of structural changes in the kidney which gives rise to a recognizable clinical syndrome, and fitting in as closely as possible with the modern knowledge of pathogenesis and symptomatology, the author classifies the disease

as being of three main types: (a) an exudative or 'haemorrhagic' group; (b) a degenerative group, and (c) a vascular or ischaemic group. These types are rarely seen in pure form except in their initial stage, and are not meant to be a guide to the histopathology of the kidney.

While the author has dealt elaborately with the description of morbid changes in the kidney, it is disappointing to find that he has not given any illustration of the main histological appearance, which would have been of great help to students of clinical medicine. The treatment of the various forms of Bright's disease has been considered fully in a separate chapter, and the diet schemes given are very helpful. The chapter on oedema contains a critical survey of the various factors concerned and the conclusions drawn at the end of the chapter are useful. In the chapter on uraemia, the author has not brought out a clear distinction between the . . . of terminal renal failure and that . . . cerebral manifestation of hypertension. In the appendix, the technical details of some methods employed for estimating renal functional efficiency are given, while in a previous chapter the author has given a warning regarding the limitations of such laboratory methods.

The book is written in a clear style and will help and interest the medical practitioners in this country.

R. N. C.

CLINICAL INVESTIGATION OF CARDIOVASCULAR FUNCTION.—By V. Pachon and R. Fabre. Translated by J. F. Halls Dally, M.A., M.D. (Cantab.), M.R.C.P. (Lond.). 1934. Kegan Paul, Trench, Trubner and Co., Ltd., London. Pp. xl plus 252. Illustrated. Price, 15s.

This volume is the result of many years' experience of the joint authors. Science is ever progressing and the old methods are gradually giving place to the new. The investigation of cardiovascular functions is a difficult and complex affair, and the old methods of inspection, palpation, auscultation, etc., by the unaided senses are not complete in themselves, and do not satisfy present-day clinicians. The newer methods have brought to light many facts hitherto unknown and have furnished valuable information regarding the working of this system.

The book is divided into two parts. The first part deals with the principles for investigating the cardiac function proper and the deviation occurring in various diseased states. The second part deals with the methods investigating the condition of the vessels and the blood. In the opening chapter, the authors have described the principles of cardiography and its clinical interpretations in various pathological states of the valves, myocardium and cardiac dysfunction. The method of functional exploration of the right side of the heart in normal and pathological states has been clearly dealt with in the chapter on jugular phlebography. The chapter on electrocardiography is brief in comparison with the importance of the subject, but is clear and concise. The method of diagnosing heart disease by radiograms of the component parts of the organ . . . of recent years and the chapter on . . . numerous graphical illustrations will be of great practical value to the cardiologist. The inclusion of the recent oscillatory method with other methods of sphygmomanometry for clinical determination of arterial pressure will be helpful to the clinician. The description of the oscillogram and its working is comprehensive and clear. The problem of hypertension has been attracting the attention of the profession and the chapter on the variations of arterial pressure deals clearly with various factors responsible for such variations in health and disease. The chapters on functional investigation of capillary circulation by capillaroscopy and viscosimeter are also interesting. The concluding chapter dealing with the classical functional tests for investigating the nervous

control of the heart and the vasomotor system on the one hand and assessing the degree of circulatory sufficiency or insufficiency on the other are of great value.

The English-reading public are indebted to Dr. Dally for translating this book which will not only be useful to the clinician, but also to the research worker in this branch. The book should form part of the library of all cardiologists and practitioners interested in the subject.

R. N. C.

A TREATISE ON DISEASES IN GENERAL PRACTICE OF ADULTS AND CHILDREN IN CEYLON.—By B. S. Jayawardene, L.R.C.P. & S. (Edn.), L.F.P.S. (Glas.), L.M.S. (Ceylon). Parts I and II. 1933. Published by H. W. Cave and Co. (Colombo), Ceylon. Pp. 407. Price, Rs. 4

This book is intended to be a notebook for a qualified doctor of the sub-assistant-surgeon class rather than a systematic treatise for the use of students. The title is therefore not a very good one. Further, the subject is general diseases, seen from the point of view of the doctor in Ceylon, and not diseases peculiar to Ceylon, as the title might lead one to expect. We mention this because we think that the doctor in India may be inclined to pass this book over because its title suggests only local interest, whereas actually he will find in it information that is equally applicable in most parts of India.

The first half of the book is really a series of leaflets that the author has written for his patients and has at times distributed to them; the language is popular, and the subject is special hygiene. The chapters are entitled 'Prevention of.....' some disease or group of diseases, e.g., venereal disease, typhoid, vitamin deficiency.

The second part of the book deals with treatment of various diseases under their separate headings, e.g., malaria, tuberculosis, amebiasis. The notebook style of writing with numerous headings and terse sentences is maintained throughout. The information is on the whole very sound and the authority for many of the statements is given. The book is unfortunately marred by a number of misprints, some of which are of a serious nature, as for example on page 301 the heading 'macrocytic' should obviously be 'microcytic'.

It is a cheap book, and we can say with confidence that readers of the sub-assistant-surgeon class will find much in it that will help them in their practice.

CHRONIC NASAL SINUSITIS AND ITS RELATION TO GENERAL MEDICINE. (Chronic Sinusitis and Systemic Sepsis).—By P. Watson-Williams. Second Edition. 1933. John Wright and Sons, Ltd., Bristol. Pp. xx plus 262. Illustrated. Price, 15s.

MR. PATRICK WATSON-WILLIAMS has been the first to write a book dealing with this highly interesting subject, the systemic effects of nasal sinus infections. That he has done this well there is no doubt; the author admirably traces the relationship to general medicine of sinus disease. This relationship, though always recognized vaguely before, has never been more forcibly put before the medical profession. To the general practitioner the book is of special value as it puts before him the various conditions that sinus infections may be responsible for, and to a specialist, a very comprehensive account is given of the author's 'exploration-suction' technique in the diagnosis of infected sinuses and the operative procedures for their cure.

I feel confident that both these classes of medical men will find much to learn from a perusal of its pages.

N. J. J.

CALCIUM METABOLISM AND CALCIUM THERAPY.—By Abraham Cantarow, M.D. Second Edition. 1933. Henry Kimpton, London. Pp. xii plus 252. Price, 12s. 6d.

CALCIUM compounds are extensively used in therapeutics and during recent years a large amount of

work, both clinical and experimental, has been done and literature has accumulated. Dr. Cantarow has had an excellent opportunity of studying this difficult subject and has placed before the reader in a lucid and concise manner, the functions of calcium in the organism and the present position of calcium in therapeutics.

The book is divided into three parts: Part I deals with calcium requirement and excretion, blood calcium and functions of calcium in the body. In this part he has also dealt with the physico-chemical side of the subject. In Part II, disorders of calcium metabolism have been described, and the subject of parathyroid hormone and the indications and limitation of calcium therapy have been discussed. In the chapter on disturbances of blood calcium level and partition, the author has exhaustively dealt with the conditions of hypocalcaemia and hypercalcaemia. Part III deals in detail with the subject of calcium therapy by the oral, subcutaneous, intramuscular and intravenous routes. A chapter has also been devoted to hypoparathyroidism and tetany in which the author has described the incidence of the disease in infants and other conditions where tetany is only a symptom. The non-specific calcium therapy in dental caries, pregnancy, milk fever in cattle, eclampsia, acute hepatic insufficiency, jaundice, oedema, etc., has been fully discussed in the last chapter.

The book is well written and is a useful contribution to the literature. It will appeal both to the general reader and the research worker. The publishers are to be congratulated on the excellent get-up of the book.

R. N. C.

RHEUMATISM IN GENERAL PRACTICE: A CLINICAL STUDY.—By M. B. Ray, D.S.O., M.D. (Edn.). 1934. H. K. Lewis and Co., Ltd., London. Pp. viii plus 404, with 6 plates. Price, 16s.

THIS attractive volume gives a wide survey of the conditions belonging to the group of rheumatic diseases, from the aetiological, pathological, clinical and therapeutic view-points. Lord Horder in his foreword has expressed the opinion that this is the best book on rheumatism in the English language and in this we are inclined to agree.

The opening chapter of the book deals with the physiology of the skin, heat regulation, diathesis and the various adaptive functions of the body. The idea of enumerating these details is good, and it is superfluous to add that the preliminary conception of the various factors at work in the production of the disease is of fundamental importance and essential to the general practitioner before he can arrive at a proper appreciation of the disease. In the next chapters the author deals with acute and subacute rheumatism and rheumatism in children. He has taken, *seriatim*, the various conditions such as chorea, myocarditis, pericarditis and endocarditis, and discusses their causation and pathology in a simple and concise manner. The subcutaneous nodules and joint pains form *inter alia* an interesting survey and the chapter concludes with a useful reference to their treatment, which will repay careful perusal. The inclusion of Still's disease in this section is perhaps not a happy one; it is essentially a manifestation of rheumatoid arthritis in young subjects, the general enlargement of the glands and of the spleen is a peculiarity of the age of the subject and not of the disease. The chapters on fibrositis and arthritis are well written and give a comprehensive idea of the various manifestations of these reactions. The reviewer agrees with the author in dealing with rheumatoid arthritis as a separate clinical entity. Then follow chapters on treatment dealing with diet, physical methods, manipulation, baths, actinotherapy, orthopaedics, spa and climatic treatment. These chapters will be of special interest to the practitioner with a clear description of treatment which can be easily carried out even at home. The tone is stimulating and encourages the practitioner to attack rheumatic disease with some hope of success.

The volume is divided into two parts. The first part deals with the disease in general, while the second part treats of the rheumatic affections considered regionally. This arrangement is of great help from the view-point of differential diagnosis. The anatomical notes are also of great help to the reader, but the short notes on treatment appear to be redundant and somewhat out of place.

The arrangement of the book on the whole is admirable. In view of the fact that rheumatic affection has a wide incidence and has assumed a large proportion in the daily work of every practitioner, the book can be warmly recommended to medical practitioners. A practical solution of most of the difficulties of diagnosis and treatment is offered with an enthusiasm which is essential in a field that has hitherto proved for many one of disappointment and failure.

The get-up of the book is excellent, the paragraphing and clear headings make reference easy. The reproduction of the x-ray photographs and diagrams are of real assistance in diagnosis.

R. N. C.

CLINICAL TOXICOLOGY: MODERN METHODS IN THE DIAGNOSIS AND TREATMENT OF POISONING.—By Erich Leschke. Translated by C. P. Stewart, M.Sc., Ph.D., and O. Dorrer, Ph.D. 1934. J. and A. Churchill, London. Pp. viii plus 346, with 25 illustrations. Price, 15s.

THE book under review is an English translation of a treatise on the modern methods in the diagnosis and treatment of poisoning, written in German by Professor Leschke of the Berlin University. Both in India and Europe cases of poisoning, suicidal and homicidal, are on the increase. The ever-increasing use of poisons in industry, the increasing number of suicides and homicides with poisons due to world-wide social, political and economic upheaval which has followed the war, and the use of various poisonous gases in warfare, have lent additional importance to the subject of toxicology during recent years. Though a number of excellent treatises on this subject are available, the present volume justifies its publication as one which deals with the problem of poisons from the point of view of the clinician.

The book is divided into two parts. The first part discusses in detail the signs, symptoms and treatment of poisoning with inorganic substances and the second part deals with poisoning by various organic substances. A chapter on poisoning by food-stuffs and another on the poisonous animals is included. Illustrative cases given along with different poisons increases the value of the book. Further material has also been incorporated in the three appendices, one dealing with the prevention and compensation of industrial poisoning, the second with the detection of poisoning by post-mortem examination, and the third gives the English and chemical names for the drugs mentioned in the text under German trade names.

The English translation of such an excellent book on toxicology is very welcome. This translation has further been enriched by incorporating, in the body of the original text, a valuable contribution from Professor Koelsch dealing with the subject of occupational and industrial poisoning. We warmly recommend this book to the practitioner and are of opinion that every emergency hospital should have a copy of this book in its library.

R. N. C.

CLINICAL PATHOLOGY.—By P. N. Pantou, M.A., M.B., B.C. (Cantab.), and J. R. Marrack, M.A., M.D. (Cantab.). Third Edition. 1934. J. and A. Churchill, Ltd., London. Pp. x plus 484, with 12 plates (10 coloured) and 50 illustrations in the text. Price, 15s.

Books on clinical pathology do not fall in heavy showers from the cornucopias of the medical publishers of Great Britain, as they do, annually, from those of

North America; this book, therefore, was particularly welcome. It is a book that already has an established reputation, in London from where it originates, in the provinces, and probably in every part of the globe where British graduates are working, as it has that particular practical quality that will always appeal to them. The writers are obviously discussing subjects and describing methods with which, in most instances, they are themselves very familiar, and they are not attempting to demonstrate their erudition and to fill the pages of their book by going beyond the essentials of a subject or giving details of unfamiliar variations of technique. When the subject is beyond the scope of their own practical experience, they have usually obtained outside assistance, as for example in the histological section which has been contributed by Dr. W. W. Woods.

For the benefit of those not familiar with the earlier editions of this book we will give a short list of the various sections, because books on clinical pathology have not yet reached a stage of standardization as have those on many other medical subjects.

The first section is on the blood; this chapter contains some good coloured illustrations of different blood pictures. The second chapter is the longest one in the book, necessarily, as its scope is a wide one; it is on parasitology, and it includes the pathogenic micro- and macro-organisms, from filterable viruses to arthropoda, and the methods by which they are examined and on occasion grown. The subject of immunology is, surprisingly, also included here. The remaining sections are on puncture fluids, the urinary system, including some good figures of urinary casts, etc., the alimentary system, the eye and skin, the respiratory tract, and, finally, histology.

It is a very curious thing that writers who will admit that they are not experts on histology, and have therefore got someone else to write the chapter on this subject, will not make the same admission about protozoology, with which they are probably even less familiar. The impression obtained from some parts of this section is that one is reading the examination answer of a very studious and intelligent candidate. Take for example the paragraph on leishmaniasis; the allusion is maintained by the description of a herpetomonas form as being like a trypanosome without an undulating membrane; we should have cut the candidate a few marks for depicting leishmania, in its somatic stage, only as an extracellular parasite, whereas it is essentially an intracellular organism which is occasionally seen free when a cell has been burst in the process of making the smear; even then we should certainly have given him 95 marks had it not been for the last gratuitous remark—with which the candidate, flushed with success, so often ruins the otherwise good impression he has made—'Natural reservoirs are provided by the dog in some areas and a small rodent, the hamster, in others'. The dog, yes, but as far as we know only one hamster has been found infected in nature, and there was some doubt about that one being an escaped experimental animal. However, even in this section of the book the information is usually sound, and tropical workers will find it very helpful.

We can without any hesitation recommend it as the book on clinical pathology for the student, the practitioner, and the junior laboratory worker; the information is concise, accurate and up to date; and the format is quite up to the best American style, and the price is only about half what it would have been had it been published in that country.

L. E. N.

THE SCIENCE OF RADIOLOGY.—Edited by Otto Glasser, Ph.D. 1933. Baillière, Tindall and Cox, London. Pp. xiv plus 450, with 108 figures. Price, 25s.

THIS is a history of the progress of radiology from the time of the discovery of the x-rays and the emanations of radium.

It will be mainly of interest to American practitioners because it is principally, an account of the progress of radiology in the United States.

Although one must of necessity style this publication a book, it is really a series of short collected papers by different authorities on the various aspects of radiology, for twenty-nine authors have assisted in writing the twenty-five chapters that the book contains.

This practice of many authors combining to produce medical books seems to be growing, especially in America, and while one must admit it has certain advantages in that each aspect of a subject is dealt with by an expert, it destroys the individual character that a book by one author possesses, and gives a very disjointed presentation of any subject. It also leads to a good deal of repetition and the present volume is an excellent example of this fault for almost every chapter opens with a variant of the value of Röntgen's discovery.

RADIOTHERAPY IN THE DISEASES OF WOMEN.—

By M. Donaldson, B.A., F.R.C.S., M.B., Ch.B. 1934. Hodder and Stoughton Limited, London. Pp. xv plus 131. Illustrated. Price, 7s. 6d.

This is a short treatise by one of the best-known British workers in radiotherapy in the field of gynaecology. It is temperate in tone and cautious in opinion, and it utters at the outset a much-needed word of warning on the danger of uninstructed application of radiation by inexperienced persons. It is not enough to have control of a quantity of radium and to push it up against a carcinoma in the vault of the vagina or elsewhere and hope for the best. Such methods only bring discredit on the worker and on radium therapy, and little or no benefit to the patient, but they appear to be common in India where radium work is usually under no recognizable specialized control.

The book deals adequately with the physics of radium and x-rays and with the methods of their application. A section is devoted to the clinical consideration of cancer in the female pelvis (with special reference to carcinoma of the cervix), and with the technique and results at different well-known centres in Europe and America. The importance of proper recording of cases and following up results is well stressed. In this country, where the population in the towns is of a very shifting type, it is usually impossible to trace out more than a very small proportion of cases over any length of time, let alone get an intelligent answer to a questionnaire.

A further section deals with radiation in relation to benign conditions in gynaecology, such as menorrhagia and fibroids, and a chapter is devoted to the dangers of radiation treatment.

Inevitably there are certain inequalities in the composition and proportions of different sections. We are given in detail the elementary anatomy of the uterus, but a very inadequate description of its lymphatics. On p. 55 the author makes the surprising statement that cancer is a disease usually of old age, whereas it is a disease of just-past-middle life. The paths of spread of carcinoma of the cervix are given as (1) by the lymphatics and (2) by spread along the vaginal walls. Later, the commonest mode of all, by direct growth extension in the cellular tissue, comes inevitably under notice. The differential diagnosis of carcinoma of the cervix given on p. 59 is so inadequate as to be better omitted altogether, but the classification of extent of growth (p. 61) is thoroughly up to date and should be taught in all our schools of medicine.

The author is at his best in dealing with operation *versus* radiation in treatment of carcinoma of the cervix, and all operators of experience in this country will sigh for the day when they can be relieved of the awful task of operating on the just-operable case, with its fearful primary mortality and disheartening later results. The stamina of our patients is low and the widespread sepsis following a Wertheim's hysterectomy

so devastating that surgeons are only too ready to use radiation treatment in those clinics where radium is available.

It is surprising to find in a work otherwise so up to date a good deal of space devoted to the treatment of adolescent menorrhagia by radiation of the ovaries. It is true the method is not recommended, but it ought to be categorically condemned. The statement that subsequent pregnancies may result in deformed progeny might have been supported by a reference to the statistics of series published both in America and on the Continent showing (1) that the abortion rate of conceptions following after ovarian radiation is extremely high and (2) that the fetuses are frequently deformed, showing conclusively that, where the egg-cell does ultimately mature, its chromosomes are often severely damaged by the previous radiation, bearing out laboratory evidence to the same effect. Surely the author might have mentioned prolan treatment or irradiation of the pituitary as alternative measures in place of ovarian radiation, giving as they often do brilliant results in pubertal menorrhagia without any danger of damage to the egg-cell? Irradiation of the pituitary is also advocated in the Continental schools for the treatment of menopausal symptoms except in the hyperthyroid type of case. The danger of irradiating inflamed and septic tumours and those associated with pyosalpinx is scarcely referred to, but is a very real one.

In spite of these defects, some of which are minor, the book gives a good account of the scope of radiotherapy in gynaecology and rightly leads us to foresee at no very distant date a great and triumphant future for the methods of radiation, especially in the treatment of carcinoma of the cervix.

W. C. S.

A SHORT HISTORY OF OPHTHALMOLOGY.—By

Arnold Sorsby, M.D., F.R.C.S. 1933. John Balo, Sons and Danielsson, Ltd., London. Pp. vi plus 103. Illustrated. Price, 3s. 6d.

This little book is one of the short history series, a number of which have been recently written, and shows that the ophthalmic art has an interesting history which goes back to ancient times, and the author has very successfully endeavoured to trace the various components of ophthalmology up to the present age.

The history is divided into different periods, the ancient East, the Greek period, the Arabian period, the Western Middle Ages, and the modern period.

Special chapters are devoted to the evolution of the anatomy, physiology and pathology of the eye. There are also special chapters on the pathology and treatment of cataract and glaucoma, ocular therapeutics, spectacles, the ophthalmoscope, and finally ophthalmology in the British Isles.

It is of interest to know that ophthalmology benefited at the hands of Hippocrates who was born in 460 B.C., and there was a continual development up to the time of Galen who was born in A.D. 130. During the long period that followed, up to the 16th century, it hardly advanced at all. The study of the anatomy of the eye and understanding of the mechanism of vision were the work of the 16th and 17th centuries. Great strides in the pathology and clinical examination of the eye were made in the 18th century which was the century of cataract extraction and the artificial pupil.

The second half of the 19th century produced the operative treatment of glaucoma and the discovery of the ophthalmoscope which opened up a new world in the study of clinical ophthalmology.

It is probable that the operation for depression of cataract was known in India from early days, and Celsus' account of cataract and its treatment was the teaching that persisted with hardly any modification up to the 18th century, when Daviel published his account of extraction of the lens which up to this day is one of the recognized methods for the radical treatment of cataract.

Glaucoma in ancient times stood for no definite entity. It was not until 1840 that hypertension was generally recognized as the essential feature in the disease, and prior to 1857, when von Graefe introduced iridectomy for the cure of acute glaucoma, the diagnosis was tantamount to a sentence of blindness. The medical treatment by miotics was unknown till 1875. The great achievement of the 19th century in ophthalmic surgery was the operative treatment of the various varieties of glaucoma. The introduction of asepsis and general anaesthesia produced a new era, in operative eye work as in surgery in general. Local anaesthesia with cocaine was introduced in 1884.

The treatments of squint and lacrimal obstruction were perfected in the same century, although both conditions were recognized in antiquity.

The early history of spectacles is shrouded in mystery. Legend has it that St. Jerome invented glasses (c. A.D. 340-420), although the fact that Pliny records that Nero watched gladiatorial contests with an emerald suggests that they were discovered in remoter antiquity. References to glasses began to appear towards the end of the 13th century. The first medical reference is by Bernard Gordon in 1305, and towards the middle of the 14th century glasses began to have quite a vogue.

It is interesting to find that spectacles were not well received by oculists and met with a remarkable hostility till Donders made the problems of refraction and the rational use of glasses part of the ophthalmic creed.

The book is most interesting, is well written and will prove of great interest to students and workers in ophthalmology.

E. O'G. K.

DIABETIC MANUAL FOR THE MUTUAL USE OF DOCTOR AND PATIENT.—By Elliott P. Joslin, M.D. Fifth Edition. 1934. Henry Kimpton, London. Pp. viii plus 224. Illustrated. Price, 10s. 6d.

We welcome the fifth edition of this popular book of Professor Joslin written mainly from the point of view of educating diabetic patients. The book is full of information which should be of use not only to laymen but also to junior members of the profession who will get substantial help from it to advise their diabetic patients.

The present edition has been thoroughly revised and has been lucidly and popularly written for those for whom it is intended. We have no doubt that it will prove to be as popular as its predecessors.

J. P. B.

DIAGNOSIS AND TREATMENT OF DIABETES MELLITUS.—By O. Leyton, M.D., D.Sc., F.R.C.P. Fifth Edition. Adlard and Son, Limited, London. Pp. 144. Illustrated

This is a more-or-less practical treatise on diabetes intended to help the practitioner to deal with cases of diabetes in a practical and methodical way. The book begins with a description of the method of case-taking, and then goes on to describe methods for the proper diagnosis of the case. In discussing the treatment of diabetes, the author lays great stress on starting insulin without delay as soon as the case is diagnosed. As regards diet, the author does not seem to be in favour of restricting the total diet of the patient, if the disease is not well advanced, but is content to rest on an arrangement whereby the carbohydrates are so distributed at the several meals that the greater part is taken during breakfast and dinner, unless the patient is willing to submit himself to three injections of insulin daily. The author's views on the subject may be summarized as follows:—

Since insulin is now obtainable in any quantity and at a cheap rate the majority of the patients may eat what they like, but it is absolutely necessary for them

to eat the same allotted quantity of carbohydrates, protein and fat distributed in the same manner.

The author's method of treatment, different as it is from that of many other workers, may be quoted in his own words. 'At the present day the skill of the physician has to be devoted not so much to actual quantities of carbohydrate, protein, and fat suitable for individual patients, as to the correct distribution of the food throughout the twenty-four hours and the determination of the number, size and times of administration of the doses of insulin'.

We are of opinion that the general practitioner will find the book useful in his practice.

J. P. B.

THE CHEMISTRY OF ANTIGENS AND ANTIBODIES.—By J. R. Marrack. 1934. (Medical Research Council. Special Report Series, No. 194.) Published by His Majesty's Stationery Office, London. Price, 2s. 6d.

The nature of the reaction between antibody and antigen is a subject that particularly lends itself to theorizing. At the outset Ehrlich gave us a theory which is not generally accepted to-day, but is in some ways as good a theory as any, and is the one on which all modern theories are built. Recent advances in our knowledge of physical chemistry, more especially with regard to the size and shape of molecules and the radii of atoms, which have been effected through the x-ray study of crystals and other new methods, have provided opportunities for approaching this problem from a new angle. Of this opportunity Dr. Marrack has taken full advantage and his report forms a valuable contribution to the subject of immunology.

A STUDY OF GROWTH AND DEVELOPMENT: OBSERVATIONS IN SUCCESSIVE YEARS ON THE SAME CHILDREN.—By R. M. Fleming. With a Statistical Analysis by W. J. Martin. (Medical Research Council. Special Report Series, No. 190.) Published by His Majesty's Stationery Office, London. 1933. Price, 1s. 6d.

We realize more and more how important it is to obtain normal standards. The obtaining of these is usually a very laborious and monotonous task, and the collection of the anthropometric records that are analysed in this report can have been no exception. Over four thousand children, between the ages of 3 and 18 years, were examined, some of them as often as six times.

Many interesting differences between the two sexes are brought out; amongst these are the earlier development and the earlier cessation of growth of girls. About 60 per cent of girls have ceased to grow in height at the age of 17, whereas this applies to only 25 per cent of boys. Others, mostly boys, grow as much as 5 inches during their 18th year of life; such children are very liable to break down and require special medical attention.

The actual figures in this report will, of course, not apply in India, but they will be of great value to the worker in this country for purposes of comparison.

INDIAN PSYCHOLOGY: PERCEPTION.—By Professor Jadunath Sinha. 1934. Kegan Paul, Trench, Trubner and Company, Limited, London. Pp. xvi plus 384. Price, 15s.

The author has collected together in this volume the theories held by Hindu psychologists regarding different forms of perception including those of space, time, 'the universal' cognition, the self-illusions and dreams, and abnormal and yogic supernatural perception. The present-day experimental psychologist as well as the psychologist trained in the academic school will find much that is of interest in this volume. In explaining the different forms of perception and in elaborating theories and criticisms the Hindu mind indulged in subtleties scarcely found amongst western scholars. The author in his preface asserts that there

was no empirical psychology in India yet in the next paragraph he says that Indian psychology is based on introspection and observation. There is no doubt that the ancient Hindu mind showed a special introspective ability. The materials obtained by introspection had to be treated from the epistemological standpoint for the purposes of metaphysics and philosophy. Indian psychology and metaphysics are mainly based on psychology hence psychological problems have been discussed by all the different schools of philosophy founded in India. The author has translated the Sanskrit term 'Indriya' as 'sense organ' and has consequently divided the 'sense organs' into two groups, namely, five organs of knowledge (Buddhindriya) and five organs of action (Karmendriya). The term 'sense organ' has now been borrowed from the modern physiologist and it is an unjustifiable liberty to include organs of action within the term 'sense organ'. This, however, is a minor point. There are many interesting discussions in the chapter on time which seems to be the best in the book. The theories of perception of movement and of 'the universal' propounded by ancient Hindu psychologists will no doubt be read with very great interest by the modern *gestalt* school. In the chapter on dreams we do not find any mention of the Upanishadic and the Puranic theories on the subject. No western scholar who deals with the problem of perception could afford to neglect this book. The main defect of the book lies in the fact that no synthetic presentation of Hindu psychology has been attempted. The different chapters of the book read like so many pages of disconnected lecture notes. The book could have been written in a more interesting way, but all the same we have no hesitation in saying that the book removes a long-felt want and will be of immense help to those who want to do research work in Indian psychology.

G. B.

A NEW PHYSIOLOGICAL PSYCHOLOGY.—By W. Burridge, D.M., M.A. (Oxon.). 1933. Edward Arnold and Company, London. Pp. vii plus 158. Illustrated. Price, 7s. 6d.

PROFESSOR BURRIDGE differs from the neurological doctrine concerning the nature of the fundamental processes, which had its foundation in the conception of synoptic resistance. He has developed a new system of physiological psychology on the basis of his intimate physiological studies of different organs, especially the heart and the eye, and proceeds to state that the central neurones and end-organs are rhythmically active structures whose energy exchanges are mediated by two kinesiophores, the interaction between the two providing the dynamic energy for evoking response.

The new doctrine is well summarized in this brief treatise and the hypothesis of balance is assumed. Suggestion has been made that Freud's psychological principles regarding the relationship between kinesiophores should be looked upon as synergist and not as antagonist.

Professor Burridge next proceeds to make a scholarly and interesting examination of the memory and dream, from the point of view of central neurone-rhythm outlined by him, and develops a picture 'of an organ of mind consisting of a vast complex of discrete groupings of neurone, each group dancing to its own rhythm with its own strength'. All the problems of mental functions and disorders, as well as his concept of shock, fits and spasms, are well embraced within the scope of his theory.

This thoughtful volume should be studied by all interested in the relationship between the body and mind. It is an admirable attempt on the part of the author to correlate the mental phenomena and the processes taking place in the nerve cells and will interest psychologists and neurologists.

R. N. C.

AN INTRODUCTION TO THE BIOCHEMISTRY OF NITROGEN CONSERVATION.—By Gilbert J. Fowler, D.Sc., F.I.C. 1934. Edward Arnold and Co., London. Pp. viii plus 280. Illustrated. Price, 12s. 6d.

THE subject of nitrogen conservation was discussed in the February number of the *Gazette*. The economic importance of the subject to an agricultural country like India was pointed out and two papers were published showing how town refuse and nightsoil could be treated in such a manner as to fix the organic nitrogen by biochemical processes, the result being a compost containing nitrates and phosphates of high agricultural manurial value. Dr. Fowler has devoted the whole of his life practically to the study of nitrogen conservation and the present book is a summary of modern work and knowledge on the subject, much of which has been done by Dr. Fowler himself or at his instigation and under his guidance. The activated-sludge process initiated by Dr. Fowler is so far the most successful method of treating sewage and conserving nitrogen. The original source of organic nitrogen was probably and is still largely atmospheric nitrogen. This can be fixed from air in organic combination by some species of free living organisms (*Azotobacter*, *B. lactis aerogenes* and *clostridium*), and by various micro-organisms symbiotic on leguminous plants. Nowadays, such fixation of atmospheric nitrogen is being done by electrical, thermo-electrical and thermo-chemical methods. In the nitrogen cycle of nature, fixed nitrogen may be lost as atmospheric nitrogen and ammonia. This loss is due to the action of certain micro-organisms. In sewage disposal, by dilution in water, fixed nitrogen is lost by dissipation in the sea. The main problem is to prevent the loss of fixed nitrogen which occurs by biochemical action. The obvious thing is to counteract this by other biochemical agencies. The question therefore includes study and knowledge of the chemical structure of nitrogenous organic materials, the changes these may undergo by enzyme and other action, and also a knowledge of the living agencies in soil and water and excretal matter that act in any way in nitrogenous matter. Experimentation has been ahead of precise knowledge and it is hardly realized yet what a big field of work still remains untouched.

The book deals in detail with the various chemical changes that take place in the building up and breaking down of nitrogenous matter, with nitrogen fixation and the chemistry of sewage purification. The book will be of great value to sanitarians and public-health chemists, and, despite the unavoidably large number of chemical equations, the book makes intensely interesting reading. We are indebted to Dr. Fowler not only for his original work, but for bringing together in a comprehensive and logical manner a very complete résumé of one of the most important biochemical problems in nature. Physiologists, biochemists, sanitary engineers, and public-health workers will find the book invaluable.

A. D. S.

LA GANGOSA ET LES RHINO-PHARYNGITES MUTILANTES DES TROPIQUES.—By Dr. Georges Galinier. Paris Jouve & Cie, Editeurs, 15, Rue Racine, 15, 1934. Page 76. Bibliography—127.

THE literature on this disease is carefully reviewed in the light of the geographical distribution and pathology. Diagnosis and differential diagnosis are considered carefully. Dr. Galinier considers that the importance of the yaws factor is less than is usually estimated, and that, though the disease may be caused by or connected with yaws, it is also connected with many other diseases, such as syphilis, leishmaniasis and blastomycosis. He considers it to be a disease the history of which is unable to offer a proof of aetiological connection with any of these diseases. He considers that the term 'gangosa' or 'mutilating rhino-pharyngites' should be applied to secondary affections which accompany or follow leishmaniasis, tertiary yaws

and syphilis. The distinctive lesions are found only in tropical countries, and include all ulcerations of the nose and pharynx which are exceedingly chronic in nature and which cannot be recognized as caused by any other definite disease.

E. M.

AIDS TO NEUROLOGY.—By E. A. Blake Pritchard, M.A., M.D. (Camb.), M.R.C.P. 1934. Baillière, Tindall and Cox, London. Pp. vi plus 376, with 44 figures. Price, 5s.

DR. PRITCHARD'S *Aids to Neurology* is a handy book on the diseases of the nervous system, intended for the use of students in the early years of their clinical training. The book comprises five chapters, a preliminary one being devoted to anatomical and physiological considerations of different parts of the nervous system and a description of symptoms arising out of regional disturbances of this system. The other chapters include the peripheral nervous system, the spinal cord, the brain and the autonomic nervous system. The subject-matter has been clearly dealt with, without any unnecessary detail as to the various theories embracing it, and is thus eminently suitable for the students for whom it is intended. There are numerous diagrams in the text to illustrate the effects of lesions of the peripheral nervous system including sections of brain and the spinal cord. The author has done well in including a chapter on the function and disturbances of the autonomic nervous system—a subject which is gradually growing in importance. The appendix contains a scheme for systematic examinations of the nervous system. The book will be useful to the students going up for examinations.

R. N. C.

HANDBOOK FOR HEALTH VISITORS IN INDIA.—By Dr. Ruth Young, M.B.E., B.Sc., M.B., Ch.B., W.M.S. 1933. Maternity and Child-Welfare Bureau, Indian Red Cross Society, New Delhi. Price, Re. 1-8

THIS invaluable handbook should be of the greatest service to health visitors and to all those, whether doctors, nurses or others, who have to do with the training of health visitors or the organization of child-welfare work in India. It is meant to be used along

with another book by the same author, *Antenatal Work in India*, published in 1930. The present volume therefore begins with the care of the newly-born infant and does not deal with antenatal work. Continuing it deals with the general development and care of the normal child, and his feeding. A chapter deals with the premature baby, and several chapters are devoted to the all-too-common disorders and ailments of infancy and childhood which can be so easily avoided with knowledge and care, but which neglected can lead to such dire results. Stress is laid on the prevention of these by efficient teaching of the mothers, and early recognition. The teaching is short, pithy and to the point. The author's unrivalled knowledge of conditions among women and children throughout India enables her to advise the health visitor of the difficulties that are likely to arise, and the best way of tackling those and of securing the co-operation of the women. The remaining chapters which are of great interest deal with the history and aim of the child-welfare movement, the organization of child-welfare work, and the work and duties of the health visitor. The final chapter gives an illuminating account of how vital statistics should be understood and used by the health visitor. Dr. Young insists that those who promote child-welfare schemes should have a clear idea of what they aim at, and of the best organization to realize that aim. 'Prevention is and must be the guiding principle'. Too often in India 'the movement degenerates into an agency for dealing inadequately with children's ailments, or for doling out charity'. The best organization is one which allows of thorough and scientific work, better to confine the work to a small area and do it properly than to cover a wider area inefficiently. Great stress is laid on home visiting as the basis of the work. The visitor must visit the homes of all infants born in her area, and must keep constantly in touch with these infants during the first year of life. The work of the clinic is secondary and complementary to that of visiting. Dr. Young calculates that one health visitor can deal efficiently with an area in which 200 births occur annually, if she is expected to do more she cannot carry out her work properly. This book will prove inspiring to all those interested in the problems of preventive medicine.

J. M. O.

Abstracts from Reports

THE ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1931

It is with considerable interest that we turn to this report. It is Major-General Graham's last report, as he has now handed over the reins of office of Public Health Commissionership after 10 years' work of first-rate quality. He has been an outstanding personality in international and Indian public health and his departure is a matter of deep regret.

We naturally turn to the last section of the report headed 'Retrospect; Reflection and Conclusions'. Here we are treated to an excellent résumé and history of public health matters in India during the last 10 years, and a concluding paragraph on the future possibilities and likelihood of progress in this most important aspect of Indian welfare. General Graham describes the position of the Central Health Organization at headquarters in 1924, and the circumstances which the adoption of the recommendations of the Retrenchment Committee (Indcape's) had produced. The Government of India Act of 1919 had transferred public health responsibility largely to the provinces and had limited the serious activities of the Central Health Department almost entirely to external matters. In this respect

General Graham has been a true ambassador. Previously, India had not counted much in international health matters and had been very inadequately represented. General Graham's attendance at the bi-annual meetings of the Office International in Paris, at the League of Nations Health Committee at Geneva, at the Eastern Epidemiological Bureau (as Chairman) at Singapore, at various international conferences on rabies, plague, malaria and other matters, placed the work of medical and research workers in India at once in a proper perspective, and instead of being ignored, India's opinion on medical and public health problems was not only listened to with respect and interest but sought.

It is interesting, as General Graham points out, to forecast the lines of development of Indian public health policy, and to speculate whether it will follow the lines indicated in the Government of India's resolution on 'Sanitary Policy' published in 1914. Just at present, the financial crisis is made an excuse for refusing every expansion of expenditure on public health, but it is likely that in the more advanced provinces, informed opinion is beginning to demand an expenditure on public health measures commensurate with their importance.

The formation of a Central Health Board which will function as a Federal Health Board is a point which naturally must have recently received very close attention from the Government of India. General Graham has been anxious that there should be a considerably strengthened Central Health Board formed now at once, which would form the backbone of a Federal Health Organization. We trust this will be so. The international health work for India during the last 10 years has been assiduously fostered by General Graham and it is to be hoped that the framework of such a Federal Organization which he has indicated should be at once constructed.

One of the difficulties at present is to appraise exactly the health position of India. On several occasions, the annual Conference of Research Workers has unanimously passed resolutions calling for a comprehensive enquiry into the state of health of the country, particularly with a view to evaluating the causes of its present unsatisfactory condition. This proposal has been strenuously supported by Sir John Megaw and General Graham. Such a commission would be representative and would consider all the factors influencing health, viz, population, finance, wages, disease, diet, etc., and would be able to pave the way for some more permanent and practical scheme of economic uplift.

In the last chapter of his report General Graham passes in review the progress of research in India, the formation and activities of the Indian Research Fund Association, the Scientific Advisory Board, the Research Workers' Conference, and the various publications sponsored by the Indian Research Fund Association, and the question of a Central Research Institute. Two important Royal Commissions, viz, on Labour and on Agriculture, have been closely connected with health, and the Drugs Enquiry Committee was also of great importance. The problems of education also are closely and intimately connected with health progress, and General Graham thinks he sees indications that the stage has become set for a distinct advance in this direction. The fact that Indian women reformers are advancing educational movements so much is he also thinks particularly hopeful.

The last chapter of General Graham's report has been reprinted and is now available separately. We heartily recommend it as one of the most interesting publications of the year to those interested in India's welfare and in its health progress.

Turning to the review of India's public health in 1931. This is compiled from the statements received from provinces and as these are not compiled until late in the following year, the Public Health Commissioner's report must appear much later than the year it reviews. General Graham points out that as this is the only comprehensive review of the health questions of all India, it is a publication perhaps more referred to outside India than in India itself. He indicates how it may be improved by a better arrangement of the statistical tables, the removal of much statistical matter from the narrative and the introduction of observations of more general interest. For these, additional expert staff is necessary.

Several interesting diagrams illustrate the death rate, birth rate and infantile mortality rates of India compared with other countries. The birth rate of British India for 1932 was 34.3 per 1,000, the highest of the countries cited, except Palestine. The death rate was 24.8, again the highest, except Palestine. The infantile mortality was 179 per 1,000 births, the highest rate of any amongst the countries quoted.

The population was taken in February 1931 and was 271,526,933, an increase of 10 per cent over that of 1921. The increasing population of India has been the subject of many discussions in the scientific and lay press, and much considered opinion tends to be pessimistic of any hope of improvement in the economic state and health of Indian masses, as long as the present rate of population increase goes on. Many are in agreement with this point of view, but there is a

danger that with unthinking people it may be the excuse for a slackening of effort in health education. Many health administrators think that the best way to restriction of population is by a reduction in death rates and all the advances in education and intelligence and foresight which such reductions must imply. How best to get on with this is the question.

Features of recent reports are the excellent diagrams and maps illustrating the distribution and incidence of the main diseases of India. 'Fever' claim 15 per 1,000 out of the total death rate; this represents 60 per cent of the total mortality; 25.2 per cent is accounted for by 'other causes'; 6.4 per cent by respiratory diseases; 4.1 per cent by dysentery; 3.3 per cent by cholera; 0.7 per cent by plague and 0.6 per cent by smallpox. An attempt is being made, particularly in Madras, to disentangle the multifarious diseases included under 'fevers'. Details are given of the incidence of disease in each province and of the measures taken to combat these. It is difficult to extract matters of interest as the report itself is a compilation of the most important parts of the provincial health reports.

An interesting review of the public health administration all over India is given in section IV. The health administration of ports, railways and jails is commented on, and medical education has a section to itself, in which details are given of the various medical schools and colleges in India and their work, and the number of medical men turned out from them annually. Medical research is fully dealt with in summary form, while much useful and interesting information is given of the work and administration of the various voluntary health organizations such as the Indian Red Cross Society, The St. John Ambulance Association, the British Empire Leprosy Relief Association, the Countess of Dufferin Fund, the Lady Chelmsford All-India League for Maternity and Child Welfare, etc. The present form of the report is perhaps rather terrifying to the ordinary reader and we agree that if the interesting parts could be separated from much of the statistical matter, there would be a greater chance of the report receiving the careful reading and attention which it so thoroughly deserves.

THE REPORT OF THE EUROPEAN MENTAL HOSPITAL AT RANCHI FOR THE TRIENNium 1930-32

This report covers a period of three years, namely, 1930, 1931 and 1932.

During the period under review, this hospital continued to receive patients, European and American, including those of mixed blood, from Bengal, the United Provinces of Agra and Oudh, the Punjab, Bihar and Orissa, the Central Provinces, Berar, Assam and British Baluchistan. It also received patients on transfer from any mental hospital in India, provided the governments of the provinces in which they were domiciled agreed to bear the proportionate cost of maintenance of this hospital on account of those patients.

It is noteworthy that during the triennium under review, the Government of India authorized reception of European-mental patients into this hospital from the French Settlement of Chandernagore.

A new system of inspecting and reporting on patients was introduced. Hitherto patients were inspected and noted on in routine with the result that many patients were not seen often enough and some more often than necessary. It is now the business of the house physicians, occupational therapists and nursing sisters to put up patients for inspection whenever any change, for better or worse, is noticed in them. This procedure keeps the medical superintendent and the deputy superintendent better informed than did the old one of signs of improvement or the opposite in patients. Improvements now meet with instant encouragement, and relapses can be met by appropriate measures for prevention.

Special methods of treatment

Seven male and seven female patients were treated with sulfosin. One per cent solution of sulfosin in olive oil was injected intramuscularly bi-weekly starting from 1 c.cm. and increasing to 12 c.cm. Of the males, only one patient showed signs of improvement and was eventually discharged. Of the females, two patients improved sufficiently to be discharged, two showed only temporary improvement, and three did not improve.

Organotherapy had been tried on three female patients but without effect. Injections of thylin and posterior pituitary gland tablets were used to raise the blood pressure, but without success.

Two cases of general paralytic insanity and one of hypomania had been treated with induced malaria. The mental state of the first two showed slight improvement, but in the case of the third the improvement was only temporary, but the physical state improved considerably.

Occupational therapy.—This important treatment continues to maintain its efficiency, in spite of our having to work short-staffed on account of retrenchment. Although no new occupations, other than those mentioned in the previous year's report, were introduced, patients continued to display as much interest as ever in what they were doing, so the therapeutic value may be regarded as undiminished.

The percentage of attendance of patients in the occupational therapy department increased from 93 per cent to 94 per cent this year (1932), and there were many voluntary workers who occupied themselves even out of occupational therapy hours. The articles manufactured in the occupational therapy class were, as usual, exhibited for sale, and it was very gratifying to find that sales increased considerably.

Route marches, swimming, rowing and weekly picnics were carried on as usual and the interest shown in these pastimes by even quite apathetic patients was very encouraging.

Physical culture, conducted by an instructor, has improved wonderfully. Physical culture has proved a very satisfactory therapeutic measure. An instructor has been sanctioned by the Board of Trustees of this hospital from the beginning of this financial year to train the patients in various exercises as well as in boxing and outdoor gymnastics.

My eldest son arranged a boxing tournament in which a few patients took part, and it is very satisfactory to note that one of them won his fight against an outsider.

Sports and amusements.—During the year, games, amusements and physical exercises have been developed to an extent that has never existed before. The appointment of an experienced and zealous physical instructor, Mr. S. K. Bose, has done wonders in promoting interest in boxing, physical training and gymnastics. Male patients gave a number of exhibitions of physical exercises and gymnastic 'pyramids'. All this has done a great deal to dispel the apathy of introverted patients as well as to improve their physique.

Football, cricket and hockey matches were played according to the season, as usual.

In respect to other forms of recreation, it is important to record the installation, during the year, of a stage with scenery and two green rooms. The acquisition of a stage has given a great impetus to the development of tableaux, physical displays such as gymnastics and pyramids as well as step-dancing and choral singing. Both Mrs. Mason, the music and dancing mistress, and Mr. S. K. Bose, the physical culturist, have worked wonders in this department. There have also been two or three 'cabaret' shows. A concert that was held during the Pujah holidays realized Rs. 127-8-0. Besides our own entertainments, two travelling troupes performed during the year, the Laprotti's and the Sequins. Through the generosity of the Board of the Trustees the hospital was permitted to acquire at a cost of Rs. 1,000 an electric gramophone

with a 'wireless' installation. The latter has enabled us to listen-in to the music, speeches, etc., in different parts of the world.

Band.—The loss of our band, through its retrenchment, was felt so keenly that the staff decided to sustain a small band of nine players through private subscription. This band under the leadership of Captain A. T. Mayes, the steward of this hospital, has given a great deal of pleasure to both patients and staff. During the year it obtained some engagements to play in Ranchi and its earnings were a very welcome addition to the band fund.

I would like to take this opportunity of thanking the children of the staff including my own for their help in contributing to the displays given on the stage. We, parents, may congratulate ourselves and one another in having children who are so ready and eager to assist us in promoting the welfare and happiness of those committed to our care and treatment.

Games.—Outdoor and indoor games were kept up to standard throughout the year. Improvements and additions worth noting are the introduction of mixed hockey and basket ball. About 60 per cent of the residents were able to participate in them.

During the year, ten cricket, thirteen football and four hockey matches were played with outside teams.

During the year the hospital teams both A and B, entered for the Namkum Football Cup Tournament and went up to the semi-final.

Cinema.—The hospital cinema continued to give regular displays throughout the triennium under review. This has added to the entertainment of the patients and has been of great therapeutic value.

The above abstract indicates that the efforts at making the inmates lives as happy and useful as possible is being continued with unabated energy and success.

THE REPORT OF THE FIFTY-NINTH YEAR'S WORK IN INDIA OF THE MISSION TO LEPERS. SEPTEMBER 1932-AUGUST 1933

THE Mission to Lepers is able to report that in spite of the universal depression they have been able to show an expansion in their work by treating more patients in their homes than during any other year in its history and there has also been an increase in the number of out-patients at institutions aided by the Mission.

For many years now it has been recognized that occupation suited to individual patients is of distinct benefit when they are under treatment in an institution and a striking example of the practical application of this principle is reported from the home at Raniganj in Bengal. A certain sum of money was contributed by friends in Dublin and with this aid the inmates themselves, quite unaided by outside help, built an operating theatre and sick room even making the bricks themselves.

The general report is followed by short separate reports from the numerous homes throughout India and at the end there is a review of the medical work for the year. This is by Dr. E. Muir, research worker in leprosy at the School of Tropical Medicine, Calcutta, and it is abstracted at length, below.

'After expansion—consolidation': this is the natural course of things. While the homes of the Mission to Lepers in India still show expansion along certain lines, as more in-patient accommodation has been provided, the most notable feature of the year is more along the lines of consolidation. There is a marked increase (20 per cent) in the number of cases in which the disease has become arrested without deformity. This means that cases have been treated earlier and also that more labour and skill are being used in the care and prevention of ulcers and abscesses.

Equally important is the after-care of those who have recovered after years spent in the homes; when discharged once more into the outside world the strain

may be too great and relapse may occur. In the after-care of tuberculosis the Papworth Colony in England, by providing employment graded to the strength of the patient, has smoothed the way to complete and confirmed strength. We need something along similar lines for the after-care of those discharged from the leper homes.

We cannot yet say that we have any sovereign remedy for the treatment of leprosy. Advance is at present being made rather along the lines of more uniform and consistent application of such remedies as we have. Fresh light is beginning to break through on some of the factors which control the spread of infection and it is likely that while due importance will continue to be given to treatment, more and more stress in future will be put on preventive work. It is easier to prevent the disease in ten cases than to remove it in a single one.

The Mission to Lepers is the only organization in India that has emphasized in a practical way the importance of the care of children and their separation from their leprosy parents. All recent work tends to show the value of such precautions. Statistics show that 40 to 50 per cent of children who remain in contact with their leprosy parents develop the disease, while there are only 2 to 4 per cent of conjugal infections. If we take the number of children who remain in contact with infectious leprosy parents (that is with the more advanced cutaneous cases), the number infected would probably be nearer 100 per cent. Children are obviously less resistant to leprosy in their earlier years, and the chief stress in any campaign against leprosy must be laid on the separation of children from their leprosy parents at birth, however that may be accomplished.

The Mission to Lepers in India is now, as in the past, readily adapting itself to new methods once these have been shown to be of real value, and often it has led the way in the practical demonstration of these new methods.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF BIHAR AND ORISSA FOR THE YEAR, 1932

BIHAR AND ORISSA forms a composite province stretching from the Himalayas to the Bay of Bengal, and touching Nepal, the United Provinces, the Central Province, Madras Presidency and Bengal.

Its population as shown by the 1931 census was 37,677,576; the total percentage increase over 1921 is not given in the report. The birth rate for 1932 based on the 1931 census population was 33.8; the death rate 20.6 per 1,000; the infant mortality rate was 128.8 per 1,000 births.

The registration of vital occurrences is admittedly defective. In the rural areas they are not compulsorily registrable, and the reporting agency is the police. In the municipalities, attempts are being made to transfer the registration duties from the police to the municipalities themselves. In Patna, the health officer is now the registrar and the results are satisfactory.

Of the causes of death, 'fevers' account for a very large proportion, the figure for 'fevers' being 15 out of the total of 20.6 per 1,000. The Director of Public Health notes that malaria is the chief direct and indirect cause of the fever mortality. As the respiratory disease figure is only 0.1 per 1,000, it would appear that these causes of death are probably being reported under 'fevers'. One naturally turns to the section on cholera for information and opinion as to the results obtained in treatment and prevention of this disease in an endemic province by the various measures, sanitation, disinfection, inoculation and bacteriophage, now being adopted. Eleven districts now have health officers; government maintains a permanent staff of epidemic doctors of the assistant-surgeon class who are available for duty on demand from any district. Provision is also made for 100 epidemic vaccinators for employment anywhere in emergency. A reserve of disinfectants is also maintained which are available to assist local

bodies in dealing with epidemics. Cholera vaccine is also given free on demand. In the districts of Purnea and Muzafferpur bacteriophage was experimented with for the second year in succession, other methods being in abeyance in these two districts. Taken all over, cholera was prevalent only to a slight degree in the province in 1932, accounting for 9,348 deaths, with a death rate of 0.2 per 1,000, compared with 1.1 in 1932, and 1.5 for the previous 10 years average. The Director of Public Health is evidently convinced of the efficacy of bacteriophage in the treatment of cholera in the district and adduces figures in support. In Muzafferpur in 1932 the case mortality for 'treated' cases was 6.1 and in the untreated 69 per cent. In Purnea the case mortalities were respectively 29.89 and 84.3 per cent. No indication is given of how cases were selected for treatment and otherwise, and it would appear possible that the 'untreated' side was very likely loaded with many severe cases who had no opportunity for treatment by bacteriophage, or perhaps by anything else. The figures as stated are not quite convincing. The length of individual epidemics appears in Muzafferpur to have been shortened considerably by the use of phage.

There are several large fairs and melas held regularly in the province—especially at Gaya, Puri and Sonapur. The sanitary control of the fairs is improving year by year, special attention being paid to water supplies. Puri apparently still draws its water supplies from shallow wells. If we remember rightly, some years ago the report mentioned that experiments were being tried with tube wells. These have evidently not been successful. An abundant and safe water supply for a town of this size and importance is a necessity. Water supplies all over the province, especially in Orissa, are not very satisfactory; in Orissa diarrhoea and dysentery are very prevalent and cause high mortality.

Smallpox mortality (0.4 per 1,000) was double that of 1931 (0.2 per 1,000). The Vaccination Act is in force in some areas, but, as the Sanitary Commissioner to the Government of India pointed out some years ago, primary vaccination is just as efficiently carried out in places where there is no compulsion as in places where there is.

Plague was prevalent only to a small degree, giving a mortality of 0.09 per 1,000, compared with 0.3 for the last 10 years.

In the matter of administration, progress is being made in the employment of health officers either governmental or local in municipalities and districts, but financial stringency has largely stopped expansion in this direction. The inspection work of the assistant directors of public health seems to be thorough and effective.

Correspondence

THE NEW BRITISH PHARMACOPŒIA AND INDIAN USAGE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—It is of more than passing interest to note the effort made in previous pharmacopœias to popularize drugs peculiar to India and other tropical parts of the British Empire, first by their introduction in the form of an addendum to the British Pharmacopœia of 1898 and then by their introduction into the actual text of that of 1914.

That this effort has not been a success, the perusal of the new pharmacopœia will abundantly prove. No fewer than 357 articles and preparations have been deleted from the present British Pharmacopœia, and in this wholesale clearance of dead wood from the pharmacopœial tree nearly all of the Indian drugs more or less on trial since 1898 have been swept away.

First of all we may take the case of those drugs which were admittedly introduced as substitutes for

the better-known foreign article. Of these, Gummi Indicum in the place of Acacia, Kaladana in the place of Jalapa, Uriginea in the place of Scilla and Valeriana Indica Rhizoma in the place of Valeriana are all well known. Since the foreign drug remains official we may well ask why have not the Indian alternatives remained in the Pharmacopœia?

The answer surely is, that these substitutionary articles, though equal to the foreign drug, have not obtained the support of the Indian medical profession for whose benefit they were especially introduced into the 1898 and 1914 Pharmacopœias.

Here is a proof that practise is often far removed from precept; for whilst many blame government for its indifference in the matter of developing the indigenous drug trade, and others are professing a love for Indian medicines with the slogan 'Back to the Vedas', here is a case in point that Indian drugs even with the powerful backing of the official pharmacopœia cannot obtain a foothold in the Indian doctor's armamentarium, he rightly or wrongly being obsessed with the idea that the foreign article is to be preferred.

The case of other former British Pharmacopœia Indian substitutes for their foreign rivals is different to those mentioned above, inasmuch as not only the Indian preparation but also the foreign article for which it stood has been removed from the Pharmacopœia. If the original be deemed unworthy of a place within the covers of the 1932 Pharmacopœia we can hardly expect that the alternative Indian drug would survive. This has happened in a number of cases, e.g., *Galla* has gone and with it the substitute *Myrobalanum*, *Hæmatoxyli Lignum* and with it the substitute *Sappan*, *Kino* and with it the substitute *Butæ Gummi*, *Scammonie Radix* and with it the substitute *Turpethum*. One feels that the loss of these drugs both original and substitutionary will hardly be mourned, but can we say the same of some other Indian drugs which were in the 1914 Pharmacopœia and have been deleted from the present one? Readers will hold views of their own, but for my part I place a value on old friends with a distinct value on their own account such as *Alstonia*, *Bela Fructus* and *Ispagula*, though many may not agree that this selection is either wise or discriminatory, it would at least appear to be as reasonable as the retaining under a separate monograph of *Podophyllum Indicum*. One wonders why *P. emodi* was not included with *P. peltatum* as the source of *Podophyllum*.

Turning from omissions to additions we find very few (if any) of the 128 new articles and preparations of purely Indian origin. Probably *Oleum Hydnocarpi* and *Oleum Hydnocarpi Aethylicum* come near to this distinction, whilst others not so far removed from it are:—*Ephedrine Hydrochloridum*, *Totaquina*, and *Oleum Gossypii Seminis*.

Again, one wonders, are there not some really valuable drugs of Indian origin worthy of a place along with the select few? I think there are, and of these I venture to put forward *Holarrhena antidysenterica* (*Kurchi*), *Psoralea corylifolia* (*Bouchi*), *Saussurea lappa* (*Kuth*).

The well-known properties of *Kurchi* and its specific action in chronic amœbiasis surely demand for it a place in an Empire Pharmacopœia. For leucoderma I do not know of any drug to equal Oil of *Bouchi* and in Asthma we need an extensive pharmacotherapy which might well be augmented by the addition of *Saussurea lappa*.

May I suggest that the pharmacopœial authorities have made a mistake in not recognizing the goat as on an equality with the sheep in all cases where the latter animal is referred to?

I imagine that Indian makers of *Extractum Hepatis Liquidum* and *Siccum* will not be careful to specify *ovis*; they will be equally well pleased to obtain from Indian abattoirs the much more frequently slaughtered *capra*. This observation will also apply to other official preparations where sheep and not goat is specified:

e.g., *Sevum* and *Thyroideum*. In the latter case, oxen, sheep, or pigs are directed to be used. Local circumstances might make it difficult to obtain any one of these animals, but I feel sure a goat or any number of goats would be easily obtainable.

Appendix XIX, page 637, paragraph 4, directs that for fresh lemon peel dried lemon peel may be substituted (in certain preparations named) where the fresh lemon peel cannot be obtained, but in the same page, paragraph 1, it states that, where bitter oranges cannot be obtained, fresh sweet orange peel may be used. Then why not allow for the substitution of fresh lemon peel the fresh peel of the lime *Citrus medica*, which though not containing an amount of volatile oil equivalent to *Citrus limonia* could easily be adjusted by using an extra amount. Fresh lime peel is nearly always obtainable, fresh lemon peel only in localized areas.

Yours, etc.,
T. D.

JOBAT STATE,
CENTRAL INDIA.

PLANOCAINE IN SPINAL ANÆSTHESIA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—May I point out, to any who feel reluctant to use percaine on account of the waste of time entailed in keeping the patient in the prone position for ten minutes after injection, that the prone position is now considered unnecessary.

I now give percaine, the usual hypoboric solution, with the patient sitting up. Depending upon the height of anæsthesia required, the patient is allowed to sit up from twenty to forty seconds after the commencement of the injection.

He can then be placed in the dorsal position, with the table tilted downward by the head through an angle of 15°, the tilt being reduced by 5° after five minutes.

A detailed description of this method will be found in the *Proceedings of the Royal Society of Medicine* for February 1934.

Yours, etc.,
M. M. CRUICKSHANK, B.Sc., M.D., CH.M.,
MAJOR, I.M.S.

MADURA,
26th April, 1934.

RESULTS OF GOLD THERAPY

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the March issue of your journal, we read the article 'Results of Gold Therapy' on page 179.

Referring to the dosage mentioned in the article for Solganal B Oleosum, we observe that the strength advocated is 0.005 to 1.0 gramme of the preparation twice a week.

We feel that the dosage advocated is too high and perhaps these doses have been confounded with the aqueous solutions of Solganal, i.e., Solganal and Solganal B.

From the circulars we issue with these drugs you will find that our largest dose of Solganal B Oleosum is 0.4 gramme and in the scale of dosage we advocate for tuberculosis you will observe that we recommend the doses ranging from 0.1 gramme to 0.2 grammes. The last-mentioned dose is to be repeated until complete recovery.

Admitting that each case must be treated according to its merits, we think that, in order to avoid any possibilities of secondary manifestations, the dose should be kept within the limits of the scheme we have suggested.

Yours, etc.,
SCHERING-KAHLBAUM (INDIA), LTD.

YUSSUF BUILDING,
HORNBY ROAD,
BOMBAY.
4th May, 1934.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL W. J. SIMPSON, an Agency Surgeon, on return from leave, is posted as Residency Surgeon, Mewar, with effect from the forenoon of the 6th March, 1934.

The services of Lieutenant-Colonel C. M. Plumptre, Officiating Superintendent, St. George's Hospital, Bombay, are temporarily placed at the disposal of the Government of Madras, with effect from the afternoon of the 31st January, 1934.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal staff:—

To be Honorary Surgeon

Lieutenant-Colonel A. J. H. Russell, c.n.r., *vice* Major-General H. R. Nutt, vacated. Dated 9th April, 1934.

Major J. C. Pyper, o.m.e., an Agency Surgeon, is posted as Residency Surgeon in Kashmir, with effect from the forenoon of the 2nd April, 1934.

Major D. R. Thomas, o.m.e., is appointed to officiate as Imperial Serologist, Calcutta, with effect from the afternoon of the 6th April, 1934, *vice* Lieutenant-Colonel R. B. Lloyd granted leave.

The services of Major J. Carey are placed permanently at the disposal of the Government of the Central Provinces, with effect from the 24th March, 1934.

The services of the following officers are placed permanently at the disposal of the Government of Bihar and Orissa, with effect from the dates mentioned:—

Major H. M. Strickland, 24th January, 1932.

Major F. H. Whyte, 22nd January, 1932.

Major J. Rodger, an Agency Surgeon, is posted as Civil Surgeon, Sibi and Loralai, with effect from the forenoon of the 1st April, 1934.

In supersession of previous notification, Captain S. M. K. Mallik, an officer of the Medical Research Department, is appointed to officiate as Assistant Director, Central Research Institute, Kasauli, with effect from the date on which he assumes charge of his duties.

Subject to His Majesty's approval, the undermentioned officers who were appointed on probation in 1933 are confirmed in the following order on passing the necessary courses of instruction and on completion of one year's satisfactory service.—

Captains

W. J. Moody.

A. E. Kingston.

Captain (provl.)

B. A. Porritt.

Lieutenants

J. M. Selater.

J. D. Murdoch.

C. F. Garfit.

D. K. L. Lindsay.

D. R. Tweedie.

A. T. Andreasen.

W. S. Morgan.

M. S. Purvis.

M. E. Kirwan.

G. S. N. Hughes.

J. W. Richmond.

A. D. Barber.

The seniority of the undermentioned Lieutenants (on probn.) is antedated to the dates shown against their names:—

R. R. Prosser, 5th February, 1933.

J. Scott, 5th February, 1933.

C. J. Hassett, 5th February, 1933.

E. Parry, 15th February, 1933.

LEAVE

Lieutenant-Colonel R. B. Lloyd, Imperial Serologist, is granted combined leave, preparatory to retirement, for 2 years and 8 days, *viz.* 3 months and 8 days on average pay and 1 year and 9 months on half average pay, with effect from the 1st April, 1934, or subsequent date from which he may avail himself of it.

Notification granting leave to Lieutenant-Colonel W. L. Harnett, Professor of Surgery, Medical College, Calcutta, and Surgeon to the Medical College Hospitals, is hereby cancelled.

Major S. D. S. Greval, Officiating Assistant Director, Central Research Institute, Kasauli, is granted leave on average pay for 4 months, with effect from the 23rd April, 1934, or the date from which he may avail himself of it.

Major J. G. Bird, an Agency Surgeon, is granted under Fundamental Rules, leave on average pay for 8 months combined with leave on half average pay for 4 months, with effect from the forenoon of the 6th March, 1934.

PROMOTIONS

Majors to be Lieutenant-Colonels

R. Hay. Dated 7th April, 1934.

W. P. Hogg. Dated 10th April, 1934.

RETIREMENTS

Lieutenant-Colonel A. N. Dickson, m.c., 22nd February, 1934.

Lieutenant-Colonel C. G. Howlett, 9th March, 1934.

Captain J. F. O. Bodman, receiving a gratuity, 17th January, 1934.

Captain E. V. Claydon, with a gratuity, from 13th March, 1934.

Notes

A CONTRIBUTION TO THE PERORAL THERAPY OF DIABETES MELLITUS

The action of insulin in diabetes is a classical example of the successful treatment of disorders of internal secretion by means of glandular preparations. The disadvantage, however, that insulin can only be administered by injection, and that its action passes very quickly, induced men of research to look for a specific, which, administered orally, would bring the hormone action of the pancreas to its fullest advantage. At first only specifics whose action was insufficient were discovered. The research work of Krauss and Zondek helped to solve the difficulties. The hormone activation, brought about by the addition of a suitable electrolyte, discovered by these workers, made it possible to increase the development of the hormonal action very considerably.

It has now become possible to find as an effective mineral vitamin, an electrolyte of the right physiological composition, which actually activates the pancreatic hormone preparation in the body.

C. von Noorden has recently made mention of a method by which the sugar-retaining substance in the pancreas can be isolated. The combination of this pure and effective pancreas-hormone preparation with the new catalyst, resulted in the highly effective peroral preparation, which reduces the urinary sugar, without having any detrimental secondary effects. This preparation has been introduced under the name of Pancresalets.

In the *Munch. med. Wochenschrift* 1931/18, Tennenbaum reports about his experiments with the carbonate

combination of the decamethylendiguandin (claimed to be one of the essential constituents of Pancreasalets), and has ascertained that it has a strong blood-sugar reducing action.

It is claimed that in Pancreasalets we have an effective physiologic pancreas-vitamin preparation, which, when taken internally, quickly reduces and prevents the excretions of sugar. It must be looked upon as an advantage of this preparation that, on the one hand, it is absolutely free from detrimental secondary effects, and, on the other, that no special dose need be administered to each individual patient, as the diminution of the excretion of sugar progresses slowly and regularly.

Dr. med. Gleichmann, in the *Allgemeine Medizinische Zentral-Zeitung*, 25th July, 1933, No. 11.

TONOVAN

TONOVAN the new Schering food tonic complies with all the demands made of a preparation intended to compensate for the lack of variation in Indian diets. It contains carbohydrates—the most readily available form of energy—in a concentrated form, valuable proteins, lecithin, vitamins A, B and D and mineral salts. It is free from any artificial constituents, meat extracts or fats of any kind, and contains no colouring matter or preservatives. Its high calorific value and special content of vitamin B make Tonovan a valuable food-stuff for building up and maintaining bodily and nervous strength. It is very palatable.

BOVRIL, LIMITED

THE Thirty-seventh Annual General Meeting of Bovril, Limited, was held on 5th March, 1934, at River Plate House, Finsbury Circus, London, E.C.

Lord Luke, K.B.E. (Chairman), who presided said that Bovril sales for 1933 exceeded those of 1932.

Sir James Crichton-Browne, in proposing the re-election of the Duke of Atholl, recalled that when he was a schoolboy at Glenalmond they used to steal over to a place on the Duke's estate to taste of a delightful confection called 'Atholl brose' but 'Atholl brose' had entirely vanished from the scene, having been supplanted by Bovril.

He had been partaking of Bovril for five-and-twenty years and turned to it to-day with undiminished relish and a growing appreciation of its merits.

They were all familiar with the salient properties of Bovril; with its power of contributing to nutrition and body-building in its own capacity, and by promoting the assimilation of other foods. It was an invaluable restorative. It promptly stimulated the functions of the stomach and was, therefore, an invaluable remedy in states of shock, collapse, exhaustion and extreme debility.

Apart from its helpfulness in shock and collapse, a Bovril thermo in the motor-car might be serviceable in other ways. Every motor driver sometimes experienced fatigue and a sense of strain, which no doubt a little alcohol would dissipate, but it did so at the price of some slight diminution of attention which was always the motorist's supreme need. But a cup of warm Bovril fortified attention, and made for promptness and precision of action. It would not, as it was said of a small quantity of alcohol, postpone the application of the brake by the fifth of a second—a very minute particle of time, but sometimes of vital consequences.

LIQUID MYCOZOL

LIQUID MYCOZOL is offered as an effective agent for the treatment of skin mycoses fungous diseases commonly referred to as 'ringworm', 'athlete's foot', etc. Such diseases are caused by parasitic fungi, such as *Trichophyton interdigitale*, *Epidermophyton rubrum* and other dermatophytes. If used with ordinary

caution Liquid Mycozol does not macerate the skin but causes desquamation.

It contains alcohol, 48 per cent; salicylic acid, 2 per cent; benzoic acid, 2 per cent; chloretone (chlorbutanol), 5 per cent; malachite green, 0.01 per cent (1:10,000). It dries rapidly, and the treated skin may be noted to have a resinous feeling due to the small amount of gum turpentine present. Liquid Mycozol, when allowed to dry on the skin, will not discolour clothing.

It may be most conveniently applied to the affected area with a small soft brush or pledget of cotton. It may be applied night and morning and should always be permitted to dry before clothing is brought in contact with the treated area. At first it produces a momentary stinging sensation; following this the effect is soothing, and itching is quickly relieved. It has a drying effect which is desirable in treating moist areas since it assists in checking the spread of infection from bursting vesicles.

Liquid Mycozol should be kept tightly corked since both alcohol and chloretone will evaporate if exposed to the air.

Caution

Since this lotion contains an active keratolytic agent its use should not be continued indefinitely. The application of such agents if continued without proper caution may result in excoriation. This may be easily avoided, however, by frequent observation of the treated area, discontinuing the treatment if any untoward irritation appears.

It is supplied in bottles containing 50 cubic centimetres.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

GRANULOMA GENITO-INGUINALE

By V. GOVINDAN NAIR, M.R.C.P., F.R.F.S. & C.

Venereologist and Dermatologist, King George Hospital, Vizagapatam

and

N. G. PANDALAI, M.B., B.S., D.T.M.

Medical College, Vizagapatam

GRANULOMA GENITO-INGUINALE is a mildly contagious, chronic and progressive disease of unknown aetiology, characterized by granulomatous ulceration of the inguinal and the anogenital regions, showing little or no tendency to spontaneous healing; it yields to intravenous antimony therapy, but depigmented scars are left. It is auto-inoculable, affects all races and both sexes, and is endemic in many countries of the world.

The condition has numerous synonyms; the multiplicity of these denotes disagreement among workers about the real nature of the disease. All the names are open to objection. Granuloma inguinale, ulcerating granuloma of the pudenda, groin ulceration, peri-anal granulomata, all lay stress on the regional distribution of the disease. The names granuloma tropicum, granuloma pudendi tropicum, and tropical granuloma suggest a tropical limitation of the prevalence of the disease, although its occurrence in regions outside the tropics also has been widely recognized. Infective granuloma, ulcerating granuloma, and granuloma contagiosa are too indefinite to be specifically applied to any one of the granulomata. There remain only two names, chronic venereal sores and granuloma venereum, of which the latter seems to find favour with the majority of writers on this subject.

As, however, its common sites are the inguinal and the genital regions, the name 'granuloma genito-inguinale' is proposed as it is more comprehensive. It is also very desirable that all the writers on the subject should confine themselves by common consent to one name so as to avoid confusion in the matter of reference to it in the literature. In this paper the name 'granuloma genito-inguinale' is used throughout.

There seems to be some confusion between this disease and tropical or climatic bubo, probably due to the latter being also known as 'lymphogranulomatosis inguinale'. This is a distinct and separate disease which is an affection mainly of the inguinal and less commonly of the iliac and the pelvic glands.

History.—The disease was first recognized by McLeod in 1882 and described as 'serpiginous ulceration', though no specific name was given to it. In 1896, in British Guiana, Conyers and Daniels were the first to describe the condition as 'the lupoid form of so-called groin ulceration' and as a distinct disease entity. Then in 1897, Galloway, in England, reported

a case as ulcerating granuloma of the pudenda. This was followed, in 1898, by Dempwolff in New Guinea, who described it as granuloma contagiosa, having seen it among the Papuans and the Melanesians. In 1899, Maitland in Madras gave this condition the name 'chronic venereal sores'. Donovan in 1905, also in Madras, described certain intracellular bodies in smears from a month lesion and considered them to be the causative organisms. In 1911, Jackson in Australia described a kind of ulceration in the genitals and the perineum occurring in the aborigines which he had been observing since 1882. He thought the condition to be a form of syphilis in the blacks and so called it 'black pox'. In 1913, Aragao and Vianna were the pioneers in using potassium antimony tartrate intravenously in the successful treatment of this disease having been encouraged to do so by their success with this drug in the treatment of espundia. In the United States of America, the disease was first described by Grindon in 1913. Recently, Bhaskara Menon (1933) has supported the suggestion that the disease, like syphilis, may have a primary lesion which heals readily; and that it develops granulomatous ulcers later on as a secondary stage.

Geographical distribution

Cases have been reported from almost all parts of the world. Roughly speaking, the disease is prevalent in the countries lying between the latitudes of 60 degrees north and 20 to 30 degrees south of the equator. It is endemic in India, particularly south India, southern China, Italy, Spain, France, Germany, Australia, North and South Africa, practically the whole of South America, portions of Central America and 'almost all the states of the United States of America except in the inland rocky mountains section and the far western plains'. It is fairly common in the Circars as evidenced by the experience of the venereal department of the King George Hospital, Vizagapatam.

Aetiology

The aetiology is still obscure. Different observers who studied the disease at different periods thought it was a manifestation of tubercle, syphilis, neoplasm or of trophic disturbance; but there is little evidence to substantiate any of these views. In 1905, Donovan in Madras described certain bodies found inside large mononuclear cells and considered them to be the causative agent; he regarded them to be protozoal in nature. In the words of Donovan they looked 'like gigantic bacilli with rounded ends'. Markham Carter, in 1910, described them as 'bean-shaped bodies resembling the gregarine stage of a herpetomonas or crithidium'. Sibert thought them to be encapsulated intracellular diplococci. He placed them in the same aetiological relationship to the disease as the organism of rhinoscleroma to it. In 1913, Aragao and Vianna called them 'calymmatobacterium granulomatis'. Walker was inclined to regard them as intracellular capsulated diplococci, one of the Friedländer group (Manson-Bahr, 1929). Castellani and Mendelson (1929) considered the Donovan bodies as 'nosp. parasites', like proteus X19 of typhus.

In 1926, Goldzieher and Peck, after exhaustive studies, came to the conclusion 'that the aetiological agent is a pleomorphic organism which assumes the form of a bacillus or coccus. Its most typical form is that of a bacillus 1 to 6 microns in length, containing 1 to 3 inclusions which tinctorially behave like the nucleus of the cell'. They also proposed the name 'bacillus venereogranulomatis'. Though the Donovan bodies have been fairly constantly seen in the lesions by all observers they have not so far satisfied Koch's postulates; and so they cannot be accepted as the causative organism. Some consider the Donovan bodies to be only secondary organisms and the primary causative agent as yet to be discovered. Donovan bodies were observed by us in some of the cases in which smears were examined.

For the detection of the Donovan bodies smears should be taken either from the exudate or preferably from the scrapings deep enough at the edge or base of the lesion where the most advanced pathological changes are taking place. These bodies are pleomorphic and in appearance they are either coccoid or bacillary. They are generally seen as capsulated bodies within the large mononuclear cells. They may also be met with in the connective tissue cells and leucocytes and rarely in the plasma cells. Within these host cells they are seen either discretely or in groups of 15 to 20. These bodies later destroy the cell protoplasm and, rupturing the cell membrane, scatter themselves free into the tissues. They stain readily with the Romanowsky stains and are Gram negative. When stained with Giemsa's stain the capsule takes a bright red stain and the bacterium appears very dark violet. These organisms often show a constriction in the middle giving the impression that they are diplococci. In 1913, Martini succeeded in growing them in blood agar. He was also successful in inoculating mice and producing the disease in them; but he was unsuccessful with guinea-pigs and rabbits. They grow easily in Sabouraud's medium under both aerobic and anaerobic conditions and in the latter with the production of gas. The optimum temperature for their growth is that of the body; but growth may occur also at the room temperature. In litmus milk, dextrose and mannite acid is formed. They do not liquefy gelatine, but they coagulate milk. One of us (N. G. P.) isolated a similar organism by culture and by directly inoculating guinea-pigs with the tissue obtained from an active lesion. This organism was non-motile and Gram negative, staining feebly with aniline dyes. It had rounded ends and did not form spores.

McIntosh (1928) reported successful transmission of the disease to man by the transplantation of tissue obtained from a case with active lesion. He subsequently recovered Donovan bodies from the lesion thus produced experimentally. Campbell (1928) contests the view of McIntosh that granuloma genito-inguinale is caused by the Donovan bodies. He argues that in the transplanted tissue other organisms also might have been present. Campbell, after culturing the Donovan bodies in Sabouraud's medium, was unable to transmit the disease by inoculation of the culture into laboratory animals or human beings, including himself. But many workers including one of us (N. G. P.) have been able to produce in the laboratory animals a nodule or an abscess at the site of inoculation with material from an active lesion and to demonstrate the Donovan bodies in the lesions thus produced. In the course of a week these lesions break down discharging pus and heal spontaneously in about two to three weeks. But so far typical granulomatous lesions have not been produced by any of the workers, either in animals or in human beings, inoculating them with the Donovan bodies obtained from culture or from an experimental abscess. Until this is done successfully, Donovan bodies cannot be accepted as the causative agent.

Race, sex, and age incidence

Race is said to have no influence in the occurrence of this disease. Cases have been reported in all races, but the black races seem to be more susceptible than the white. In America, the disease is more common among the negroes, and some observers think the greater incidence in them is due to lack of personal hygiene. In India, it is more common among the Hindus.

In our series of 73 cases 72 were Hindus (all Telugus) and one Mohammedan (Bengal); in Bhaskara Menon's series of 61 cases 4 were

Mohammedans. At the same time, it should not be forgotten that the Moslem population in this part of the Circars is very small. Madras has a proportionately larger Moslem population and that seems to have been reflected in the greater incidence of the disease among the Mohammedans in Bhaskara Menon's series. Moreover, the Madras cases were drawn from all over the province. In this connection, it is interesting to note that the Mohammedans practice circumcision in early childhood. Wolff also has reported that the disease has not been observed in the Arabians with whom also this practice obtains. There were no Anglo-Indians nor Europeans in either series.

The disease is much more prevalent during the period of early adult and middle age (see table I). It is rare in persons of over 50 or under 15. Almost all the cases in our series (86.3 per cent) were between 18 and 40.

TABLE I
Age and sex incidence

Age period.		15 to 20 years.	21 to 30 years.	31 to 40 years.	41 to 50 years.	Total.
Males	..	5	16	10	4	35
Females	..	6	25	6	1	38
TOTAL	..	11	41	16	5	73

This table brings out another factor, i.e., that the disease is more common in females between 15 to 30 years of age and after that it is more common in males.

The youngest case in the literature was that reported by Shattuck, a male child of 2 years who was circumcised while he was a month old. Cases have also been reported in children of 6, 13, and 14 years. The oldest case on record was in a man of 67 years of age. According to some it is more prevalent in one sex and according to others in the other sex; the majority of observers think that the disease has preference for the female sex, and in our series also the preponderance was in women.

The disease appears to be more common in women than in men, at least in India; for women here do not present themselves for treatment in the general hospitals so readily as do men, especially for lesions in the genitals. If the proportion of men and women attending a venereal clinic is worked out it will be seen everywhere, even in the advanced European countries, that men predominate over women, though both should be affected in approximately equal numbers. In India, where there are not only untouchables but also unseeables (*Gosha* women), if according to hospital statistics the number of men and women suffering from this disease be equal, or even if the number of

women be only slightly less, it is safe to infer that the incidence in women is considerably higher than the statistics show.

The disease is not inherited and no case of congenital or inherited granuloma genito-inguinale has so far been reported. In Wilson's (1930) series of 14 pregnant women suffering from the disease none gave birth to a child with the disease. There were two patients in our series who were pregnant and gave birth to apparently healthy children.

No seasonal variations in the incidence of the disease are noted.

The disease is generally met with in the poorer classes. All our patients were from this class. Other conditions that may influence the onset of the disease are insanitary surroundings, overcrowding, lack of personal hygiene, promiscuity and polyandry.

The disease is endemic in many parts of India particularly in the south; so far it is not known to have prevailed as an epidemic form in these parts. de Vogel (1928) in Dutch Guiana has reported the existence of granuloma genito-inguinale in an epidemic form amongst the Marindene. He estimated that 12 to 15 per cent of the population had been affected. He also thought that the disease had been endemic there for a long time, and has only recently taken the epidemic form due to the improved communication between the villagers and the loose habits of the people, e.g., wife prostitution. Kalthofen (1928) has also reported the existence of the disease in epidemic form amongst the Kaja-Kajas of South New Guinea since 1915. It has been successfully combated since.

Transmission.—How the disease is transmitted from one individual to another is not definitely known. *Pediculus pubis* has been mentioned as a possible vector. Infected clothes, finger nails and the barber's common razor should also be thought of as other modes of transmission. All are agreed that it is infectious and mildly contagious. Most authors presume that the disease is a venereal one and transmitted by sexual contact, though prolonged contact, according to some, is required. The view of sexual transmission is advanced for the following reasons :—

(1) That in many cases a history of sexual exposure before the onset of the disease can be obtained. But no one seems to have gone far enough, to find out if the other party was suffering from the disease at the time of exposure. Ross and Kaup traced the source in the case of four men to one and the same individual; but they failed to report if the latter was actually suffering from the disease at the time. This is the only instance in which more than one person is reported to have contracted the disease from the same source.

(2) That the disease is more common at an age period when the sexual activity is at its height. But cases are reported in children sexually inactive and not exposed; for example, Shattuck's case in a male child of two years, McLean's case in a male child of six years, and Sabella's case in a girl of six years with an intact hymen.

(3) That the commonest site of the disease is the genitalia; but the granulating ulcer is equally commonly met with also in other parts of the body without the implication of the genitalia.

Points against venereal origin are :—

1. The consort, or in the case of married people the other partner, always escapes. Only one single case of a husband and wife being treated together for this

disease is so far reported. In Wilson's 14 cases in pregnant women, the husbands of all the fourteen were free from the disease. Maciel (1929) reported a case of a man suffering from the disease for four years and living all the time with his wife, who conceived and gave birth to a child that was free from the disease for the four months under observation.

In our own series, 51 were married and none of their partners according to the patients had the disease. But three women gave a history of their husbands having had some kind of ulcer in the genitals. It is very easy to get a history of exposure in the case of men, but in the case of women such a history, at least in our experience, is not easily obtained. Women suffering from the disease have sworn to us that they were never exposed but had only marital relations with their husbands, who were free from the disease.

McIntosh failed to see the disease develop in persons who were given many chances of intimate contact by sexual acts with infected persons; these experiments were conducted in the Memphis General Hospital under direct medical supervision. The existence of an individual susceptibility has been invoked to explain this failure.

2. The preponderance of the disease in women. If the disease is infectious and of venereal origin, both men and women should be equally affected. If the analogy of venereal disease is taken, of those attending venereal clinics, men predominate over women.

3. In spite of the greater prevalence of the disease in women, the disease is not as commonly seen as the other venereal diseases in professional prostitutes.

4. The comparative rarity of the disease as against the wide prevalence of other accepted venereal diseases.

5. The comparative frequency of extra-genital lesions without a genital focus.

6. The occurrence of the disease in those who are not sexually exposed and in sexually inactive children who were never exposed. In our series there was a case of a young unmarried man of twenty who, though never exposed, had the ulcer on both sides of the anal margin. Another patient of our series developed the disease 16 years after amputation of his penis. In this case it is needless to say that there was no question of sexual intercourse.

7. That granulosomatous ulcers develop after trauma, particularly after operation for bubo, circumcision, piles and anal fissure.

8. The absolute freedom from infection of the internal genitalia.

If the disease is venereal in nature why should the external genitalia alone be affected? The disease generally starts in women in either the labia majora or minora, more often in the latter, and then spreads to the skin of the labia or to the muco-cutaneous junction, or to the vaginal introitus and to a slight extent into the vaginal wall. We have not come across any reported case nor any one in our series with the history of the disease making its appearance first in the fornices or on the cervix uteri. Extension of the disease to these structures has not been reported, nor did it occur in any of our series though some of the cases were of long duration, lasting from 2 to 6 or even 15 years. In this connection, it is worth noting that the lesions are fairly frequently seen on the prepuce and glans penis. If granuloma genito-inguinale were of venereal origin, at least a small percentage of the lesions should be on the cervix; but no such case is on record.

In conclusion, we are inclined to think that the disease cannot be taken to be of venereal origin until more convincing proof is forthcoming.

Pathology

Most of the cases start as a papule or a small nodule; the surface epithelium of these excoriates or erodes and an ulcer is formed. Some have

observed a thin greyish membrane covering the ulcer. Such a membrane was observed in one of our cases. This membrane can be easily scraped off, when the usual pink ulcer underneath is exposed. The ulcer itself is red or pink and presents the appearance of granulation tissue, studded all over with papules or small nodules. Therefore its surface is not even, but presents elevations and depressions, the former having been aptly described as 'mountains in a relief map'. The edges are not undermined and there is no induration in the early cases. Particular attention is drawn to this fact because the textbooks describe the ulcer as having a hard and indurated edge. In our experience, the induration is found to be present only in chronic cases of long standing. We have also come across cases which show no induration in the parts that are recent but induration in the older parts of the same ulcer. The same is the case even with the scars; those of recent ulcers are soft and supple while those of chronic ones are hard and unyielding. The normal tissue beyond the edge of the ulcer appears in some cases to be a little raised above the surface; this is probably due to infiltration or exudation. In a few cases, 3 or 4 in our series, the lesions were definitely raised above the surrounding skin, and were ribbon-like in appearance. The ulcer is soft to the feel and bleeds easily. There are no areas of suppuration, caseation, nor necrosis. No purulent discharge is present even when the ulcers are extensive. The ulcer is dry in a few cases, but more often it is moist, exuding a thin watery, or blood-stained and sticky, fluid—with a peculiar unpleasant odour of its own—in which the Donovan bodies can be demonstrated. In a fair proportion of cases the exudation is so profuse as to be a source of nuisance to others while it is a source of inconvenience to the patient. It wets the clothes of the patient; the skin around the ulcer gets sodden; and one gets the unpleasant odour on approaching the patient.

The ulcer is very superficial being only a few millimetres deep. The subcutaneous tissues are invaded only rarely. It is not definitely known whether the infection spreads through the lymphatics. Goldzieher and Peck claimed to have seen the Donovan bodies in a regional lymph node which was apparently normal. The lymphatic glands are enlarged only in a few cases while in the great majority they are not. In our series of 73 cases only 11 (15 per cent) showed definite enlargement; and in another 13 the regional glands were just palpable. In this country where many persons walk barefooted and where filariasis is fairly common, it is not unusual to find palpable inguinal glands without any apparent lesion. It is evident that lymphatics, particularly of the genitalia when the lesion is situated there, are affected producing a pseudo-elephantoid condition of the skin of the

surrounding areas (figure 1). In the case of males, the prepuce and the skin of the penis or the scrotum or both may become thickened. In the case of females, the labia may become

Fig. 1.—A case with elephantoid condition of the labia with excessive scar formation in and around the perineum: this case remained refractory to tartar emetic treatment for a long time.

thickened, hard, indurated and granular and at times studded all over with large nodules. In some cases a mass of hypertrophied nodular tissue is seen hanging from the crura of the clitoris as a pedunculated tumour. The pseudo-elephantoid condition is much more common in

Fig. 2.—A case with extensive ulceration and deformity with complete occlusion of the vagina: duration 15 years.

women; in our series 16 cases were in women and 2 in men. The ulcers are single or multiple; and they enlarge by continuity or contiguity of surface and by auto-inoculation. They spread very slowly taking many months for the development of a good-sized ulcer.

On healing a depigmented scar is left. The scars of recent ulcers are soft and yielding, but the scars of chronic ones, though soft at the time of healing, become sclerosed in course of time and are then hard and unyielding (figure 2). It is common to see an ulcer with one portion healing and another portion advancing. The healed scars may easily break down even during the course of active treatment. In the females, though the ulcers are superficial, extensive damage may be done to the external genitalia resulting in deformity, disability and even in the occlusion of the vagina (figure 2). In one of our cases the vulva was a mass of scar tissue without the labial cleft, necessitating the operation of hysterectomy to prevent the retention of the menstrual fluid (figure 3). Ulceration of the rectum and the urinary meatus results in stricture of the respective parts. In males, when the ulcer is all around the root of the penis the stem of the penis, becomes involved in the ulcer and cannot be mobilized. On healing, the glans penis alone is visible in such cases (figure 4).

Fig 3—A healed case showing complete destruction and obliteration of the external genitalia; this patient is periodically attending the hospital for dilatation of what was once the urinary meatus. Though long standing, the scar is still soft, supple and depigmented.

Histopathology

It is generally accepted that there is nothing characteristic histologically to warrant a diagnosis from a microscopical examination of the section alone. Still there are certain features which may enable an experienced pathologist to identify the condition. Granuloma genito-inguinale, as the name implies, is a granuloma and the initial lesion is a papule or a small nodule. If a section made from an early nodule

or from the edge of the ulcer be examined it will be found to be made up of nodules or

Fig. 4—A case in which the penis is embedded in the ulcer: the glans alone is visible outside.

masses of nodules which consists of an infiltration of cells into the corium of the skin. The essential histologic characteristic is cell infiltration. A variety of cells is seen, chief among them being polymorphonuclear leucocytes, lymphocytes, connective tissue cells, large mononuclears, and plasma cells. There is an accompanying vascular dilatation and engorgement; the papillae of the skin are elongated eight to ten times their normal size; inter-papillary plugs also become very long; and the superficial layers of the epidermis are absent, being denuded by excoriation or scratching by the patient. The deeper layers of the epidermis also proliferate thus adding to the exaggerated size of the papillae already mentioned. This papillary elongation and cellular infiltration are by no means characteristic, as these are also met with in other chronic ulcerative conditions of the skin. Though there is an abundance of newly-formed granulation tissue with its concomitant new capillaries, evidence of hæmorrhage into the tissue is very rare. In the mononuclear cells, clumps of Donovan bodies are seen. As the lesion becomes chronic the inflammatory reaction spreads deeper into the skin and we see many lymphocytes and plasma cells, but few polymorphonuclears in it. Giant cells are conspicuous by their absence; there is no evidence of endarteritis obliterans; there are no areas of suppuration nor caseation, and there are no tubercle bacilli present. Although granuloma genito-inguinale has a striking resemblance to

rhinoscleroma, the characteristic large cells of Mikulicz and the bacillus of von Friesch, associated with the latter condition, are absent in this. In very chronic cases large masses of non-pigmented fibrous tissue are seen. When the ulcer begins to heal the cellular infiltrate is absorbed and its place is taken by fibrous tissue. Microscopic sections also show the presence of a few hair follicles and sweat glands and these are thickened and infiltrated with round cells. At the periphery of the lesions the cellular infiltration extends to a short distance into the normal skin; this is the evidence to show that the disease is extending to the surrounding tissues which appear normal to the naked eye.

Incubation period

This has been differently stated by different workers. It has been claimed by some observers that the incubation period is two to eight days after sexual contact; others state that it may extend to twelve weeks; the extremes thus are two days and twelve weeks. In our series, judging from the date of the last illicit sexual intercourse to the date of the first appearance of the lesion, the incubation period ranges from one day to twelve weeks the average being eighteen days for twelve cases. But these observations have been made on the assumption that the disease is venereal and is transmitted by sexual intercourse. Until the mode of infection is definitely known, it is not possible to determine the period of incubation.

Modes of onset.—Many observers think that the disease starts as a papule, small nodule or an ulcer, or subsequent to trauma, particularly surgical trauma. The following are the modes of onset in our series as noted from the history of the patients :—

1. As a superficial ulceration.
2. As a circumscribed nodule or papule which later on ulcerates and spreads.
3. As a post-operative development.

(a) After circumcision a typical granuloma develops on the line of the incision (figure 5). Another of our patients came under observation for a few small ulcers on the glands and the mucous surface of the prepuce. Clinically, these ulcers appeared to be non-syphilitic; and no *Spirochaeta pallida* was found in the exudate on examination under darkground illumination. A dorsal slit was first made preparatory to circumcision and when the ulcer had almost healed circumcision was completed. But the sutures did not hold, and in three days they had to be removed. In the line of incision the typical ulcer developed which readily yielded to tatar emetic intravenously.

(b) After operation for piles or anal fissures.

(c) After operation for inguinal bubo

4. As an intolerable itching followed or accompanied by the eruption of a crop of papules; this is more common in women. The incessant scratching leads to the formation of multiple superficial ulcers which slowly take on the granulosomatous character.

These small ulcers coalesce and form large ones. In these cases the ulcers are spread rapidly by scratching. When papules are present they erode and then ulcerate, or they fall off leaving small ulcers with a punched-out appearance. In the words of one of our patients, small bits of tissue (papules) about the size of a split pea used to fall off on scratching, leaving small ulcers.

Fig. 5.—A case with history of circumcision preceding the onset of the disease.

6	Vesicle ..	3	4.1
7	Undetermined ..	8	11.0
TOTAL ..		73	100

Sites of the lesion.—The commonest sites are the external genitalia, the groin and the pubis, the perineum and the peri-anal region, the mouth,

lips and the palate. The disease has been reported to occur in all regions of the body except the scalp. The following sites are also mentioned in the literature:—Nose, ears, pharynx, larynx and pillars of the fauces, cheeks, gums, tonsils, face, forehead, mastoid region, neck, chest, lower part of abdomen, back over the kidney regions, sole of the foot and fingers.

Symptomatology.—The disease usually makes its appearance insidiously without any

Fig 6.—A case showing the onset of the disease as an ulcer on the glans penis.

premonitory symptom or constitutional upset, but two of our patients gave a history of rigors followed by high temperature at the time of the appearance of the vesicles which burst and formed into typical ulcers.

The disease as stated above often starts as a papule, small nodule, vesicle or ulcer on the prepuce or the glans penis (figure 6) in the case of males and on the labium minus in the case of females. The perineum in females (figure 7) and the peri-anal and inguinal regions in both

Fig. 7.—A case showing the onset of the disease on the perineum preceded by intolerable itching and a crop of papules: note the absence of induration of the scar tissue.

the sexes are other common sites. The ulcer is superficial and may be single or multiple. The progress of the lesion is very slow, taking weeks to months to develop to the size of a rupee. It spreads peripherally, by auto-inoculation to the opposing surface and also by infected clothes and finger nails. It extends over large areas and in places is destructive to the deeper structures. Its surface is generally moist, but occasionally dry. A fair amount of thin, watery, or blood-stained and sticky, fluid with a characteristic unpleasant odour exudes from the surface. In a few cases this exudation is continuous and profuse so as to wet the patients' clothes. In men the ulcer in the glans penis and the prepuce may extend to the stem and the root of the penis, to the pubis, the groin and the lower abdomen; and from the groin it may spread down the thighs; from the root of the penis to the scrotum or all around the root of the scrotum, as a band as in one of our cases, and downwards into the perineum, peri-anal region, anus, and rectum; from here it may

spread to the buttocks. The urinary meatus is also at times involved and in one of our male patients the urethral opening was at the corona, as a result of the lesion spreading up into the urethra. In the case of women, starting on the labium minus, the disease may spread by continuity externally to the labium majus and from there upwards to the mons veneris (figure 8); or downwards to the perineum, peri-anal region and

Fig. 8.—Extensive lesion in a pregnant woman

parts about it as in the males, or it may spread internally to the vaginal introitus and for a short distance up the vaginal wall. Extension to the fornices or the cervix is practically unknown. The clura of the clitoris and the vestibule are other sites of origin. When the vestibule is affected the urethra also gets involved resulting in stricture of the urethra. The involvement of the anus may result in recto-vaginal fistula or stricture of the rectum. A third mode of spread, by the blood stream, has been reported by de Vogel. In the cases with acute onset it is surmised that the large mononuclear cells laden with the Donovan bodies get into the blood stream disseminating the disease. Metastatic lesions have been reported in the internal organs, such as the liver and the lungs. In the case of Thierfelder, the pus from the liver abscess showed the Donovan bodies.

Like condylomata lata, this disease seems to have a special preference for moist, warm surfaces such as the vulva, the perineum, the scrotum, the folds between the thighs and the

scrotum, the cleft between the buttocks and the anal margin. When hairy parts like the groin or the pubis are affected, the hair falls off as the ulcer develops and spreads. Simultaneously with the peripheral spread healing also occurs in other areas with the formation of soft and uneven scar tissue that breaks down readily. In some cases, the scar formation is so rapid as to bridge over the active ulcers with the formation of tunnels and sinuses. In one of our cases such a condition developed in the groin forming sinuses that necessitated opening up later. The newly-formed scar tissue may easily break down even during active treatment. Some time after complete healing the scars become hard, sclerosed and depigmented appearing as white or lighter coloured patches. In both sexes the regional lymphatic glands are enlarged in some cases (15 per cent in our series), markedly in a few and slightly in a few others. In the large majority of cases the regional lymphatic glands are not enlarged. Sometimes cases are seen with extensive ulceration, but with no lymphadenitis or lymphangitis; and these cases have no purulent discharge, though the ulcer is not kept clean by any antiseptic dressing nor even by simple washing. When the lesion is on the genitals a pseudo-elephantoid condition is sometimes noticed. This may be due to any or all of the following causes:—The actual involvement of the lymphatics in the disease process; the blocking of the lymphatics with masses of large mononuclear cells packed with the Donovan bodies; or the obliteration of the lymphatics in the process of formation and contraction of the scar tissue. As already pointed out this hypertrophy is almost exclusively seen in the genitalia and in the great majority of cases in the female. It looks as though the pseudo-elephantoid condition is not the sequel of the sclerosing of the scar tissue only, as this hypertrophied condition is found present in very early cases also, before the formation of any scar tissue. Again, cases of long standing are found with very hard and sclerosed scars but without any pseudo-elephantoid condition. Further, cases have come under our observation with superficial ulceration of the labia which are hypertrophied and also those with sclerosed protuberant masses of scar tissue in the perineum and extending to the buttocks, but without any hypertrophied condition of the surrounding skin.

Almost all workers in this field report that granuloma genito-inguinale is a symptomless disease and that the patient seldom complains of anything except the mental uneasiness caused by the presence of the ulcer. Our experience, on the contrary, is that most of our patients complained of one or more of the following symptoms: pain, burning sensation, intolerable itching or a peculiar sensation as of the crawling of worms on the skin. Pain is a more-or-less common symptom. Sometimes it is so severe as to necessitate the ordering of a sleeping

draught. In those cases in which the anus or the peri-anal region is affected, pain during defaecation was more-or-less constant. Besides, in all those cases the patients complained of difficulty in sitting. The mouth lesions cause pain and difficulty in swallowing. One of our patients, a woman with ulceration of the genitalia of 12 years' duration and pseudo-clephantoid condition of the labia, said that sexual intercourse became painful for her from two years after the onset of the disease. Burning during micturition is another symptom when the urethra is involved. Mechanical difficulty in walking is experienced, especially in extensive ulceration of the genitalia, the perineum, the peri-anal region and the groin. This is particularly seen in women who develop a peculiar gait. Intolerable itching is another common complaint particularly among women. Some have it throughout the course of the disease till the ulcer begins to heal; while others complain of it at the actively-spreading stage only, and scratching, the unavoidable concomitant of itching, undoubtedly helps the spread of the ulcer.

Recurrence is common and in our series 18 patients have returned with recurrence, nine females and nine males. The new lesion occurs in the same old site, and is due to the breaking down of the scar. Such recurrences may take place more than once. In our series we have seen two and three relapses. These recurrent cases do not heal so readily as the primary ones.

Fig. 9.—Secondary infection of the mouth involving the whole of right half of the palate and upper lip.

Sequelæ

These depend on the site of the lesion. If in the prepuce, glans or stem of the penis only a scar results, at times, with a pseudo-clephantoid condition of the skin of the penis and the consequent deformity and impaired function. If the condition is present all around the root of the penis the latter gets embedded in the ulcer as in three of our series and it becomes immobile resulting in deformity and loss of function (figures 4 and 10), if at the peno-scrotal junction, a pseudo-clephantoid condition of the

Fig 10—A case of twenty years' standing, the penis is embedded in the scar

scrotum may follow. Involvement of the urethra or the anus may result in stricture. In the other regions, contraction of the scar tissue produces deformity. Deformity due to the destruction and the contraction of the scar tissue and other causes mentioned above may result in pseudo-clephantoid condition of the labia, forming at times a nodular tumour-like mass hanging from the crura of the clitoris barricading the vaginal opening thus causing deformity and loss of function. Painful sexual intercourse, stricture of the vagina and recto-vaginal fistulae are other sequelæ in women. Pregnancy aggravates the condition; while its termination tends to ameliorate it. Wilson, who has reported fourteen cases in pregnant women, thinks that pregnancy ends in premature labour in a fair proportion of cases. In our series, there were two pregnant women both of whom had premature labour. It is stated in some textbooks that women are rendered sterile by this disease. This statement is not supported by the available statistics, nor by any theoretical considerations. Non-conception as an indirect result of the disease is more probable; but this is due to mechanical causes and is seen only in those with deformed and distorted or obstructed genitalia.

disabling normal sexual intercourse. In our series there were four women whose history definitely proved that women are not rendered sterile by the disease. The same is the case in Wilson's series of pregnant women with the disease. Unfortunately, Wilson has not reported whether these women were suffering from the disease when they conceived.

Case 1.—A woman, who had had seven full-term deliveries of which three children had died and four were alive and well. The ulcer started for the first time during her first pregnancy ten years ago; and at no time thereafter did it completely heal. The patient was first seen during her eighth pregnancy when she had a granulomatous ulcer of the whole of the perineum extending to the lower third of a hypertrophied left labium.

Case 2.—A married woman aged 25 years with a history of two previous pregnancies. In her the disease first started on the right labium majus as a vesicle, preceded by intolerable itching; it ulcerated and slowly increased in size. After two or three months she became pregnant for the third time and was seen first in January 1933 when she was about three months pregnant. At the time of admission she had a raised granulomatous ulcer extending from the symphysis pubis along the inner borders of both labia majora on both sides down to the anus; and on the left side there was another ulcer extending up from the lower third of the left labium majus to the left groin (figure 8). The inguinal glands were not palpable. She was given 32 cubic centimetres of a two per cent tartar emetic solution intravenously in 16 injections and was discharged on 8th March with the ulcers completely healed. She was advised to continue the injections and come back for confinement. She returned on the 6th July with ulceration of the labia which were hypertrophied and nodular. The scars in the perineum also had broken down. In addition there was a nodular hard mass of about the size of a lime hanging from the prepuce of the clitoris. This time she had a premature labour; and the delivery was instrumental, necessitated by stricture of the vagina and hard unyielding nature of the tissues.

Case 3.—A young married woman of 20 years of age. The ulcer first started during the sixth month of her first pregnancy and after confinement the ulcer is said to have healed with some injections. She became pregnant for the second time; and three months after confinement she had very bad itching which was followed by the development of the present ulcer.

Duration.—Before the patients came under our observation the ulcers were in existence for different periods in different persons, the extremes being eight and ten days at the one end and twenty years at the other. The average duration was about two and a half years from the sixty-six of our cases in which the duration of the disease could be elicited with any degree of accuracy. Of these sixty-six cases the duration in twenty-two was under one year; in eleven of one year; in three of one and a half years; in eight of two years; in twelve of three years; in one of four years; in two of five years; in two of six years; in one of ten years; in two of twelve years; in one of fifteen years and in one of twenty years.

Diagnosis.—This depends upon the characteristic granulating nature of the ulcer with slow development and chronic course; the demonstration of the Donovan bodies from the scrapings

of the ulcer; the absence of response to the treatment for the other ulcerative conditions and the healing of the ulcer on treatment with tartar emetic. Granuloma genito-inguinale may be mistaken for a variety of conditions occurring in the same sites; the points for differential diagnosis for some of these are summarized below :—

Syphilis.—Primary sore. This starts as an abrasion or papule which soon erodes and forms an ulcer. The ulcer is painless and has a red areola all round. The edges are hard, indurated and the base is built up. The regional lymphatic glands are enlarged with the characteristic hard India-rubber feel. The ulcer does not bleed readily and the serum exuding from the ulcer shows *Spirochæta pallida*. The sore heals spontaneously even without treatment.

Secondary syphilis, mucous patches or condylomata lata. In these cases there is a history of the primary sore with other secondary lesions in other parts of the body such as sore throat, general adenitis, and a positive Wassermann reaction of the blood. *Spirochæta pallida* can be demonstrated in the serum exuding from the lesions that react readily to anti-syphilitic treatment. Tertiary syphilis—broken-down gumma. The edge of a gummatous ulcer has a characteristic punched-out appearance with a sloughy base resembling wash-leather, while the patient may show other evidence of syphilis and may give a helpful history of having had lesions of primary or secondary syphilis. Further, in the large majority of cases the Wassermann reaction of the blood will be positive. Response to the anti-syphilitic treatment is yet another distinguishing feature.

Chancroid—soft sore.—This has an acute onset within a day or two after exposure and the ulcer is very painful, red and angry-looking with undermined edges. It spreads rapidly. The regional lymphatic glands are enlarged and painful with periadenitis and lymphangitis, and there is a tendency to suppuration. Smears taken deep from the ulcer show the Ducrey's streptobacillus, and the intradermal test with the specific antigen is positive.

Lymphogranulomatosis inguinale.—This condition may simulate granuloma genito-inguinale when the bubo has broken down with the formation of sinuses. It is ushered in with malaise, headache and fever and with a painful enlargement of the inguinal glands that suppurate and break down into an ulcer with sinuses. Extension to the pelvic and the iliac glands may also occur. Frei's intradermal test gives a positive reaction.

Malignant ulceration.—Of the groin and the genitalia. This condition is not uncommon. The difficulty of diagnosis from this is real at times, as even experienced pathologists may have difficulty in distinguishing sections of granuloma genito-inguinale from epithelioma. The malignant ulcer spreads more rapidly with lymphadenitis and does not respond to antimony treatment. Age also will be of some help, as the age for cancer is above 40, whereas the very large majority of cases of granuloma genito-inguinale occur below 40.

Tuberculous ulceration.—This is confined more or less to the pudendum and is pale with undermined edges. Biopsy will show areas of caseation, giant-cell systems and tubercle bacilli. In doubtful cases animal inoculation may be resorted to.

Yaws.—This disease is common in children under puberty and the initial lesion in 99 per cent of cases is extra-genital. It yields to arsenic therapy readily; while antimony has no effect on it.

Oriental sore.—This also affects the skin and the mucous membrane; and it yields readily to antimony compounds; but the diagnosis is not very difficult. Oriental sore affects the exposed parts; whereas granuloma genito-inguinale is an affection of the covered parts of the body with a predilection for moist warm places. The leishmania parasites are seen in oriental

sore, as against the Donovan bodies of granuloma genito-inguinale. Oriental sore is more frequently seen in children while the granulomatous condition is more common in the adults.

Elephantiasis.—Because of the pseudo-elephantoid condition often occurring in granuloma genito-inguinale, it may be mistaken for the real elephantoid condition due to filaria. But the clinical picture of elephantiasis is distinctive.

Blastomycosis.—This condition has a tendency to crust formation and the exudate from the ulcer is thick and purulent. The microscopical examination of the exudate will reveal the budding yeast-like cells and a culture may show the mycelial form.

Rhinoscleroma.—It is primarily a disease of the mucous membrane of the pharynx, the larynx and the nose. Mikulicz cells can be demonstrated and the bacillus of von Friesch can be cultured from the discharge. Any treatment including the application of radium seems to be ineffective.

Prophylaxis

Until the nature of the causative agent and the mode of transmission are definitely determined anything done by way of prophylaxis can be only empirical. With our present knowledge, the only useful prophylaxis consists in segregation and the early and effective treatment of the afflicted; and the improvement of general sanitation and hygiene.

Treatment

General. In the early stages and in patients with small ulcers ambulatory treatment is sufficient. When the ulceration is extensive and when there is difficulty of locomotion patients should be hospitalized. As there are no constitutional symptoms no general treatment is indicated. But those with secondary anaemia may be given iron and arsenic either by mouth or hypodermically.

Special. In the earlier days, surgical interference was considered the only effective and successful method of treatment. Excision was done with or without cauterization and a good margin of normal tissue was also removed with it. But the resulting scar tissue often used to break down subsequently. McCord was the first to use x-ray therapy for this condition. Sequiera next tried the rays in a case of his. Fairly extensive trial was given to röntgenotherapy in the Government General Hospital, Madras, with some amount of success. In 1913, Aragao and Vianna introduced intravenous therapy with the injections of potassium antimony tartrate in the treatment of this disease. These injections proved very successful and still form the mainstay of treatment. It is difficult to accept it as a specific for this condition, as success is not universal. The ulcers, unless very chronic, heal readily but relapses are common. In the early cases complete cure can be assured practically, as recurrences are rare. Even in long-standing cases when they come under treatment for the first time the initial improvement is satisfactory. In a small percentage of chronic cases, 4 in our series of 73, the ulcer improved under treatment with antimony injections but

only up to a certain stage when the condition became stationary or even worse. Such cases are referred to as antimony-fast, on analogy to the arsenic-fast cases in syphilis. These resistant cases, some of them at any rate, react to non-specific protein therapy. T. A. B. vaccine or Dmlecos (Ducery's bacillus) vaccine intravenously in increasing doses are useful for this purpose. The resistance to antimony disappears and thereafter the ulcer begins to yield to it. The ulcer which was indolent, pale and unhealthy shows a marked change for the better even the very next day after the protein shock; it becomes clean, red and healthy and heals rapidly. But a very small percentage of cases remains refractory to treatment even after the shock. Potassium antimony tartrate is usually given intravenously as a one- or two-per-cent solution in normal saline or five-per-cent solution of glucose. The injections are repeated regularly on alternate days. The dose depends upon the individual tolerance. Coughing fits during or immediately after the injection and pain in the joints 6 to 12 hours after the injection are the usual signs of intolerance. When cough is noticed the dose for the next injection should be reduced. When pain in the joints appear, interrupt the treatment for a couple of days and after the pains have disappeared treatment can be resumed. Another rare complication is jaundice. When this occurs further treatment should be stopped and the usual treatment for jaundice carried out. Of late, pentavalent compounds of antimony are used instead of the trivalent tartar emetic. The commonly used preparation of this class in this country is urea stibamine, which is reported to be more efficacious than tartar emetic. Fouadin, another organic compound of antimony, is under trial in this disease (Williamson *et al.*, 1933). It is too early to give an opinion about its efficacy. Diathermy, radiant heat and application of radium are other treatments recommended.

Local. Any tried antiseptic dressing is all that is necessary. Manson-Bahr recommends the application of an ointment containing 1 per cent antimony as a dressing for the ulcer for two hours to be followed by boric ointment. This local treatment is very painful besides being messy; it is devoid of any reasonably good effect, and so it is better avoided.

Prognosis

This is good as far as life is concerned. Most of the cases, even if untreated, go on for a long time without any constitutional symptoms except a slight secondary anaemia. Though not a fatal disease, it causes serious annoyance and misery to the patient. In very rare instances death may result from extensive ulceration involving the subjacent viscera, as in a case reported by Rice. There was one death in our series. It was a case of a woman with

(Continued at foot of next page)

A NOTE ON THE TREATMENT OF INFECTIVE GRANULOMA WITH 'FOUADIN'

By R. V. RAJAM, M.B., M.S. (Madras), M.R.C.P. (Edin.)
Venereal Specialist, General Hospital, Madras

IN the treatment of this condition, the specific action of antimony compounds has been recognized for over two decades, but the tendency to frequent recurrence, and the development of antimony-fastness of the recurrent lesions, have been annoying to the tropical venereologist. Further, the patients with recurrent granulomas quickly exhibit a toxic intolerance to the particular drug employed. On account of the great tendency of the lesions to break down, the treatment should be continued far beyond the time when they heal. It is difficult to lay down any rule regarding the duration of the treatment. The treatment of cases should be individualized, and courses of treatment separated by short

(Continued from previous page)

extensive ano-genital lesions. A post-mortem examination was not obtained, therefore it was not possible to know whether there was any visceralization. With proper and prompt treatment, success can be assured. In the early cases, a few injections of potassium antimony tartrate will cure the disease. In one of our cases with three or four injections of antimony tartrate, the ulcer had completely healed. In long-standing cases recurrence in the healed portion is common. Chronic recurrent cases are refractory to antimony treatment, and complete healing in them is often difficult to effect; so the prognosis should be guarded in such cases.

We have great pleasure in thanking Dr. C. Ramamurthi, B.A., M.B., B.S., B.Sc., Professor of Bacteriology, Medical College, Vizagapatam, for the help rendered to us, and Dr. P. Kesava-swamy, the radiologist of the King George Hospital, Vizagapatam, for the photographs.

rest intervals over a period of four to six months should be instituted. As in the case of organic arsenicals in the treatment of syphilis, it appears to us that the trivalent antimony compound is therapeutically more effective than the pentavalent compound in this cutaneous venereal disease.

Of all the antimony preparations used in the treatment of this disease, 'Fouadin' seems to be superior to others (Williamson *et al.*, 1933). 'Fouadin', named in honour of King Fouad of Egypt, is a trivalent antimony preparation, made by Bayer-Meister Lucius and is being used very successfully in the treatment of Egyptian bilharziasis. It is an antimony compound of pyrocatechin-sodium-disulphonate, the preparation is used in a seven-per-cent solution, and is put up in 25 c.cm. and 50 c.cm. bottles. The manufacturers have stabilized the solution so that it does not undergo oxidation on exposure.

Twenty-five cases (18 males and 7 females) of infective granuloma have been treated in the venereal department of the General Hospital during the past nine months with this preparation and the results have been very encouraging. Its superiority over other antimony compounds in the treatment of infective granuloma may be seen from the following points:—

1. The drug is in ready-made stabilized solution for direct use from the bottle.
2. It can be injected intramuscularly without causing any pain or infiltration. In two cases it was even given subcutaneously and nothing untoward happened except slight pain at the time of injection. It is well known that only a few antimony preparations can be given by the intramuscular route, and certainly a drug injected intramuscularly has certain advantages over one that has to be introduced into the veins.
3. The injections can be given at frequent intervals and even daily.
4. There are no immediate side-effects, no cough, vomiting, fainting or other forms of nitritoid crises.
5. The late effects are negligible, the only complaint in our series was joint pains which occurred during the later part of the treatment. The occurrence of joint pains did not prevent us from continuing the treatment as they were only temporary and disappeared with lesser dosage.

6. No toxic effects were observed either on the kidneys or liver.

7. The rapidity of healing of the lesions is a very striking feature, hence the duration of treatment is shorter than that by other compounds. This is a great advantage both from the point of view of the patient and the hospital.

The following is the course of treatment adopted in the department for an adult male weighing between 100 and 120 pounds. Females receive three-fourths of the male dose. The

injections are given intramuscularly, preferably in the gluteal region. This course is a slight modification of that recommended by Professor Khalil, Parasitologist of the University of Cairo:

Day		Number of c.c.m. of 'Fouadin'
1st day	..	15
2nd day	..	20
3rd day	..	25
4th day	..	30
5th day	..	35
6th day	..	40
8th day	..	40
10th day	..	45
12th day	..	45
14th day	..	50
16th day	..	50
Total		395

In some of the cases, we have administered as much as 60 to 70 c.c.m. of the solution spread out over a month without any ill-result.

Report of a few of the cases of infective granuloma treated with 'Fouadin'

Case 1.—Hindu male, aged 22. Duration of the condition four and a half years. Has been attending the department off and on since 1930. In 1931 he had received 42 grammes of urea stibamine in the space of four months and the granuloma healed. Reported again on the 10th May, 1933, and the condition on admission was as follows:—patient emaciated and anemic, suffers from great pain and loss of sleep—six months' duration; extensive infective granuloma of both groins, root of the penis and anterior aspect of the scrotum.

Fig. 1.—Case 1. Before treatment with 'Fouadin'.

the edges of the ulceration are thin and irregular, the base of the ulcer is crateriform in some places; the discharge from the ulcer is thin and offensive. The

patient has developed a deformity of the hips which are kept fixed and adducted; blood Wassermann negative; Frei's test negative.

Fig. 2.—Case 1. After treatment with 'Fouadin'.

He was given injections of urea stibamine twice a week for six weeks. The condition did not show the slightest response; on the other hand, he was becoming toxic, suffering great pain from the ulcers and running a hectic temperature. He had received 125 grammes of urea stibamine and was showing intolerance to the drug. The treatment was stopped and he was given

Fig. 3.—Case 2. Granuloma of the groin before treatment.

x-ray exposures for three weeks with very little benefit. As he did not improve, the patient insisted on being discharged. He reported again on the 17th August. The condition was stationary if not worse. It was decided to try 'Fouadin' as a last resort, and the result of treatment with 'Fouadin' was dramatic. He

was given thirteen injections of 'Fouadin' and the lesions completely healed in 25 days. After the fourth injection the granulomatous mass began to dry up and crust, and the excruciating pain subsided. He put on weight. No untoward reaction, either immediate or late, was observed (*vide* figures 1 and 2).

Case 2.—Hindu male, aged 34. An old case of infective granuloma. Attended the department two years ago and had received injections of urea stibamine.

Fig. 4.—Case 2. The same condition after treatment.

Condition on admission.—Infective granuloma of the left groin, extending downwards to the perineum and posterior part of the scrotum. Scars of healed

Fig. 5.—Case 2. Granuloma of the mouth before treatment.

granuloma on the right groin. Extensive granulomatous ulceration involving the mucous membranes of the lips, gums, cheek and palate on the right side. Salivation and fetor were marked. Patient unable to swallow. Wassermann reaction negative. Frei's test negative.

Patient was given eleven injections of 'Fouadin' in the course of 19 days. After the fifth injection, both the mouth and groin lesions started drying up rapidly

Fig. 6.—Case 2.

and by the end of the tenth injection they had completely healed. No reaction, either immediate or late, was observed (*vide* figures 3 to 6).

Fig. 7.—Case 3. Before treatment.

Case 3.—Hindu male, aged 26. History of sore on penis two years ago for which he underwent a circumcision.

Present condition.—Ulceration of groin of one year's duration. An extensive granulomatous ulceration involving the whole of the right groin and extending downwards and inwards into the perineum and buttock on the same side; patient emaciated and anemic; both

Fig. 8.—Case 3. After treatment.

Wassermann and Frei's tests were negative. A series of seven injections of urea stibamine were given on alternate days for a fortnight. The ulceration did not show any sign of healing and the patient became intolerant to the drug. The treatment was changed to 'Fouadin'.

He had ten injections of 'Fouadin' on alternate days which produced the result seen in the photograph (*vide* figures 7 and 8).

Case 4.—Hindu male, aged 35. An old case of recurrent infective granuloma. Has been attending this department off and on for three years.

Fig. 9.—Case 4. The condition, after treatment.

Present condition.—Infective granuloma involving the inner halves of both groins, the pubic region encircling the root of the penis and extending on to the

CARBARSONE IN INTESTINAL AMOEBIASIS

PART II

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

and

S. SEN, M.B. (Cal.), D.T.M. (Bengal)

(From the Department of Pharmacology, School of Tropical Medicine, Calcutta)

THE successful treatment of chronic intestinal amoebiasis presents many difficulties to the physician practising in the tropics. The permanent eradication of the firmly established and chronic relapsing infection, with the mucous membrane of the colon more or less extensively involved, is unachievable in a short time by drug therapy alone. What probably happens in such cases

(Continued from previous column)

upper and anterior surface of the scrotum; double hydrocele with elephantiasis of the scrotum; the penis is fixed to the anterior surface of the scrotum.

A course of nine injections of 'Fouadin' in the space of 18 days resulted in complete healing (*vide* figure 9).

Case 5.—Hindu female, aged 23. Prostitute by profession.

Condition on admission.—Extensive nodular ulceration involving both labia and extending to the perineum—one and a half years' duration; both Wassermann and Frei's tests were negative.

A course of ten injections of 'Fouadin' cured the condition in 20 days.

Case 6.—Hindu female, aged 35. Married. Pregnancies, nine, of which five children are alive and well.

Condition on admission.—Infective granuloma of the left labium and fourchette with an elephantoid condition of the former—two years' duration; groin glands not palpable; no skin or mucous membrane lesion; a granulomatous ulceration of the buccal mucous membrane on the right side extending from the angle of the mouth to the last molar tooth; she was unable to open the mouth; the blood Wassermann was strongly positive and Frei's test was negative. Anti-syphilitic treatment was given without any therapeutic result.

A course of ten injections of 'Fouadin' cured the ulceration both of the vulva and mouth. This is a case of active infective granuloma probably in a latent syphilitic.

Conclusions

1. We have treated 25 cases of infective granuloma with 'Fouadin', in the past nine months, with very satisfactory immediate results.

2. It seems to be superior to the other antimony compounds used in the treatment of this troublesome malady.

3. The therapeutic action of the preparation is rapid.

4. No dangerous reaction nor toxic intolerance was observed in any of our cases.

5. This is a preparation eminently suited for the follow-up treatment to prevent recurrence.

My thanks are due to the director and staff of the x-ray institute for the photographs.

REFERENCE

Williamson, T. V., Anderson, J. W., Kimbrough, R., and Dodson, A. I. (1933). *Journ. Amer. Med. Assoc.*, Vol C, p. 1671.

is that the parasitic infestation is reduced to a low level, in which condition both the parasites and the invaded tissue cells live in a state of equilibrium and the symptoms are abated. Ultimately, if there is no further fresh local injury or damage, or if the general resistance of such a patient who is a carrier be not unduly lowered from other causes, complete dissolution of the infection may be effected in time by the patient's natural or possibly acquired powers of resistance against the disease. Of the various methods of treatment recommended for this condition none has given uniformly satisfactory results. In the case of an effective remedy like emetine, the toxic effects produced often overbalance its beneficial effects in chronic relapsing cases (1934). We have, therefore, endeavoured to find drugs which could be effectively given by the mouth without producing serious untoward effects.

The alkaloids of *H. antidyenterica* have given satisfactory results in our hands, but it has been difficult to get a supply of the raw material of uniformly good quantity for their manufacture (Acton and Chopra, 1933). Carbarsone has given such good results in a small series of cases that we have thought it important to carry out more extensive trials with it. This drug is a synthetic compound that is not difficult to prepare, and samples of the drug of a uniform quality are forthcoming. The drug is at present expensive, costing about Rs. 5 per treatment, but with increased demand for it, the manufacturers will probably be able to bring down the cost of production considerably and in this way reduce its price.

We have adopted a uniform method of treatment and a criterion of cure practicable for this country. The ordinary effective dose of carbarsone is 0.25 gramme, administered in gelatine capsules twice daily by the mouth for 10 consecutive days. No other auxiliary treatment is needed, except a daily dose of a mild saline purgative to relieve constipation. Our experience is that the drug acts more effectively if the bowels are kept slightly loose. Where there was an associated bacillary infection, immunization was produced by injection of the autogenous vaccines prepared from the stools. Patients failing with the usual 10-day course were given the drug for 5 days more, i.e., a 15-day course. The additional treatment for 5 days frequently renders the relapsed cases parasite-free without producing any untoward effects. As organic compounds of arsenic are liable to produce toxic effects, we have purposely refrained from giving more prolonged treatment with this drug. In cases who have resisted a 15-day course, we give standardized extract of kurchi, one drachm twice daily for two or three months, and then repeat the course of carbarsone if necessary after this period. In a number of patients kurchi extract given in this way eradicated the infection.

As regards the criterion of cure, there is considerable difference of opinion as to the time after which a relapse might occur after treatment. Some authorities believe that this may occur from the day the treatment is completed up to 2 years afterwards. In the tropics, however, it is hardly possible to differentiate a true relapse from a reinfection as the opportunities for reinfection are abundantly present. Dobell *et al.* (1918) pointed out that the vast majority of relapses occur before the end of the third week after treatment. He, therefore, considered that six negative examinations of the stools, one in the first week, one in the second and the remaining four in the third week, after treatment very carefully made by a competent protozoologist, are adequate enough to be regarded as an index of permanent eradication of the infection. It is fully realized that the proper assessment of the therapeutic activity of a drug in the treatment of this condition is only possible, where the patients can be followed up for some months after the cessation of treatment, with repeated and careful examinations of the stools all the time. However, such a procedure is quite out of the question when one is dealing with patients from a civil population and we have only been able to keep our patients under observation for about a fortnight after treatment. In this way only six to ten examinations of stools, prior to their discharge from the hospital, could be made. Those included in this series as 'cured' are only presumed to be so, on the following grounds:—

1. That the minimum of at least 6 examinations of the stools after treatment proved negative.
2. That the patients were completely relieved of all clinical signs and symptoms prior to their discharge from the hospital.
3. That we were unable to trace any case of relapse, although every patient was instructed, before discharge from the hospital, to report immediately the reappearance of any symptom of the disease.

In the table we have given the results of our observations on a series of 22 cases in which careful daily examinations of the stools were made while the drug was being administered, in order to observe its effect on the infection from day to day, and also to compare its effect with some other remedies. A perusal of the table will show that relapses after treatment occurred as follows with different drugs under trial:—

- I. *Gavano* (a derivative of ipecacuanha).
 - Case 1, the parasites reappeared on the third day after treatment.
 - Case 2, the parasites persisted throughout the course of treatment.
- II. *Arsemetine*.
 - (1) Case 15, the parasites reappeared on the fourth day after treatment.
 - (2) Cases 16 and 20, the parasites persisted throughout the course.

III. *Kurchi bismuth iodide*.

Cases 16 and 19, the parasites persisted throughout the course of treatment.

IV. *Emetine*.

(1) Case 1, the parasites reappeared on the second day after treatment.

V. *Carbarsone*.

(1) Case 6, the parasites reappeared on the sixth day after treatment.

(2) Case 8, the parasites reappeared on the third day after treatment.

(3) Case 20, the parasites persisted throughout the course.

On analysing the data obtained, it will be seen that in 6 cases the parasites persisted throughout the course of treatment and in the remaining 5 they reappeared from the second to the sixth day after treatment. It would appear from this that the chances of detecting a relapse with six examinations after cessation of treatment are considerable and that the criterion of cure employed by us gives a fair estimate of the efficacy of a drug. A further study of the table will show that the reduction in the number of parasites in the stools occurred on an average within 4 to 5 days after the treatment was started and the stools became entirely parasite-free in most cases in this period.

Of the 22 patients treated with carbarsone in this series, five had blood and mucus in their stools prior to treatment, *i.e.*, had acute dysentery; the remaining 17 were cases of chronic amebiasis with clinical manifestations. The results may be summarized as follows:—

Total cases treated—22.

Probable cures—17 (77.3 per cent) (nos. 1, 2, 3, 5, 7, 8, 9, 10, 11, 12, 13, 14, 16, 18, 19, 21 and 22).

Failures—2 (9.1 per cent) (nos. 6 and 20).

Indeterminate—3 (13.63 per cent) (nos. 4, 15 and 17).

Ratio of probable cures to failures—1:0.12.

Number of acute dysentery cases treated—5.

Probable cures—4 (80 per cent) (nos. 1, 2, 3 and 5).

Failures—nil.

Indeterminate—1 (20 per cent) (no. 4).

Number of chronic cases treated—17.

Probable cures—13 (76.5 per cent) nos. 7 to 14, 16, 18, 19, 21 and 22).

Failures—2 (11.7 per cent) (nos. 6 and 20).

Indeterminate—2 (11.7 per cent) (nos. 15 and 17).

Amongst the cured chronic cases, one case relapsed after the usual 10-day course of carbarsone, but responded to a further 5-day course.

Indeterminate cases.—In the 3 indeterminate cases (no. 4—acute, and nos. 15 and 17—chronic) referred to above, though the stools in all the cases became parasite-free during the course of treatment and remained so throughout the course, they could not be followed up. One (no. 8) died of intercurrent disease the day after the end of the treatment, two cases (nos. 15 and 17) left the hospital as soon as their treatment was finished; the last two were however relieved of their symptoms prior to discharge.

Failures.—Two cases (nos. 6 and 20) failed with the usual 10-day course of carbarsone, and the patients could not be put on an additional 5-day treatment as they left the hospital. In one case (no. 6) the parasites disappeared from the third day of treatment but reappeared 6 days after the course. The second case (no. 20) was the most resistant one in the whole series, as parasites persisted in the stools throughout the whole course, a finding which was not observed in any other case in this series.

Disappearance of the parasites from the stools during treatment with carbarsone occurred as follows :—

3rd day of treatment	12 cases.
4th " "	4 "
5th " "	3 "
7th " "	1 "
8th " "	1 "

A perusal of these results shows that it takes on an average three to four days to make the stools parasite-free with carbarsone. In one case (no. 8) the stool became parasite-free on the third day of treatment, but he was positive again three days after the course; he was then put on a further 5 days of treatment, became parasite-free from the second day (12th day of carbarsone) and remained so during the follow-up period. In the failure case (no. 20) the parasites were persistent throughout the whole course of treatment.

Cases associated with bacillary infection.—Ten cases (45.4 per cent) in this series suffered from infection with non-lactose-fermenting organisms :—

(1) <i>Bact. pseudo-carolinus</i>	in 7 (70 per cent).
(2) <i>Bact. morgani</i>	2 (20 ").
(3) <i>Bact. asiaticus</i>	1 (10 ").

In these patients immunization by injections of autogenous vaccines was carried out along with carbarsone treatment with good results.

Cases 1, 2, 15, 16, 19 and 20 (see table) are interesting because they afford an opportunity of comparing the relative efficacy of this drug with some of the others under trial.

Summary and conclusions

(1) Carbarsone is an organic arsenical preparation put on the market by Messrs. Lilly and Co., of Indianapolis, U. S. A., for the treatment of intestinal amœbiasis. It is ordinarily administered in capsules of 0.25 gramme twice daily for 10 consecutive days by mouth, but in persistent cases the treatment may be prolonged to 15 days. In our present series of 22 cases, the probable cure rate was 77.3 per cent, certain failures 9.1 per cent and indeterminate 13.6 per cent. Thus, the proportion of probable cures to failures was 1:0.12.

(2) The drug appears to be equally efficacious both in the acute and chronic phases of the disease, the cure rate in the acute form being about the same as in the chronic cases.

(3) Daily examinations of the stools in this series showed that it took 3 to 4 days, on an average, to make the stools parasite-free. The results obtained compare favourably with those obtained with other antidyenteric remedies.

(4) Our general impression, from the small series of 53 cases published in this and the previous paper, is that carbarsone is likely to prove

THE VALUE OF SANOCRY SIN TREATMENT IN PULMONARY TUBERCULOSIS

By P. V. BENJAMIN, M.B., B.S. (Madras)
T.D.D. (Wales)

Senior Assistant, Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle

SANOCRY SIN has been in use as a remedy against tuberculosis for over eight years. There are advocates both for and against the drug. Those who saw in it a specific against tuberculosis have been disappointed and those who were sceptical as to its usefulness have also proved to be wrong. A recent review (Henrichsen and Sweany, 1933) of a vast amount of

(Continued from previous column)

a very valuable drug in the treatment of intestinal amœbiasis. It certainly fulfils many of the requirements of an ideal remedial agent, as :—

- It can be administered by the mouth.
- It promptly relieves clinical symptoms.
- It is suitable for general outpatient or dispensary use.
- No toxic or other untoward effects have so far been observed in doses mentioned in this paper.
- The treatment with the drug does not need the patient to be in bed and it often does not interfere with the ordinary work.
- Lastly, the drug being an arsenical exercises a remarkable tonic effect on the system in general.

We are very grateful to Messrs. Lilly and Co. for their generosity in supplying us with large quantities of this drug free of cost for trials in our hospital.

literature on this subject shows that those who condemn sanocrysin are in the minority and are those who have treated only a very few cases. Those, however, who have used the drug in a large number of cases, although some of them have had to revise their original ideas, are yet still continuing to use it, as they have all found in it a definite advance over other drugs which had been advocated earlier.

The action of sanocrysin

A review of the original experiments and opinions regarding the action of sanocrysin was given in an article by Primodt-Möller (1927).

Möllgaard's original supposition that the effect of sanocrysin is due to the direct destruction of tubercle bacilli in tissue cannot be maintained (Schroder, 1933, and Secher, 1931). The theories which soon gained ground are those which attribute the effect of sanocrysin not to direct destruction of the bacilli in the organism but to action on the tuberculous tissue for which it has a special affinity. This action brings into circulation protein-containing products of the tissue broken down which stimulates phagocytosis and formation of connective tissue. Recently, many workers have shown that sanocrysin has a special influence on the reticulo-endothelial system in the cells of which the gold is stored up and only gradually released, thereby causing a long-continued action of the gold salt, through an activation of this system so important in resisting infection.

Doses

When first introduced, sanocrysin was used in large doses, which according to our present usage would be called *massive*. The initial dose as used in western countries in the earlier years ranged from 0.25 to 0.5 gramme, followed by doses of 1 gramme with an interval of 3 to 5 days, up to a total amount of usually 9 to 10 grammes. This was often followed by very severe reactions sometimes resulting in death. Secher (1931) still advocates the use of large doses, but the majority of those who use sanocrysin have found smaller doses not only less dangerous but also actually much more beneficial (Stub-Christensen, 1931).

When sanocrysin treatment was first started in the Union Mission Tuberculosis Sanatorium, Madanapalle (in 1925), we gave smaller doses than those used at that time in western countries. Our initial dose was usually 0.1 gramme followed by 0.25, 0.37, 0.5, 0.62, 0.75 and 1.0 gramme giving a total of 3 to 4 grammes. More recent experience has shown that we can get equally good results with even smaller doses, and we now give an initial dose of 0.01 gramme; when there are no reactions, this is followed by doses of 0.02, 0.04, 0.08, 0.16, 0.24, 0.32, 0.4 and 0.5 with weekly intervals, hence our average total amount for one course is now only 1.5 to 2 grammes. A second course after an interval of 6 to 10 weeks is sometimes given.

With the lessening of the dose the usefulness of sanocrysin has also considerably widened as it may now be used in cases with high fever; this was not possible before.

Types of cases suitable for sanocrysin treatment

The results of sanocrysin treatment vary with the type of cases treated. It is generally agreed that the most suitable cases are of the exudative type provided they are not too acute or too extensive (Smith, 1932). This was the type of disease in animals in which Möllgaard carried out his original experiments and obtained such good results. Gravesen (1930) has pointed out that, in comparing the results obtained in man with those obtained by Möllgaard in his animal experiments, the cases selected should as far as possible be of the same type of disease as in the original experiments. This means that we could expect the best results to be obtained in cases with recent actively-developing disease with exudative infiltration or with disseminated nodular deposits or with a combination of both, but without definite cavity formation or marked fibrotic changes. Such cases have in actual practice been found to benefit best by sanocrysin treatment, but unfortunately it is rare to find such ideal cases among patients coming for treatment to a tuberculosis institution in India. The majority of patients, by the time they seek expert medical advice, have reached the stage of cavity formation or have extensive fibrotic changes, and one cannot expect the same good results in them as in the cases best suited for sanocrysin treatment. Yet one can expect some improvement in advanced tuberculosis with mixed fibro-cavernous exudative types of disease, but the extent of the improvement depends on how much the disease is of the fresh exudative type and how much of the later cavernous or fibrotic type. Where there is mainly a cavernous or a fibrotic type with very little fresh exudation, sanocrysin has little effect, but where, although there may be definite cavity formation, there is yet a fresh spreading exudative process, sanocrysin is of use in checking the activity and clearing up the exudative part of the disease, while leaving the cavities unaffected. These must be dealt with by collapse therapy, as for example pneumothorax.

Experience gained in treatment with sanocrysin has also shown us that a combination of collapse therapy with sanocrysin is a definite advance in the treatment of mixed types of pulmonary tuberculosis where cavitation or fibrosis and exudative processes coexist. Sanocrysin may be given either before, or after, or at the same time as collapse therapy, this entirely depending on the nature of the disease in the individual case. A fresh exudative process may predominate and treatment with sanocrysin appear as the treatment of choice, but cavities which were masked by the exudative processes may become obvious during the course of treatment, requiring the induction of collapse

therapy. On the other hand when cavitation is definite, collapse therapy is indicated as the primary procedure, with sanocrysin as an adjunct to clear up any exudative disease in uncollapsed portions of a partially collapsed lung, and to clear up any fresh disease which may appear during treatment in the contralateral lung.

When there is cavitation in one lung and exudative, but not extensive, disease in the other, collapse therapy and sanocrysin treatment may be begun simultaneously.

Further, there are frequently cases in which the disease is so extensive in both the lungs as to preclude collapse therapy. In some of these cases a course of sanocrysin may clear up the disease in the one lung to such an extent as to make it possible to begin collapse therapy in the other side.

Contra-indications

Sanocrysin is contra-indicated in cases where there is albuminuria showing kidney affection, dermatitis, stomatitis, intestinal tuberculosis, and extreme cachexia. High fever used to be considered as a contra-indication when large doses of sanocrysin were used, but, since the introduction of smaller doses, it is not so considered. In selecting cases for treatment with sanocrysin these contra-indications must always be considered.

Complications

During the treatment the patients have to be observed carefully, both by laboratory examinations, chiefly of urine for albumin, two or three times a day, and clinically for complications arising out of the treatment, such as dermatitis, stomatitis, pigmentation of the skin and intestinal ulceration—all signs of metal poisoning.

Two of the three severe dermatitis cases and the four cases of pigmentation of skin occurred during the earlier years of the sanocrysin treatment when we were using the larger doses. Even with the smaller doses one occasionally comes across mild dermatitis shown by itching, towards the end of the sanocrysin course or sometimes a few weeks after the sanocrysin treatment has been stopped.

Results of treatment

Since the year 1925, 440 patients have been treated with sanocrysin at the Union Mission Tuberculosis Sanatorium. Of these 350 had four or more injections of sanocrysin and therefore can be considered in statistics. A review of the results of these 350 patients shows that 257 or 73.4 per cent were discharged with positive results, 163 or 46.6 per cent as 'clinically well', under which term are included patients discharged as 'arrested' and 'much improved'. The value of any special treatment in pulmonary tuberculosis is best judged by its results in the advanced cases (III stage).

Of the 350 patients 264 were in stage III of whom 66.7 per cent obtained improvement as the result of treatment, and 36 per cent were discharged as 'clinically well'. If we compare these results with those of a group of 471 consecutive patients in stage III treated during the years 1920 to 1925, that is, before the introduction of sanocrysin, we find that only 39.3 per cent of this group obtained improvement as compared with the 66.7 per cent of those treated with sanocrysin, and 19.5 per cent were discharged as 'clinically well' compared with the 36 per cent of those treated with sanocrysin.

This is shown in table I.

TABLE I
Results of treatment of stage-III patients with and without sanocrysin

	Total	POSITIVE RESULTS		CLINICALLY WELL	
		Number	Percentage	Number	Percentage
Patients treated before introduction of sanocrysin, 1920 to 1925.	471	185	39.3	92	19.5
Patients treated with sanocrysin, 1925 to 1933	264	176	66.7	95	36

Sanocrysin may have to be stopped temporarily or permanently, or the dose may be decreased or the intervals between doses increased, if complications arise.

The complications we have come across during treatment of 440 patients with sanocrysin are as follows :—

Albuminuria	trace	82
	moderate	61
	severe	3
Dermatitis	mild	4
	severe	3
Pigmentation of skin (due to gold deposit, chrysiasis).				
Stomatitis	mild	7
	severe	4

The value of sanocrysin treatment can also be seen if we consider the results from the point of view of disappearance of tubercle bacilli from the sputum and disappearance of fever. Of the 264 stage-III cases, 151 received sanocrysin without any additional treatment besides the basic routine sanatorium treatment. Of these 143 had bacilli in the sputum at the time of beginning sanocrysin treatment. Bacilli disappeared in 21.7 per cent as compared with 12.3 per cent in a similar group of 423 sputum positive patients treated with routine sanatorium treatment only, during the years 1920 to 1925.

Of the same group of 151 stage-III patients 119 had fever at the time of starting sanocrysin

treatment. Of these 50.4 per cent lost their fever as a result of the treatment compared with 32.2 per cent of 301 patients treated with routine sanatorium treatment only, during the years 1920 to 1925.

These results are shown in table II.

shows that in the group that had sanoerysin 33.8 per cent lost bacilli as compared with 16.7 per cent of those without sanoerysin, and 53.2 per cent became free from fever as compared with 22.5 per cent of the second group.

This is shown in table IV.

TABLE II

Results of treatment of stage-III patients with and without sanoerysin
(The disappearance of tubercle bacilli from the sputum and disappearance of fever.)

	TUBERCLE BACILLI			FEVER		
	Patients positive on admission	PATIENTS NEGATIVE ON DISCHARGE		Patients with fever on admission	PATIENTS WITHOUT FEVER ON DISCHARGE	
		Number	Percentage		Number	Percentage
Patients having routine sanatorium treatment only, before the introduction of sanoerysin, 1920 to 1925.	423	52	12.3	301	98	32.2
Patients having sanoerysin in addition to routine sanatorium treatment, 1925 to 1933.	143	31	21.7	119	60	50.4

Earlier in this paper the value of sanoerysin treatment as an adjuvant to collapse therapy was pointed out. We have analysed our results of treatment of patients who had artificial-pneumothorax treatment combined with sanoerysin because there was a contra-lateral affection. Ordinarily these patients would have had a bad prognosis, but sanoerysin has considerably improved their prospects of getting well. Of the 264 stage-III patients, 86 had artificial-

This demonstrates clearly how the introduction of sanoerysin has improved the results of artificial-pneumothorax treatment in patients having disease in the contra-lateral lung.

Summary

1. Since the year 1925, 440 patients have been treated with sanoerysin. Of these 350 had four or more injections. Two hundred and sixty-four of these were in the advanced stage

TABLE III

Results of treatment of stage-III patients with artificial pneumothorax with and without sanoerysin

	Total	POSITIVE RESULTS		CLINICALLY WELL	
		Number	Percentage	Number	Percentage
Patients with artificial-pneumothorax treatment and contra-lateral affection who did not get sanoerysin.	152	42	27.6	22	14.5
Patients with artificial-pneumothorax treatment with contra-lateral affection who received sanoerysin.	86	62	72	31	36

pneumothorax treatment combined with sanoerysin for the above reason. Of these, 72 per cent obtained improvement with 36 per cent 'clinically well', as compared with only 27.6 per cent with 14.5 per cent 'clinically well' in a similar group of 152 patients treated with artificial pneumothorax and having a contra-lateral affection but who did not get sanoerysin as these patients were treated before the introduction of sanoerysin.

This is shown in table III.

A further comparison of these two groups with regard to disappearance of tubercle bacilli from the sputum and disappearance of fever

(III stage) of the disease.

2. The results of treatment of these patients are compared with the results of treatment of groups of patients (who serve as controls) treated before the introduction of sanoerysin.

Conclusions

1. When sanoerysin treatment is combined with ordinary sanatorium treatment the results obtained are much better than those obtained by sanatorium routine treatment alone. This is best seen in the more advanced cases (III stage).

2. When sanoerysin is combined with collapse therapy, it increases the scope of the latter

TABLE IV

Results of treatment of stage-III patients treated with artificial pneumothorax with and without sanocrysin

(The disappearance of tubercle bacilli from the sputum and disappearance of fever.)

	TUBERCLE BACILLI			FEVER		
	Patients positive on admission	PATIENTS NEGATIVE ON DISCHARGE		Patients with fever on admission	PATIENTS WITHOUT FEVER ON DISCHARGE

Patients with artificial pneumothorax and contra-lateral affection who received sanocrysin.	80	27	33.8	62	33	53.2

considerably. This is specially seen in cases with contra-lateral affection, where a very bad prognosis may frequently be changed to a better, and even to a good prognosis. This would not have been possible without sanocrysin.

OLEOTHORAX

By Y. G. SHRIKHANDE, B.Sc., M.B., B.S., T.D.D. (Wales)
King Edward VII Sanatorium, Bhowali, U. P.

THE importance of rest in the treatment of pulmonary tuberculosis is universally recognized. After all the years of study of the disease and for the search of a 'cure', the principle of rest still remains the foundation of the treatment of tuberculosis, and during the last fifty years several attempts have been made to improve the efficiency of the rest treatment. While fifty years ago rest could only be enjoined in a general way by making the patient lie quietly in bed, to-day we can carry it further and apply it to the diseased organ itself. It was Foralini who, in 1882, applied the principle of rest to the diseased lung by inducing artificial pneumothorax. Since then, rapid strides have been made in this direction by the use of procedures like phrenicectomy, extrapleural thoracoplasty, extrapleural pneumolysis and scalenectomy.

Lately, a new procedure has been added to the list of collapse-therapeutic measures under the name of 'oleothorax'. This procedure was introduced by Bernou in 1921 for chronic and purulent effusions of tuberculous origin. It consists in introducing olive oil or liquid paraffin into the pleural cavity. The antiseptic most commonly used with the oil is gomenol which is an essential oil distilled from the leaves of *Melaleuca viridiflora*. Experience has shown that the vegetable oil is more quickly absorbed by the pleura than the mineral oil; this is why olive oil with gomenol is used in cases of purulent effusions as by such absorption gomenol is liberated and can act as an antiseptic for the infected pleura. Olive oil is also milder and less irritant to the pleura than the mineral oil, liquid paraffin.

Crocket (1931) prefers gelatinothorax to oleothorax, as he believes that gelatine-acriflavine acts more satisfactorily by intermingling freely with the effusion in the pleural cavity. He uses 2 to 5 per cent of gelatine in normal saline and neutral acriflavine is added in the proportion of 1 in 1,000 to 1 in 5,000.

Indications.—The use of oleothorax is indicated in the following conditions:—

(1) Pleural effusions.—These may be divided into two groups—(a) benign and simple and (b) severe and recurrent. The first group needs no interference as the fluid gets absorbed in due course. It is the second group where the effusion is recurrent or when it gets purulent that oleothorax is indicated. By maintaining a 'complete antiseptic bath' over the pleural surfaces, as Fishberg (1932) calls it, the gomenol oil reduces or completely stops the formation of pus, maintains the collapse of the lung, and improves the general condition of the patient.

(2) Pleuro-pulmonary perforations.—These may be classified into three groups—(a) temporary and benign, which are generally symptomless and need no interference, (b) large and gaping, which are usually fatal and cannot be benefited by oleothorax, and (c) valvular, where

the weight of the oil by immobilizing the lung gives the fistula a chance to heal.

(3) Adhesions.—Formerly the treatment for this condition was only surgical, Jacoebaeus's procedure for small ones and thoracoplasty when they were extensive. Bernou was the first to show that with oleothorax we may avoid and prevent their formation. Oleothorax can also postpone the onset of obliterative pleurisy following pneumothorax treatment. The injection of oil separates the pleural surfaces and keeps them so by its mechanical action, and the good results of pulmonary collapse are maintained.

(4) Flexible mediastinum.—When the mediastinum is very flexible and is pushed to the other side even under low pressures in pneumothorax treatment, small quantities of the oil injected over a long period render the pleural surfaces more rigid and impermeable, and the mediastinum is tied more or less by the formation of partial adhesions.

(5) Better compression in pneumothorax treatment.—When the collapse is incomplete and ineffective under pneumothorax treatment, the injection of the oil effects better compression of tuberculous lesions, especially cavities which remain uncollapsed under pneumothorax treatment.

(6) As an alternative to pneumothorax treatment.—Under exceptional conditions when the refills are too frequent and cannot be arranged easily, the pneumothorax may be replaced by oleothorax when the oil refills may be given every two or three months. In the opinion of Morristone Davies (1932) here the mediastinum should be mobile and the pneumothorax treatment must have lasted for at least six months.

Technique of oleothorax.—As mentioned above, the oil used is olive oil or paraffin oil. Olive oil is used for disinfecting purposes while liquid paraffin has the advantage of slow absorption and is therefore of value where blockage of the pleural cavity is desired. Olive oil must be absolutely pure and neutral in reaction; it can be tested by the use of ordinary litmus paper. It must be sterilized for an hour and a half at a temperature of 220°F. and must be warmed again at the time of use to body temperature. Gomenol is added in the strength of 5 to 10 per cent at the time of injection.

A number of methods have been employed for the introduction of the oil into the pleural cavity, but we have found that the use of Dieulafoy's two-way syringe is very convenient. It is portable and reliable and can be used alternately for removing the pus from and introducing the oil into the pleural cavity through the same needle.

In performing the operation the patient is made to sit up in bed or on a table and the arm of the side to be treated is raised up. The site selected for puncture—usually the eighth or ninth interspace a little anterior to the mid-axillary line—is cleaned with rectified spirit and

painted with tincture of iodine. The whole of the needle track is anaesthetized by a 2 per cent novocain solution, two cubic centimetres of which is usually sufficient for the purpose. When the novocain needle has entered the pleural cavity, a little of the pleural fluid is drawn into the same syringe for laboratory examination. Five cubic centimetres of gomenol oil is then drawn into another syringe and injected into the pleural cavity, through the same needle left in the chest wall, as a test dose. If there is no reaction, larger quantities of the fluid are aspirated at subsequent sittings and about one-half to two-third the amount of gomenol oil is injected by Dieulafoy's syringe. After the injection of the oil the site of puncture is thoroughly manipulated and a large bandage is applied over the chest and the patient is advised to lie on the opposite side to allow the needle track to close. Unnecessary coughing should be allayed by the use of suitable linetus.

The object of oleothorax in cases of pleural effusion is not to fill the pleural cavity with the oil, but by repeated aspirations and replacement with sufficient quantities of the oil—we have given as much as 600 cubic centimetres of the oil at a sitting—to sterilize the pleural cavity and arrest the recurrence of the effusion and the toxic state produced by the absorption therefrom. Once this is done the lung may either be allowed to re-expand or the oleothorax may be changed into pneumothorax again. Some physicians do air-replacement before commencing oleothorax in order to adjust the intrapleural pressures.

It is important to remember that the air pressure within the pleural cavity above the oil-level should remain slightly negative; then pressure may be determined and if necessary reduced by the use of a pneumothorax apparatus; otherwise with high pressures, compression symptoms and external and internal fistulae may arise.

When the pleural cavity is completely blocked by the oil, the use of Bernou's oleomanometer may give some indication, but there is really no accurate method of determining the pressure of the oil, and here one has to depend principally upon the symptoms of the patient and the experience of the doctor.

The use of oleothorax in pleuro-pulmonary perforations is very limited. It is contra-indicated in cases of large gaping perforations. Its use is, however, indicated in the 'valvular' type where after testing the tolerance of the pleura, the air in the pleural cavity is replaced by the oil until its level is above the valvular rupture, which thereby becomes sealed and further entrance of air into the pleural cavity is prevented. If fluid has already formed, it is aspirated and replaced by the oil. The oleothorax may in these cases close the perforation, sterilize the pleural cavity and make the patient fit, in due course, to undergo a thoracoplastic operation.

Accidents and complications

(1) Febrile reactions.—It is for febrile reactions that the tolerance of the pleura for the oil must always be tested before the treatment is commenced. The febrile reaction may be transitory when it is not dangerous, or it may be severe and be accompanied by an effusion. One of our cases gave a febrile reaction with irritation of the pleura and formation of more effusion.

(2) Compression symptoms.—These may result from over-pressure of the oil. The mediastinum and diaphragm may be displaced too much and cause breathlessness and feeling of oppression. In such cases, the oil must be removed from the pleural cavity until relief is obtained.

(3) Pleuro-parietal fistulae.—These may also be brought about by the pressure of the oil or by excessive cough or by faulty technique. Two of our cases suffered from this complication.

(4) Pleuro-pulmonary fistulae.—These manifest themselves by the taste of the oil in the mouth or by the coughing out of the oil. One of our cases had this complication before oleothorax was tried. Sometimes late perforations occur, but these do not seem to be due to over-pressure, but rather to the renewed activity of old foci of the disease situated under the pleural surfaces. One of our cases suffered from late perforation. In such cases the treatment of choice is thoracoplasty preceded by phrenic evulsion.

Duration of treatment.—The duration of oleothorax depends upon the 'cause' for which it is done. As soon as the cause disappears, the 'remedy' must go with it. The oil, after all, acts as a foreign body and is liable to find its way out externally through the skin or internally through the lung.

Case results.—We have been doing oleothorax in the King Edward VII Sanatorium at Bhowali since 1930. The treatment has been employed in six cases so far. Of these, five cases were receiving pneumothorax treatment and one was a case of spontaneous pneumothorax. Of the five pneumothorax cases, four had developed purulent effusion and one was a case of hæmorrhagic pleurisy following upon the rupture of an adhesion.

Two of the cases treated with oleothorax developed external fistulae. In one, they healed by repeated aspirations, leaving the intra-pleural pressure negative, and by antiseptic dressings, exposure to sun's rays and tight bandaging. In the other, the treatment was of no avail and the patient left the sanatorium and probably died.

In two cases, pleuro-pulmonary fistulae were formed. In one, the fistula was already present when oleothorax was attempted and the treatment had to be abandoned. In the other, the

fistula developed after the patient had kept well for nearly one year and was perhaps the result of reactivation of old foci of the disease.

One case suffered from febrile reactions with increased formation of the effusion. The reaction occurred at the third 'refill' and not at the first.

Of the six cases, three are probably dead; of the other three, one has lived for over three years and the other two for over one year.

(1) M. A., Muslim male, 25 years. Artificial pneumothorax done in November 1929. Developed pleural effusion which became purulent. Oleothorax was done. Still doing well.

(2) B. B. S., Hindu male, 24 years. Joined the sanatorium in March 1931 with purulent effusion following artificial-pneumothorax treatment. Oleothorax done in May 1931. Left sanatorium in November without any improvement. Returned to Bhowali and stayed outside sanatorium in March 1932 with a big swelling in the chest-wall on oleothorax side. This was aspirated several times without improvement. Patient is almost certainly dead now. Complication: external fistula.

(3) J. K. F., Muslim female, 16 years. Artificial-pneumothorax case. Developed hæmorrhagic effusion. Oleothorax attempt showed pleuro-pulmonary fistula. The treatment had to be stopped. Patient got worse and died.

(4) S. N. G., Hindu male, 38 years. Developed purulent effusion after artificial pneumothorax. Oleothorax done in 1932, did much good. Spat blood after some months and rejoined the sanatorium in 1933. Artificial pneumothorax attempt failed. Developed pleuro-pulmonary fistula, left sanatorium. The interesting point in this case is that, although oleothorax did him good in the beginning and he was taking long walks, his blood sedimentation rate always remained high (over 100 mm.) which suggested a bad prognosis.

(5) M. W., Muslim male, 21 years. Developed spontaneous pneumothorax followed by purulent effusion. Oleothorax did much good, but he developed external fistulae. Repeated aspirations done and pleural pressures left negative. Fistulae treated by heliotherapy and tight bandaging. Patient doing fairly well.

(6) R. A., Muslim female, 16 years. Developed purulent effusion after oleothorax done. Test dose of 10 c.cm. and second dose of 50 c.cm. gave no reaction. Third injection of 100 c.cm. gave violent reaction with formation of more and more effusion. He got worse and left this sanatorium.

Conclusions

Oleothorax is a useful adjunct in the treatment of purulent effusion following pneumothorax treatment. The treatment is in no case a cure-all. It finds its chief use in combating certain serious complications and helps in prolonging the life of patients who, without its aid, might have succumbed earlier to the complications. It is a valuable collapse-therapeutic measure in the treatment of pulmonary tuberculosis and its complications.

ISOSPORA INFECTION IN INDIAN CATS

By R. KNOWLES

LIEUTENANT-COLONEL, I.M.S.

Professor of Protozoology

and

ASSISTANT SURGEON B. M. DAS GUPTA, L.M.P.

Assistant Professor of Protozoology, Calcutta School of Tropical Medicine

DURING the course of work extending over several years, in examining the faeces of kittens in connection with work on experimental amebiasis in these animals, we have been struck with the frequency of coccidiosis due to parasites of the genus *Isospora*, and the senior author mentioned this in his *Introduction to Medical Protozoology* (1928). Infection with various species of helminths is also common. On one occasion it was noticed that after a rectal injection of amebic stool a latent coccidiosis in a kitten flared up and became active, with diarrhoea.

Professor B. L. Bhatia, D.Sc., F.Z.S., F.R.M.S., Principal of the Government Intermediate College, Hoshiarpur, who is writing the Sporozoa volume of the *Fauna of British India*, wrote to us asking us if we could give him any information about the species of *Isospora* concerned, and the dimensions of the oöcysts. We had not previously paid any special attention to the matter, but in order to supply Professor Bhatia with accurate information, we decided to study it.

The stools of 21 animals (13 cats and 8 kittens) were examined. In the direct smears of faecal emulsion coccidial oöcysts were detected in only two kittens, one having a very scanty infection and the other showing numerous oöcysts; this latter was the kitten which developed diarrhoea following the injection of amebic stool. On the other hand, the employment of the concentration method introduced for detecting hookworm ova revealed a much higher percentage of infections, viz, 14 out of 21 animals were found infected and the majority of specimens showed a good number of oöcysts.

Still better results were obtained by using the 'D. C. F.' (direct centrifugal flotation) method of Clayton Lane (1923), originally introduced for the concentration of hookworm ova. Plate VII, photomicrograph 6, shows the results with this method, as applied to coccidial oöcysts*. In the case of this kitten, the direct smear showed on an average only two oöcysts per field. As is well known the oöcyst wall in *Isospora* parasites is intensely resistant and it is almost impossible to penetrate it with any fixative. In the 'D. C. F.' method the oöcysts are in contact with the saturated saline only

during the 30 seconds centrifugalization, and are then immediately transferred to normal saline. We have never seen any shrunken or damaged oöcysts by this method. Oöcysts so treated appear normal in every way, and develop in the usual manner in a wet-chamber Petri dish preparation. Plate VII, photomicrographs 1, 2 and 3, show the maturation of the oöcyst in a wet-chamber preparation, and photomicrograph 4 the final sporozoites; these have a worm-like movement, and at times bend so that tip touches tail and then straighten out again.

In order to obtain oöcysts for measurement, the faeces of an infected cat were treated by the 'D. C. F.' method, and the collected oöcysts were transferred to a tube of normal saline. The mixture was then well shaken and centrifuged. The deposit thus obtained showed a very large number of oöcysts. Coverslip preparations of small drops of the deposit were made, and the oöcysts measured and their shape noted. Measurement was carried out with a 1/6th inch dry objective and a no. 3 ocular micrometer which had previously been standardized against the stage micrometer.

Measurements.—In all 253 oöcysts were measured. The smallest oöcyst encountered measured 20.4 by 15.3 microns, and the largest 47.6 by 40.8 microns. Table I gives the frequency distribution of the lengths and breadths of the oöcysts measured, expressed to the nearest micron. Graphs 1 and 2 show the same observations, but in terms of the ocular micrometer used; of which one small division equalled 1.7 microns. Table II presents an analysis of the results.

Discussion.—There has been a vigorous controversy between Dobell (1919, 1926) and Wenyon (1923, 1926, 1926a) as to the number and nomenclature of the species of *Isospora* parasitic in the carnivora and in man. Into this discussion we are loath to enter, since both these distinguished protozoologists have studied the coccidia much more than we have; yet a discussion of our findings is inevitable, if they are to have any value at all.

In his revision of the coccidial parasites of man, Dobell (1919) gives only one species of *Isospora* as parasitic in man, viz, *Isospora hominis* (Rivolta) Dobell, 1919. Wenyon (1923) considers that there are three species parasitic in cats, viz, *Isospora felis* Wenyon, 1926; *Isospora rivolta* Grassi, 1879; and *Isospora bigemina* Stiles, 1891. The last-named is supposed to be situated in the deeper sub-epithelial tissue of the villi of the small intestine, and the development of the oöcyst may be completed in the vertebrate host, while the two former are larger and are parasitic in the epithelium covering the villi, the development of the oöcysts not taking place till after they have left the body. Supposing, by analogy, that a similar state of affairs exists in man, Wenyon concludes that 'the parasite described from the interior of the villi of man by Virchow is a small *Isospora* like *Isospora bigemina*. It bears the name *Isospora hominis* (Railliet and Lucet, 1891)'. For the larger form discovered in the faeces of man during the Great War, and formerly known as *Isospora hominis*, he proposed the new name of *Isospora belli* Wenyon, 1923. Wenyon also reviews the previous literature in support of his thesis.

To this new nomenclature Dobell (1926) takes exception. He also reviews the literature. He

* Unfortunately neither method is of any value for concentrating entamebic cysts.

for '*Isospora rivolta*', and our type B with those given by the same author for '*Isospora felis*'.

Our observations were originally collected to send to Professor Bhatia, but the fact that the matter of species in *Isospora* infections is one of considerable interest to protozoologists is our reason for publishing this paper.

Our thanks are due to Dr. N. Bhaduri, B.Sc., M.B., of the Hookworm Research Department of the School, for providing material, and to Dr. H. P. Chaudhuri, M.B. (Cal.), D.P.H., D.T.M. & H., F.R.S.S. (London), of the Public Health Laboratory, for help with the statistical side of this paper.

Postscript.—In order to further check the above results we measured a further 100 oöcysts, collected from a single stool of a second infected cat. The results were almost identical with those in the first cat, and were as follows:—

Total series	35.18 μ	\pm 6.992 μ	28—42 μ
by	27.44 μ	\pm 6.018 μ	20—33.5 μ
Type A (only)	26.50 μ	\pm 2.454 μ	24—29 μ
by	20.28 μ	\pm 2.039 μ	18—22 μ
Type B (only)	39.71 μ	\pm 3.493 μ	36—43 μ
by	31.20 μ	\pm 3.302 μ	28—34.5 μ

The graphs corresponded closely to those for the first cat, and again showed a zero point for lengths at 33 microns. In the first cat type A predominated; in the second type B.

Both animals were now chloroformed, the entire length of the gut carefully examined and any parts of the small intestine which seemed to show congestion fixed for section cutting. The sections show infection of the epithelial cells only, and not of the sub-epithelial layer. The intestinal contents at different levels were examined in the fresh state. An unexpected finding in the second cat was the occurrence of a fair number of motile sporozoites in the contents of the jejunum and ileum; both in the fresh preparation and in fixed and stained films. It would seem that an occasional *Isospora* oöcyst may develop to maturity within the lumen of the gut, although the vast majority are passed in the unsegmented state.

SOME OBSERVATIONS ON *BALANTIDIUM COLI* AND *ENTAMÆBA HISTOLYTICA* OF MACAQUES

By R. KNOWLES

LIEUTENANT-COLONEL, I.M.S.

Professor of Protozoology

and

ASSISTANT SURGEON B. M. DAS GUPTA, L.M.F.

Assistant Professor of Protozoology, Calcutta School of Tropical Medicine

BARRET AND YARBROUGH (1921) claim to have successfully cultivated *Balantidium coli* of man in a medium consisting of inactivated human serum and 0.5 per cent salt solution, in the proportion of one part of the serum to sixteen parts of salt solution.

But when faeces from the monkey *Silenus* (*Macacus*) *rhesus*, which are invariably crammed with blastocysts, are inoculated into the above medium and incubated at 37°C.—the optimum temperature for growth of most of the intestinal protozoa of warm-blooded hosts—the fungus develops with very great rapidity, with consequent destruction of any *Balantidium coli* which may be present.

Jameson (1927) has shown that *Balantidium coli* from the domestic pig can be readily cultivated in inspissated horse serum and egg white to which a little solid rice starch has been added—a medium recommended by Dobell and Laidlaw (1926) for the cultivation of the entozoic amœbæ, and especially of *Entamœba histolytica*.

Macaques of species *Silenus rhesus* obtained from dealers in the Calcutta markets are very heavily parasitized with a ciliate protozoon which corresponds morphologically with *Balantidium coli* of man, and some months ago we commenced attempts to cultivate this organism and to transfer it to human volunteers. Our earlier experiments at culture were not too successful, as the cultures were frequently overgrown with blastocysts, in spite of solid rice starch being added to the medium before inoculation.

It was noted that the starch, before it could exert its restraining influence on the development of blastocysts, was split up by the starch-fermenting bacteria which are very often present in monkey's faeces.

In order to keep down the very troublesome growth of blastocysts, a few drops of acriflavine solution were added to the medium, as suggested by Dobell and Laidlaw (1926). In the majority of instances this gave excellent results, but sometimes even this measure was of no avail, as some of the starch-splitting bacteria were able to withstand a much stronger solution of acriflavine than were the balantidium. We have isolated from monkey's faeces an organism which appears to correspond to 'bacillus 1' of Dobell and Laidlaw (1926), and which these authors claim to be highly detrimental to blastocysts,

PLATE VII
ISOSPORA IN INDIAN CATS

Figs 1 to 4—*Isospora* 'type B' Showing stages of development outside the body of the host.
Fig 5—*Isospora* 'type A' As seen in freshly-passed faeces
Fig 6—Low power view of a preparation after concentration by the 'D C F' method of Clayton Lane.

BALANTIDIUM COLI FROM A MACAQUE

Figs 7 and 8—Undergoing binary fission. The ciliates are loaded with ingested rice starch from the culture medium.
Figs 9 and 10—Showing encystation and excystation respectively.

but even previous inoculation of the culture medium with this bacillus fails to keep down the monkey blastocystis when the resistant starch-splitting bacteria are present in the monkey's faeces.

Reaction of the medium.—The inspissated serum is very alkaline. In twelve samples tested the hydrogen-ion concentration varied from pH 8.8 to 9.2. The fluid part of the medium is about neutral, but when it is left in contact with the serum slope it becomes definitely alkaline, with a pH of about 8.0. This initial alkalinity is not an objection to cultivation of the ciliate. Soon after the tube is inoculated the fluid part of the medium invariably becomes acid, owing to the presence of acid-producing bacteria in the faeces. If the growth of these bacteria is not now checked by the addition of a little acriflavine, a rich culture of *Balantidium* may be ruined very quickly.

At the beginning, subcultures were made daily for a week, by which time the strain of *Balantidium* was well established. After this subcultures were made only every third day. In this way a flourishing culture of *Balantidium coli* of the monkey was maintained for 44 days, and utilized for experimental work.

In culture *in vitro*, multiplication of the ciliate by binary transverse fission in the transverse axis of the body was very frequently observed, the body of the ciliate assuming an hour-glass shape. This process is illustrated in plate VII, photomicrographs 7 and 8. Occasionally encystation occurred, the ciliate within the cyst continuing to revolve slowly within the cyst wall, as illustrated in plate VII, photomicrograph 9. Some of the encysted ciliates showed starch granules in their cytoplasm; these had apparently been ingested by the ciliate in its motile trophozoite phase, but had not been extruded prior to encystation. Encystation did not occur with any regularity, and we were not able to investigate the factors which induced it to occur. Jameson (1927) whilst working with the *Balantidium* of pigs never encountered encystation *in vitro*.

Excystation was observed once only; the process is shown in plate VII, photomicrograph 10—from fresh material fixed with osmic acid vapour whilst excystation was occurring. Although the cysts of *Balantidium coli* possess a very thick cyst wall the cysts do not survive in culture, but degenerate within 24 hours.

Though conjugation was a prominent feature of the cultures of *Balantidium coli* of pigs, as seen by Jameson, it was of rather infrequent occurrence in our cultures of the monkey *Balantidium*. At one time we had one culture tube showing a very large number of cysts, but this encysting strain was unfortunately lost through failure to make a timely transplant.

In order to obtain cysts in large numbers for experimental purposes, the method of inducing encystation of *Entamoeba histolytica* devised by

Dobell (1928) was followed. Monkey's stools containing the ciliate were inoculated into rice-free medium, with the result that blastocystis commenced to overgrow the ciliates. At this moment transplantation into medium containing rice starch greatly improved the growth of *Balantidium*, but no great degree of success was achieved in inducing encystation. Although a very flourishing culture strain of the monkey *Balantidium* was maintained for over six weeks, the ciliate only encysted *in vitro* on five occasions.

Attempts to infect human beings with the Balantidium of monkeys

Dobell (1931) has proved that the entamoeba of macaques, resembling *Entamoeba histolytica* of man, is identical with the latter parasite. In a later paper, Dobell (1933) has shown that the amoeba of genus *Endolimax* of macaques is morphologically and culturally identical with *Endolimax nana* of man; that man can be parasitized with the *Endolimax nana* of macaques, and macaques with the *Endolimax nana* of man; the two are therefore identical.

It thus appears that possibly the other intestinal protozoa of macaques may be transmissible to man. Walker (1913) has shown that monkeys when fed or injected per rectum with *Balantidium coli* of man become infected. It thus seems possible that the *Balantidium* of macaques and man are interchangeable, and we decided to investigate this possibility.

The stools of a human volunteer were carefully examined daily for a period of five weeks. At no time was any *Balantidium* found, and the only protozoon present was *Entamoeba coli*. This volunteer was now fed on cultures of *Balantidium coli* from *Silenus rhesus* showing numerous cysts—the culture medium containing rice starch, and being administered in gelatine capsules. This attempt ended in failure; the volunteer has now been under observation for two months since the feed, but has not showed *Balantidium* at any time.

It was next decided to feed a second volunteer on cysts discharged in the monkey's faeces. This volunteer's stools were examined microscopically and culturally daily for twelve days before the experiment was commenced; at no time were any protozoa encountered,—the only parasites present being ova of *Ascaris lumbricoides* and *Blastocystis hominis*. About two grammes of a freshly-passed stool were collected in a Petri dish from a *Silenus rhesus*. On thorough examination they showed numerous cysts of the monkey *Balantidium* and more scanty cysts of *Entamoeba histolytica* of the monkey. The stool was emulsified in normal saline, filtered through glass wool, centrifuged, and the centrifuged deposit placed in the cool incubator at 22°C. for 24 hours. On very careful examination of this deposit after it had been cooled, numerous cysts of *Balantidium coli* were found,

and a fair number of cysts of both *Entamoeba coli* and *Entamoeba histolytica* (of the monkey). The centrifuged deposit was now swallowed by the volunteer.

The volunteer's stools were now examined daily. On the eighth day after the infective feed he had loose stools with some abdominal discomfort. Examination of the stools showed a fairly large number of both motile trophozoite forms and cysts of *Entamoeba histolytica*, with some mucus but no blood or cellular exudate. The diarrhoea persisted for one day, but then cleared up without any treatment. This volunteer has now been under observation daily for two months after the infective feed. No balantidium has ever been seen, but he continues to pass *Entamoeba histolytica*, chiefly in the encysted stage, in varying numbers. The strain of *Entamoeba histolytica* is a small one, with cysts down to 6 to 7 microns in diameter. On one occasion he has also shown cysts of *Entamoeba coli*—apparently also of monkey origin.

Although both experiments failed in their original intention, the transmission of infection with *Entamoeba histolytica* from a macaque to man is of interest as affording further proof that this parasite is identical in both the macaque and man. The second volunteer is still under daily observation, and, if possible, it is intended to keep him off all treatment and study the course of this monkey infection in a human host.

Summary

1. The medium advocated by Barret and Yarbrough (1921) proved quite unsuitable in our hands for the cultivation of *Balantidium coli* of macaques.

2. The 'HSre + S' medium devised by Dobell and Laidlaw (1926) for cultivation of the

entozoic amoebae of macaques and man proved an excellent one in our hands for the cultivation of *Balantidium coli* of macaques, provided that a small quantity of acriflavine was added to keep down the growth of starch-splitting bacteria and blastocysts.

3. Division, encystation, excystation and conjugation of the ciliate were observed at the height of the growth.

4. Two attempts to infect human volunteers with cysts of *Balantidium coli* of *Silenus rhesus*, one made with cysts in culture, and the other with cysts in freshly-passed faeces, both failed.

5. In the second instance, however, the *Silenus rhesus* was also infected with *Entamoeba histolytica*, and this infection was transmitted from the monkey to man and has now persisted in the human volunteer for a period of two months.

A Mirror of Hospital Practice

ATEBRIN IN HEAVY INFECTION WITH *P. FALCIPARUM*

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Pharmacology

and

B. SEN, B.Sc., M.B.

(School of Tropical Medicine and Hygiene, Calcutta)

R., AN ANGLO-INDIAN FEMALE, 59 years old, was admitted into the Carmichael Hospital for Tropical Diseases under the senior author on the 22nd March, 1934, with a temperature of 102°F., and in a low condition. The patient comes from a part of the Central Provinces where a virulent form of malignant tertian malaria prevails. Since her arrival in Calcutta she has suffered from several attacks of fever and has

been treated with injections of quinine and also quinine by mouth. The present attack started three days ago and the fever was continuous. She came into the hospital for treatment.

On admission the patient had a temperature of 102°F. and looked anæmic, weak and debilitated. Physical examination revealed no other abnormality, except that the spleen was just palpable on deep inspiration and that the pulse was of low tension. A blood slide was at once examined for the presence of malarial parasites and a heavy infection with *P. falciparum* was discovered, every field showing approximately fifteen to twenty parasites. The parasites were all ring forms and the developing stages were not met with, even on prolonged examination. A parasite count was made and the patient was put on atabrin—one tablet thrice daily. The blood was examined at frequent intervals when the drug was being administered in order to see the effect on the parasite count and the symptoms. The

results of these observations are given in the following table:—

TABLE

Date	Time of blood examination	Temperature, °F.	Number of parasites per c.mm.	Total amount of atabrin given
22-3-34	6 p.m.	100	180,000 rings	0
	9 p.m.	98.6	162,000 rings	0.1 gm.
23-3-34	12 noon	100	90,000 rings	0.3 gm.
	2 p.m.	99.4	28,240 rings	0.4 gm.
	4 p.m.	99.2	20,000 rings	0.4 gm.
	6 p.m.	99	13,800 rings (degenerating)	0.5 gm.
24-3-34	3 p.m.	98.4	0	0.7 gm.

For the next three days, i.e., 25th, 26th, and 27th, three tablets of atabrin were given daily. The peripheral blood remained entirely free from parasites.

Soon after the commencement of treatment the patient started feeling better, the intense headache, which was the most troublesome symptom, disappeared on the second day, and the temperature settled finally by the third day of treatment. Although the infection was fairly heavy, atabrin checked the multiplication of the parasites and controlled the infection. After four tablets the number of parasites came down from 180,000 to 28,240 per c.mm. with signs of degeneration in the plasmodia; after five tablets the number came down to 13,800; and after seven tablets the parasites disappeared altogether from the peripheral circulation.

Summary and discussion

Chopra and Das Gupta (1933) have shown that the destructive action of atabrin on *Plasmodium knowlesi* is exceptionally powerful. One or two small doses of this drug given intramuscularly or intravenously are sufficient to control a very heavy infection which may amount to a million parasites per cubic millimetre. These workers have further shown (1934) that atabrin has a much more powerful immediate effect on this plasmodium than quinine. In the case described here the plasmodium infection was not so intense as that encountered in the monkey, but it may be described as fairly heavy for man. Atabrin here acted at least as promptly as quinine would have done.

TREATMENT OF SOFT SORE*

By J. DURLABI DERUV, M.S. (Bom.), F.R.C.S. (Eng.)
D.L.O. (Lond.)

Surgeon, Sir Jamsetji Jijibhoy Hospital, Bombay

THE treatment of soft sore is notoriously unsatisfactory, and great difficulty is experienced in effecting a cure.

Recently we had a case in which a bubo resulting from infection with Ducey's bacillus had been incised. After the incision the ulcerated area spread slowly but steadily for ten months, so that the skin of the lower abdomen, thigh and perineum were involved in spite of all methods of treatment.

Finally, Dmelcos vaccine was tried. It was given intravenously and the first injection caused a severe reaction, the temperature reaching 105°F. Three more injections were given at intervals and within ten days the ulcer had healed.

Since then we have used this vaccine on several cases of soft sore with uniformly satisfactory results.

[*Note*.—Dmelcos is an 'atoxic vaccine' consisting of several strains of Ducey's bacillus. It is sold in ampoules containing graduated doses for a progressive course of treatment. It is given intravenously.

This is a trade preparation and the name 'Dmelcos' is registered as its trade mark.—EDITOR, I. M. G.]

A CASE OF PSORIASIS OF ENDOCRINE ORIGIN

By BHOLA NATH SHARMA, M.B., B.S.

Sharma Clinical Laboratory, Moradabad

A HINDU FEMALE had suffered from extensive psoriasis for about twenty-five years. Hardly an inch of healthy skin could be seen. The patches were typical in their physical characters, except for their distribution, both extensor and flexor surfaces being involved and also every part of the body except a portion of the face, the scalp, and the soles of the feet. The palms were partially involved. The scales were dry, slightly elevated, and covered with typical silvery scales under which the bleeding hyperæmic papillæ could be seen on removing the scales. There was very little itching. The supratrochlear glands and the glands in the posterior cervical triangle and the inguinal region were not enlarged. Kahn's test was negative.

A full course of neosalvarsan injections was given by another practitioner without effecting any appreciable difference.

Later, she developed multiple rheumatoid arthritis, and became bedridden. I prescribed iodide, salicylate, and sulphate of sodium for some days without any benefit. From the patient's age and the fact that she was approaching her menopause I thought that the case was probably one of endocrine origin, ovarian deficiency being responsible for her psoriasis as well as her arthritis. I gave her ovarian substance, and in about twenty to thirty days' time all the patches of psoriasis completely disappeared and her arthritis was also cured.

It is now about three years and her joint trouble has not recurred, but the psoriasis has reappeared. No local treatment did her any good, although on account of the cost of the ovarian therapy she has been using unguentum acidi salicylicæ combined with ehrysophanic ointment.

*Rearranged by Editor.

Another case of psoriasis has recently been sent to me. She was about 35 years of age with a history of irregular scanty menstruation and patches of psoriasis over the limbs and back. Ovarian therapy cleared her psoriasis. She however got menorrhagia. She gave a history of three miscarriages, but neither she nor her children showed any signs of syphilis. Her subsequent history is not known. A point of interest is that endocrine therapy appears to produce its effect for a time only.

In both these cases there was marked eosinophilia. The stools showed no ova, but cysts of *Entamoeba histolytica* were present in the second case.

A CASE OF CHOLERA SICCA*

By MURARI MOHAN ROY, L.M.F., L.T.M.

Medical Officer, Barda Jnanadamayee Charitable Dispensary, District Howrah

A HINDU MALE, aged 36 years, went to a *mela* during the Holi festival on 1st March, 1934. On the night of 2nd March, he vomited three or four times; he did not regard this seriously. On 3rd March at noon he began to vomit vehemently and his urine became suppressed. He had severe cramps in the muscles of the hands, legs and feet. He called in a homœopath, who prescribed medicines for acidity which did no good to the patient. Early next morning, on the 4th March, I was called for. I found the patient in a pulseless condition, with respiration slightly increased; cramps in the legs, feet and hands were very severe and he was vomiting frequently.

I diagnosed the case as one of cholera sicca, and as I had not the apparatus for giving saline intravenously I prescribed saline injection per rectum, hoping this would be of some benefit as there was no evacuation of the bowels. I injected atropine sulphate gr. 1/100 for the cramps and prescribed a mixture with acid sulphuric aromatic and stimulants, and a powder with calomel, camphor and sodium bicarbonate.

In the afternoon it was reported that the cramps and vomiting still continued. I saw the patient again and found that the pulse had reappeared, and frequency of vomiting was rather less, but the cramps were still very severe, the abdomen tympanitic, the urine still suppressed and the bowels had not moved as yet. The skin of his hands and feet was shrivelled and wrinkled.

I injected one pint of normal saline with sodium bicarbonate intravenously, gave another dose of atropine sulphate gr. 1/100, and prescribed caffeine and sodium benzoate, 5 grains in 2 cubic centimetres, for removing suppression of urine. The mixture and powder were repeated.

The next morning it was reported that the cramps had totally ceased during the night, and that the patient had passed urine three times after 32 hours' complete suppression. The bowels did not move throughout the period. From that time convalescence was uneventful.

A LARGE URETHRAL CALCULUS

By H. J. H. SYMONS

MAJOR, I.M.S.

Civil Surgeon, Dera Ismail Khan, North-West Frontier Province

A PATHAN, aged 50 years, came to the outpatient department at the municipal hospital, Dera Ismail

Khan, on 15th February, 1934, with the complaint that for the previous six months he had had difficulty in passing urine, much straining on micturition and considerable discharge of pus from the urethral meatus.

On examination it was seen that his scrotum was not of normal shape and on palpation a stony hard mass was felt in the middle line filling partly the perineum and partly the posterior portion of the penis. There was a considerable discharge from the meatus and when a sound was passed it impinged on a stone about three and a half inches from the meatus. The stone could be slightly moved laterally but not antero-posteriorly.

Under general anaesthesia an incision two and a half inches long was made in the middle line down to the stone, which was easily removed. The cavity in which the stone had lain was thoroughly inspected and was found to be lined throughout with mucous membrane; it appeared to be simply an enormously dilated portion of the urethra and not a diverticulum. A sound was passed into the bladder and no calculus was detected in that organ.

A large rubber catheter was passed from the meatus and inserted into the urethra at the proximal end of the dilatation and thence pushed into the bladder. The incision in the mucous membrane of the dilated urethra was sutured with fine catgut. The skin and fascia were united with interrupted silkworm gut sutures. His friends removed the rubber catheter overnight; this necessitated the introduction of a silver instrument early next morning and its retention for a few days, but he made an uneventful recovery, the wound healing by first intention.

After the act of micturition he is unable to empty the dilated portion of his urethra and he has been advised to empty this by external pressure on every occasion. About one ounce is expressed in this way.

A photograph of the calculus is shown with a rupee for comparison as to size. It weighed 850 grains avoirdupois, was 2½ inches in length and 3½ inches in circumference at the largest point.

Before operation the patient asserted that his discomfort was of only six months' duration. After the removal of the calculus and on its being shown to him he was induced to alter his previous statement and said that it had worried him for probably ten years.

Pathans are notoriously long-suffering, but it is remarkable that anyone, even a trans-border Pathan, should put up with the discomfort that such a stone would cause for as long a period as ten years.

Le Comte (1929) described seven cases of urethral stone, and stated that some stones have remained in the urethra for twenty years.

JULY

GRANULOMA VENEREUM

In a recent monograph on lymphogranuloma inguinale, the author claims a common ætiology for this disease, climatic bubo, esthiomene, and certain other genital and anal affections that have hitherto been considered individually, and suggests for them the name 'a sixth venereal disease'. The position of 'fourth venereal disease' has already been claimed for a genital infection by Vincent's bacillus, and the fifth position is thus left open for ulcerating granuloma of the pudenda, or granuloma venereum, as it is now almost universally called. Thus, if the extra-venereal origin of this last-named disease is established, not only will a revision of its own name be entailed, but it will then be necessary to promote lymphogranuloma inguinale to the fifth position, and a very serious dislocation in medical nomenclature will be caused!

Nobody will, we feel sure, deny that there is a *prima facie* case for the venereal origin of this granuloma, and, although at the present there appears to be a slight swing of the pendulum of medical opinion against the venereal hypothesis—the writers of an article on this subject in our present issue have very definitely ranged themselves with this reactionary element—the name granuloma venereum is so firmly established in the literature that, until the 'extra-venereal' school has established its case and from an exact knowledge of the ætiology of the condition has provided a more suitable name, the present one must stand.

In India this disease seems to be confined to the eastern side of the peninsula proper, that is to say, more or less to the Madras Presidency. Thus, in the hospitals in Madras city and in Vizagapatam there appears to be little difficulty in collecting a considerable number of cases; but on the other hand the disease has been encountered only very rarely in the large skin outpatient department of the Calcutta School of Tropical Medicine, and few cases have so far been reported from other parts of India.

Although the ætiology of this disease is not yet clear, one fact stands out—the Donovan organisms are such a constant histological finding in the typical ulcer that one is justified in demanding their demonstration in every case before it can be definitely labelled as granuloma venereum. Thus it seems certain that this micro-organism (and micro-organism it appears to be though the suggestion has been

put forward that it is a cell-inclusion body, i.e., evidence of cellular reaction to an unidentified virus) plays a part in the ætiology of the disease, there is however no evidence that it is the primary invading organism, or even that it is the only organism maintaining the specific nature of the lesions. Some workers, using a large variety of culture media and methods, have failed to grow the Donovan organism, and yet others have obtained growths that they claim were of this organism, constantly and apparently without much difficulty. Regarding the nature of these cultural forms there does not seem to be complete uniformity of opinion amongst different observers; it has been described variously as a capsulated diplococcus, a diphtheroid and a coccobacillus? For these isolated organisms some pathogenicity is usually claimed, but in no instance has the typical—either clinical or histological—lesion been produced; these failures include a number of human experiments. On the other hand a greater degree of success has been achieved, in both man and macaques, by inoculating with scrapings from the human lesions. In these experiments typical, though transient, granulating lesions were produced, and in the scrapings from these induced lesions the Donovan organisms were seen in their characteristic intracellular and encapsuled formation.

To return to the question of the venereal origin of these lesions, the *prima facie* case is that we have an infective disease, occurring in both men and women, that is confined mainly to the genital area. The fact that extra-genital lesions occur is no argument against the venereal hypothesis. Primary chancres have been reported in many unusual sites—but in this case it is not even necessary to indict human society, as with very few exceptions the extra-genital lesions are secondary to genital lesions, or to lesions in the genital area that could have been acquired during the normal sexual act. This applies in every case both in the Vizagapatam series, reported elsewhere in this issue, and in the Madras series reported in our January number last year. Thierfelder discussing a series of 6,000 cases only reports two in which there were no associated genital lesions, and in both of these he was able to trace the lesions to irregular practices. The occasional incidence of these extra-genital lesions adds strong support to the venereal hypothesis, as it demonstrates that the skin and muco-cutaneous junctions in other parts of the body are susceptible to the infection, but that in actual experience they are very rarely the site of primary infection. Conversely, the argument put forward by Drs. Nair and Pandalai, that if the disease were of venereal origin one would expect to find lesions on the cervix uteri and in the vaginal fornices, is entirely negatived by the observation, which they themselves emphasize, that, even when the

whole circumference of the vagina is extensively diseased, the infection does not spread far along the vaginal walls. Or, in other words, it is a disease with a predilection for the skin and muco-cutaneous junctions, but not for mucous membranes.

On the other hand the infrequency of this disease in the other partner when a married patient is infected is difficult to explain, on the venereal hypothesis. A possible explanation is that the disease is only infectious in an early stage; such an explanation would add support to the suggestion put forward by some American workers and adopted by Dr. Bhaskara Menon in Madras that there is always a primary genital lesion, a small ulcer, which is not very characteristic clinically and is consequently often overlooked, and that the typical granuloma is a secondary lesion. This primary lesion may be highly infectious and the secondary granulomata much less so.

Although we do not take the view that the discussion, the venereal *versus* the extra-venereal origin, is closed, we do consider that at present the evidence is so much in favour of the former hypothesis that tampering with the nomenclature is not yet justified.

* * * * *

There seems to be little doubt that antimony is a specific for the disease; the only question that arises is what is the best form in which to administer it? Sodium antimony tartrate is the drug that has been used most extensively up to the present.

The introduction, in 1915, of sodium antimony tartrate in the treatment of kala-azar, constituted one of the greatest advances in the treatment of tropical diseases that had been made for many years, yet to-day the pentavalent compounds of antimony have proved so infinitely superior that nobody now advocates sodium antimony tartrate in this disease. This superiority of the pentavalent compounds surprised chemotherapeutists, as, on analogy with arsenic, the trivalent compounds were expected to be therapeutically more active; these expectations were supported by chemotherapeutic trials in animal trypanosomiasis. Consequently, a number of trivalent aromatic compounds were tested by the workers at the Calcutta School of Tropical Medicine. Antimosan was tested as long ago as 1923 and was found, though therapeutically active in this disease, to be little superior to sodium antimony tartrate. Shortly afterwards Fouadin, a closely-allied trivalent aromatic compound, was also tested and a similar conclusion arrived at.

In the treatment of oriental sore, cutaneous leishmaniasis, sodium antimony tartrate was found to be efficacious and it was expected that the pentavalent compounds would be as corresponding more so as they had proved to be in the treatment of kala-azar, *i.e.*, visceral leishmaniasis, but analogy was again misleading, and it

was soon found that in this infection the pentavalent compounds were certainly no better and possibly not as good as the trivalent compounds, antimosan and Fouadin, or even the trivalent salt, sodium antimony tartrate.

In the literature on the treatment of granuloma venereum during the last few years there have been occasional references to the possible superiority of the pentavalent antimony compounds, but we have felt that had this superiority been real it should have been quite definitely established by now. We noted therefore, with particular interest last year, the paper by Williamson and his colleagues who reported excellent results with the trivalent aromatic compound, Fouadin. Elsewhere in this number will be found a paper by Dr. Rajam of Madras, confirming these observations of the American workers. This paper is of particular interest because kala-azar occurs in Madras and some hundreds of cases of this disease are treated each year in the hospitals in that city by pentavalent antimony compounds which will therefore most certainly have been given a thorough trial in granuloma venereum, as the writer indicates. These two papers report such satisfactory results with Fouadin that we shall not be surprised to see sodium antimony tartrate displaced by the trivalent aromatic compounds in the treatment of this disease in the way that it was displaced by the pentavalent aromatic compounds in the treatment of kala-azar. Fouadin has the advantage that it can be injected intramuscularly, whereas the closely-allied compound antimosan has to be given intravenously. Other trivalent compounds have also been prepared and should be given a trial, as experience has shown that small differences in composition occasionally make great differences in therapeutic efficacy.

Medical News

BRITISH POST-GRADUATE MEDICAL SCHOOL

CERTAIN recent announcements may justify a review of the circumstances which gave rise to the institution of this school.

London has long been realized to have a remarkable, indeed almost unique, supply of clinical material. Of this advantage should be taken not only in the training of medical students by undergraduate schools but in addition by the provision of courses for doctors resident in Great Britain, in the Empire beyond the seas, and abroad, who wish to refresh their knowledge, to obtain instruction in new developments of medicine, surgery, and obstetrics, or to participate directly in the clinical practice of a hospital.

Attempts to utilize this abundant material are by no means new. In the closing years of the last century the Medical Graduates College and Polyclinic was set up largely through the activities of Sir Jonathan Hutchinson. This organization was of great value to London practitioners, but was not run in connection with any one particular hospital, and, although there were associated with it classes in certain special hospitals and medical schools, it could not provide that regular attendance at in- and out-patient departments

which may be looked on as the principal requirement of the general practitioner and the more specialized post-graduate student.

With the next stage of the development should be remembered the name of Sir William Osler. Among others, many of whom are fortunately still with us, he made possible the formation of the Fellowship of Medicine and Post-graduate Medical Association. During the years which have since elapsed many practitioners have been thereby enabled to take advantage of the instruction provided at the various London teaching hospitals. This organization is still very active and does most valuable work, and there has been no falling off either in the facilities which it offers or in the numbers who have taken advantage of those facilities. Nevertheless, the Fellowship of Medicine suffers in some measure from not having any one hospital with which it is particularly associated and thus it has no really adequate centre for its activities.

A committee was appointed by the government in 1932 to go into the question of post-graduate teaching in London, and, to cut a long story short, one of the results of this report has been the present scheme by which an existing hospital at Hammersmith is being taken over and converted into a leading hospital, and a medical school for post-graduate teaching is being built on to it. A short description of the medical school is here given:—

On the ground floor there are the offices including accommodation for the Dean, for clerical staff, etc., and a committee room. These take up one side of the square, while the north side is chiefly occupied by the post-mortem department with an associated laboratory and class-room for histological work. Opening off the main corridor is the clinical theatre (with accommodation for close on 100 students) and rooms for the examination of patients and for the lecturers. The remaining side is chiefly devoted to a large chemical laboratory with centrifuge, polarimeter and balance rooms.

The second floor can be described more briefly: above the clinical theatre is a somewhat larger lecture theatre (both of these include full provision for the projection of cinematograph films), while over the school offices are to be found a well-lit library and two rooms for the use of the teaching staff. The remainder of the floor is devoted chiefly to five medium-sized laboratories and six smaller rooms, each of the latter suitable for a single worker. There is in addition a large museum with windows on two sides and top lighting in addition. The top or third storey is slightly smaller; it contains bacteriological laboratories, autoclave rooms, and two smaller laboratories. To turn now to the southern half of this new block—a part which belongs more closely to the hospital—on the ground floor there will be a large and carefully planned outpatient department. The main hall is lit from above and will accommodate about 300, while opening off it are various consultation and examination rooms and a theatre for minor operations. Adjacent to the general outpatient hall but with a separate entrance is the ante-natal care department, while also on the ground level are two small wards available for casualties. Though provision has been made for later expansion upwards as occasion arises, there are for the present to be only two stories in this part of the building. The upper floor is chiefly devoted to an x-ray department, on the one side to investigation work, *e.g.*, screening and photography, and on the other to therapy.

The London County Council proposes to send from their other hospitals to Hammersmith any patients who might be expected to benefit by the facilities there provided for specialized treatment or investigation and diagnosis.

The outpatient department is not the only substantial addition to the hospital; there is also being erected a new block, chiefly for maternity cases, well provided with delivery rooms, operating theatres, etc.

The London University has 'recognized' the new institution as a School of that University. There will be four professorships, three in the main clinical subjects—medicine, surgery, and midwifery and gynaecology—and the fourth in pathology. The former group will have general charge of the beds in the hospital which are devoted to their various subjects and will also be provided with facilities for original investigations in medical science. The 'research' accommodation will, of course, be supplemental to the laboratories required no less than lecture rooms for the teaching of the post-graduate student. The department of pathology no doubt requires rather more generous laboratory accommodation and equipment but this subject now includes at least three main divisions: (1) morbid anatomy; (2) biochemistry, including pathological chemistry, and (3) bacteriology.

When it has been possible to select the holders of the chairs, and these posts have now been advertised, the next stage will be to proceed to the more detailed organization of each teaching 'team' for we must presume that assistants of various grades will be needed in each unit. It may be anticipated that courses will also be delivered from time to time by eminent physicians and surgeons not permanently attached to the school.

It is of the first importance that the teaching should be of a really high level—suitable for increasing the knowledge of the better grade of medical practitioners. The provision of 'refresher courses' may well be regarded as an important item in the activities of the comprehensive post-graduate scheme. Such courses should be particularly adapted to the needs of men who are working in sparsely-populated rural areas and who have not reasonable access to a town in which hospital practice is available. Nevertheless this type of activity should not be allowed any chance of 'swamping' the more advanced work which may be expected to appeal more particularly to graduates proposing to specialize in some one branch of medical practice. For these, courses of an essentially different character will be needed.

It is not to be expected nor indeed is it desirable that the whole of post-graduate teaching in London should be transferred to Hammersmith. Such a plan would overlook the abundant clinical material and teaching ability which are to be found in the existing special and general hospitals, and which have, chiefly through the activities of the Fellowship of Medicine, been made largely available, for example to medical graduates from overseas. Rather is it to be hoped that the new school will act as a centre and that a cordial relationship will be maintained with other institutions and their valuable and generous work.

The school has an Imperial side since nowhere more keenly than in the great Dominions is the desire felt that it should be possible for medical men to find in London and among their own folk access to the latest knowledge and the most recent developments of medical technique. It also may claim to have a distinctly international side since in countries like the United States of America and the Argentine (to mention only two) the desire for such an institution in London is constantly expressed.

INDIAN MEDICAL BIRTHDAY HONOURS, 1934

The following are the names of medical men and others, associated with medical institutions, in the Indian Honours List of date 4th June, 1934. We would offer them our congratulations:

Knighthood

Major-General J. D. Graham, Indian Medical Service (retired), lately Public Health Commissioner, Government of India.

Dr. Upendra Nath Brahmachari, Medical Practitioner, Bengal.

C.I.F.

Lieutenant-Colonel J. A. S. Phillips, Indian Medical Service, Director of Public Health, Bihar and Orissa.
Lieutenant-Colonel H. H. King, Indian Medical Service, Director, King Institute, Guindy, Madras.

O.B.E.

Mr. Abdur Rahman, Director of Public Health, Punjab.

M.B.E.

Mr. W. A. Beer, Assistant to the Director, Pasteur Institute, Coonoor, Nilgiris, Madras.
Major F. H. Otto, Assistant Surgeon to the Port Health Staff, Bombay.
Mr. G. O. Schmidt, Assistant Surgeon, British Consulate, Kashgar.

Kaisar-i-Hind (Gold Medal)

Miss L. A. Benjamin, Superintendent, American Baptist Mission Hospital, Nellore, Madras.
Miss D. L. Graham, Medical Missionary, Krishnagar, Bengal.
Miss M. C. Webb, Chief Medical Officer, Women's Medical Service, and Secretary of the Funds under the Presidency of the Countess of Willingdon.

Kaisar-i-Hind Medal (Second Class)

Miss H. C. Binns, Nursing Superintendent, General Hospital, Rangoon.
Mrs. M. Simpson, Sister Superintendent, Civil Hospital, Jalgaon, Bombay.
Mr. A. Murray, Dentist, Burma.
Mr. P. C. Sen, Health Officer, Dacca Municipality, Bengal.
Mr. M. L. A. Steele, Indian Medical Department, Medical Officer, Bushire, Persian Gulf.
Mr. H. S. Thomas, First Assistant, Albert Victor Hospital, American Madura Mission, Madura, Madras.

Kaisar-i-Hind Medal (Third Class)

Miss A. C. Johnstone, retired Assistant Surgeon, Rampur State.
Miss A. M. Richards, Lady Superintendent, Lady Barton Child Welfare Centre, Secunderabad.
Mr. P. T. Jesudoss, Medical Officer of Health, Secunderabad Cantonment (Deccan).
Maulvi Habibur Rahman, Assam Medical Service (junior), Sub-Assistant Surgeon, Assam.
Mr. H. R. Wadhvani, Medical Practitioner, Bombay.
Subedar Abdul Wahid, Indian Medical Department, Military Sub-Assistant Surgeon.

I.S.O.

Lala Ram Sahai, Sub-Assistant Surgeon, Residency Hospital, Indore, Central India.

Khan Bahadur

Khan Sahib Jehangir Dhanjibhai Buxy, Deputy Director of Veterinary Service (retired), Bombay Presidency.
Munshi Mohammed Alunad Ali Shah, Honorary Dentist, Bahrampur Hospital.
Dr. Abdul Hamid Butt, Director of Public Health, Lahore.
Maulvi Mohammed Sulaiman Ashrof, Officiating Civil Surgeon, Palaman, Bihar.

Rai Bahadur

Captain Shyam Lal, Civil Surgeon, Ballia, United Provinces.
Rai Sahib Chhagan Nath, Assistant Surgeon-in-charge, Lansdowne Hospital, Udaipur.

Rao Bahadur

Mr. Natsingrai Bababhai Majumdar, Bombay Medical Service, Class I.

Khan Sahib

Ashban Padabhai Patel, Subordinate Medical Service, Dandi, Bombay Presidency.
Mr. Mohammed Abdul Kadir, Assistant Director, Veterinary Service (retired), Central Provinces.
Yusuf Ali, Civil Sub-Assistant Surgeon-in-charge, Lady Minto Hospital, Malakand, North West Frontier Province.

Rai Sahib

Lala Poran Mal, Provincial Subordinate Medical Service, Medical Officer, Basia Dispensary, Ballia District (United Provinces).
Lala Hans Raj Bhanbi, Sub-Assistant Surgeon, Punjab.
Dr. Abani Nath Chatterjee, Personal Assistant to the Director of Public Health, Bihar and Orissa.
Mr. Nalinendra Kishore Ghosh, Assam Medical Service (senior), Assistant Surgeon, Public Health Department, Assam.
Lala Saraj Narain Mathur, Assistant Surgeon, Victoria Hospital, Ajmer.
Mr. Raghunath Singh, State Surgeon, Alwar State, Central India.
Kari Tomyot Tserin, Sub-Assistant Surgeon, Tatsung, Tibet.
Sachchidananda Banerjee, Assistant Surgeon, East Indian Railway, Jamalpur.

Rao Sahib

Jemadar Ramisetty Subbaya, Indian Medical Department, Sub-Assistant Surgeon, Bahaduristan.
Joachim D'Costa, Temporary Deputy Director, Imperial Veterinary Serum Institute, Ichalmgar.

INTERNATIONAL UNION AGAINST
TUBERCULOSIS

The ninth Conference of the International Union against Tuberculosis (General Secretary, Professor Leon Bernard) will meet in Warsaw on 4th, 5th and 6th September, 1934, under the high patronage of His Excellency the President of the Republic of Poland and under the Chairmanship of Professor Plezzyński, President elect of the International Union. The discussion will be limited to three main subjects: Biological subject: 'Biological variations of *tubercle virus*', opening report by (Poland); Clinical subject: 'Tuberculosis of the lungs and joints; treatment, medical report by Professor Putti (Italy); 'The use and organization of the conference', opening report by Professor La Ten speakers, selected in advance by the forty-three countries to have been designated to open 1 of the questions on the agenda.

The Organization Committee has prepared a very attractive program and exemptions; the latter will call Congress to visit the chief anti-tuberculosis as well as the most picturesque scenery of Poland.

Members of the International Union take part in the Conference free of fee. They may forward their applications through the medium of their National Tuberculosis, or directly to the Office in Warsaw, at the following address.

Organizing Committee of the 9th of the International Union against Tuberculosis, Street 24, Warsaw, Poland.

Persons who are not members of the Union wish to take part as 'Members

must forward their application together with a contribution fee of 50 zlotys exclusively through the medium of:—

Indian Red Cross Society,
(King George Thanksgiving Fund),
Talkatora Road, New Delhi.

Reductions in hotel prices and railway fares will be granted to Members of the Congress.

PRIMARY F.R.C.S. ENGLAND

Two years ago when Major-General C. A. Sprawson, the present Director-General, Indian Medical Service, was in Madras, he and the Principal of the Medical College of Andhra University began a correspondence with the Royal College of Surgeons of England with a view to having a Primary Examination in Anatomy and Physiology for the Fellowship of the College conducted in India. The object of this was to obviate the necessity for candidates from the universities of India having to go to England in the middle of their course, as well as to diminish the expenditure of the individual candidate, and so enable those students who were not well off to be placed in a better position to obtain the higher qualification.

A cable from the Secretary of the College of Surgeons has been received agreeing to send examiners to conduct such an examination in India in the third week of December of this year, conditional on not fewer than thirty candidates being forthcoming. Though the examination is not to be held until December, it is necessary that the number of candidates should be known and the fees deposited before the end of July, otherwise arrangements cannot be made in London in time.

In order to cover the expenditure required for such an examination it would be necessary that every candidate who proposes to enter for the examination should send Rs. 360 (Rupees three hundred and sixty only) with his name and address when the exact date and place of examination would be communicated to him.

Students or graduates who wish for further information on the subject should communicate with Mr. F. Macrae, c/o the Director-General, Indian Medical Service, Gorton Castle, Simla.

PUNJAB MEDICAL COUNCIL

The following is a summary of the proceedings of the Punjab Medical Council held on the 14th April, 1934, at 11 a.m.:—

(1) Notifications regarding the appointment of the following members were read and recorded:

Colonel C. H. Reinhold, as President,
Lieutenant-Colonel T. A. Hughes,
Khan Dr. Khavja Abdul Rahman Bahadur.

(2) It was decided to approach Government with the request that a register for qualified dispensers and dressers be opened on the lines of the Punjab Medical Register.

(3) It was decided that the registered medical practitioners should not be allowed to associate their names with firms of chemists and druggists.

(4) Court judgments in the various cases conducted against bogus medical practitioners were read and recorded.

(5) A letter from the general secretary of the All-India Medical Licentiate Association requesting that increased representation be given to licentiates on the Punjab Medical Council was considered and it was decided that up-to-date enquiries be made from other provincial medical councils in India in regard to the number of licentiates who are members of the various provincial medical councils, and the replies received be placed before the next meeting.

MASULIPATAM MEDICAL ASSOCIATION

The first anniversary of the Masulipatam Medical Association was held under the presidentship of Dr. D.

S. Ramchandra Rao, M.A., M.D., in the local Town Hall on the 16th April, 1934.

Dr. P. R. Venkataramayyar spoke on 'Medical Fraternity'. Dr. M. Seshacharyulu read a paper on 'Dynamic Physiology', and Dr. R. Venkata Rao on 'Duodenal Ulcer'. An interesting case of 'Tumour of the Liver' was demonstrated by Dr. A. Umapathi Mudaliar.

Elections were held for the ensuing year and Dr. P. R. Venkataramayyar was elected as President, Dr. K. Sithapathi Rao as Vice-President, and Dr. A. Seshagiri Rao as Secretary. The function came to a close with a dinner which was well attended.

BRITISH INDUSTRIES HOUSE

NEW MEDICAL CENTRE

UNUSUAL interest is being taken in the Medical Centre which is being established in London. The enterprise is one which will tend to revolutionize the administration of our hospitals and, at the same time, result in the development of an industry of world-wide importance.

The successful achievement of the objects in view is rendered highly probable by the fact that the Centre is to be conducted under the guidance of a Medical Advisory Council, which has been formed with Dr. Alfred Cox, for twenty-one years secretary of the British Medical Association, as chairman, Sir Crisp English, Dr. E. P. Poulton, and Mr. A. R. McWhuish, M.R.S., past president of the Pharmaceutical Society of Great Britain. The association of the names of these gentlemen with the movement may be accepted as assuring that it will be planned and conducted on lines which are bound to be approved by the medical and pharmaceutical professions.

There are in Great Britain 4,000 important public and voluntary hospitals and many thousands of nursing homes, while there are 42,000 members on the Medical Register. There are some 250 retailers of surgical instruments and hospital equipment.

The retailer does not claim to be the actual manufacturer of all the articles which he offers for sale and which are called for by the hospital purchaser or general practitioner.

Take enamel ware, for instance. This is a speciality of the Wolverhampton district, although such goods are also made in various parts of the country. The retailer will make his own arrangements with two or three, or probably more, manufacturers of such goods and will submit the articles to his customer.

Another retailer will have similar arrangements with two or three other firms. The result is that the purchaser from abroad visiting this country and wishing to see a comprehensive range of hospital enamelled ware utensils, must, of necessity, visit half-a-dozen retailers in London and the provinces, and even then probably find it necessary or desirable to go over the whole gamut again and visit manufacturing firms from Glasgow to the South of England.

It must be realized that a hospital buyer, more particularly from abroad, would very rarely visit this country for the purpose of placing orders solely for enamel ware. His list of requirements would usually comprise quite a large variety of articles, such as operating tables, sterilizers, forceps, electrical apparatus, and so forth, with the result that the same process has to be gone over again in regard to each article required, if he is to return to his headquarters and report that he has made a comprehensive examination of the range of goods available from British manufacturers.

Such a condition of affairs could never exist in any industry unless the commercial aspect were regarded as of only secondary consideration.

The section will be opened on Wednesday, 18th July, just before the opening of the Annual Meeting of the British Medical Association at Bournemouth. Doctors, pharmacists, and hospital managers, as potential buyers, will be admitted on presentation of

their cards. Any of our readers who may be in England will, we are assured in a letter from Dr. Alfred Cox, be welcomed at all times at the section. We feel sure that the project will be a useful one, and will be warmly welcomed by all who have ever had to spend their time in journeying to various places in order to examine goods of British manufacture in which they are interested.

THE FORTY-THIRD CHEMISTS' EXHIBITION, LONDON

The Chemists' Exhibition, organized by the *British and Colonial Pharmacist*, was established in 1896 in

London, and there is nothing approaching it in size and comprehensiveness held anywhere else in the world. It was organized to give the chemist and druggist an opportunity each year of seeing, under one roof, all the goods he sells and the various apparatus, utensils and other requisites he uses in his profession. The management is always delighted to welcome visitors from the Dominions and Colonies, and such gentlemen will be admitted on presentation of business cards. The Exhibition has grown continuously and this year will be housed from 24th to 28th September in the New Hall of The Royal Horticultural Society, Westminster, S.W. 1, in the very heart of London, practically under the shadow of the Houses of Parliament and Westminster Abbey.

Current Topics

Pseudo-Ephedrine in Asthma

By G. W. BRAY, M.B. (Sydney), M.R.C.P. (Lond.)
and

L. J. WITTS, M.D. (Manch.), F.M.C.P. (Lond.)

(Abstracted from the *Lancet*, Vol. I, 4th April, 1934, p. 788)

THE graphic formula of ephedrine contains two asymmetric carbon atoms, so that two sets of stereoisomers, making six in all, are possible. Only two occur in nature, *l*-ephedrine, which is the ephedrine in general use, and *d*-pseudo-ephedrine, which is usually known as pseudo-ephedrine. Different species of the ephedra plant contain different amounts of these two alkaloids, and there would be a great saving in cost if they could be used interchangeably. It has hitherto been believed that the action of pseudo-ephedrine is identical with that of ephedrine, but weaker (Chen and Schmidt, 1930). In 1931, however, Chopra and co-workers reported that ephedrine and pseudo-ephedrine were equally effective in the treatment of asthma, but that the latter caused fewer unpleasant side actions. This is the statement we have endeavoured to test.

Ephedrine is of little assistance in a severe paroxysm of asthma or in the status asthmaticus, but it usually aborts a mild attack if taken early, and it usually relieves a moderate dyspnoea. It is therefore a valuable drug in the treatment of asthma, as an intelligent patient can often stave off a severe attack by its use. The unpleasant side actions of ephedrine are familiar to all who treat asthmatic patients. Most common are palpitations, trembling, weakness, sweating, feelings of warmth, chilly sensations, nausea, and vomiting, and the *tousse éméétique*. Less common are nervousness, headache, insomnia, dyspnoea, a tired feeling, thirst, drowsiness, precordial pain or distress, flushing, tingling or numbness of the extremities, anorexia, constipation, diuresis, and dysuria. These side actions are most evident at the beginning of treatment with ephedrine, and it is usual for tolerance to them to be developed, and for the patient to be able to continue the use of ephedrine with relief of the asthma and without the unpleasant side actions. In rare instances, however, toxic symptoms suddenly appear in a patient who has tolerated ephedrine well for months or years.

In the following experiments the relative value of ephedrine and pseudo-ephedrine has been assessed in two ways: (1) by the diminution in the number of attacks produced by continuous administration of the drugs; and (2) by the relief of the actual paroxysm by the administration of the drug at the onset of the attack.

PREVENTION OF ATTACKS

These experiments were carried out by one of us (G. W. B.) at the asthma clinic at the Hospital for

Sick Children, Great Ormond Street, W.C. Twenty children, 12 boys and 8 girls, aged from four to nine years, were chosen who had (a) had their asthma for at least two years, (b) had attacks more or less all the year round, and (c) had not previously had hospital treatment. These children were divided into four groups of 5 children and observed during alternate control periods, periods while taking ephedrine regularly, and periods whilst taking pseudo-ephedrine regularly. The dosage employed was a quarter of a grain morning and evening for a child under seven years, and gr. $\frac{1}{2}$ morning and evening for a child over seven years. The mothers were instructed to give an additional tablet whenever an attack threatened. During the control period all the children had two teaspoonfuls of water just coloured with burnt sugar three times a day. No other treatment, anti-asthmatic or otherwise, was given.

Group 1 had four months control period, four months on pseudo-ephedrine, and four months on ephedrine.

Group 2 had four months control period, four months on ephedrine, and four months on pseudo-ephedrine.

Group 3 had two months control period, two months pseudo-ephedrine, two months ephedrine, two months pseudo-ephedrine, two months ephedrine, and two months pseudo-ephedrine.

Group 4 had two months control period, two months ephedrine, two months pseudo-ephedrine, two months ephedrine, two months pseudo-ephedrine, and two months ephedrine.

By this means it was possible to compare the efficacy of the drugs with each other and with a control period without anti-asthmatic treatment, and at the same time to eliminate any seasonal variations that might occur.

In summary, the 20 cases during twelve months control period had 49 attacks; in eighteen months on ephedrine they had 78 attacks; and in eighteen months on pseudo-ephedrine they had 52 attacks. Or, expressing the figures in the same ratio as regards time, control: ephedrine: pseudo-ephedrine = 100: 107: 73. In other words, whilst the administration of ephedrine did not diminish the number of attacks the administration of pseudo-ephedrine to the same cases and during the same period showed a 27 per cent reduction of the number of attacks. As regards the severity of the attacks, they were most severe in the control periods, less severe whilst taking ephedrine, and least severe whilst taking pseudo-ephedrine in almost all cases.

Hence one may conclude that pseudo-ephedrine is a more efficacious drug than ephedrine in lessening the frequency of the attacks. Neither drug, if continuously administered, will prevent asthma. In two cases the asthma remained continuous in spite of gr. $\frac{1}{2}$ three times a day in children of seven years. Hence, as both ephedrine and pseudo-ephedrine were used, and the attacks ceased immediately after 5 minims of adrenaline

chloride solution had been given hypodermically, neither can replace adrenaline in allaying a severe attack.

One girl of ten years always had sickness and palpitation whilst taking ephedrine but not on pseudo-ephedrine. A boy aged eight years was always made sick by ephedrine gr. $\frac{1}{2}$ but could take the same dose of pseudo-ephedrine quite well. A male of seven years became sick, languid, and listless after ephedrine gr. $\frac{1}{2}$, and complained of palpitation each time. He took pseudo-ephedrine gr. $\frac{1}{2}$ night and morning quite well for two months during which time he had one severe attack lasting four days. Though no sickness or palpitation occurred between attacks, during attacks the tablets made him sick each time for a quarter of an hour, but there was no palpitation. Hence one may conclude that pseudo-ephedrine is less toxic to children than ephedrine in the same dosage.

RELIEF OF PAROXYSMS

These experiments were carried out by L. J. Wits at the asthma research clinic at Guy's Hospital. The standard dose of ephedrine hydrochloride was gr. $\frac{1}{2}$, to be taken as early as possible in the attack and to be repeated at hourly intervals if necessary until grs. 1½ had been taken. If relief was not obtained with this dosage it was rarely possible to improve the results by increasing the dose, on account of the supervention of toxic symptoms. In a few cases, however, the patient had an unusual tolerance for ephedrine, and occasional patients have taken as much as grs. 9 a day with benefit. An analysis of 60 adult patients, who used ephedrine in this way, was as follows:—

- 28 were relieved by ephedrine and experienced no unpleasant side actions.
- 23 were relieved by ephedrine but experienced unpleasant side actions.
- 7 were unable to take ephedrine on account of the severity of the reactions.
- 2 were totally unaffected by ephedrine.

It was soon found that pseudo-ephedrine had a weaker action than ephedrine. The standard dose of pseudo-ephedrine was therefore fixed at gr. 1, repeated at hourly intervals, if necessary, until grs. 3 had been taken. It was seldom possible for the patient to take a total of more than grs. 4½ of pseudo-ephedrine during an attack without the supervention of toxic symptoms. Reactions to pseudo-ephedrine, when a dosage larger than the standard was employed, were sensations of cold shivering, dilatation of the pupils, insomnia, lack of energy, drowsiness, palpitation, nausea and vomiting, and dysuria. The side actions of pseudo-ephedrine are therefore the same as those of ephedrine, but nausea and vomiting are more common.

In the first place the therapeutic effect of pseudo-ephedrine was studied in 21 adult patients, who had previously used ephedrine. In 15 of these 21 patients the asthma was relieved by ephedrine, but there were moderately unpleasant reactions; the remaining 6 patients were unable to take ephedrine on account of the severity of the side actions. The results with pseudo-ephedrine in these 21 cases were as follows:—

- 3 obtained relief from their asthma without any side actions.
- 5 obtained only slight relief from their asthma, but there were not side actions. Nevertheless these 5 patients preferred the stronger therapeutic action of ephedrine in spite of its disadvantages.
- 6 were unaffected by pseudo-ephedrine, either favourably or unfavourably.
- 7 experienced unpleasant side actions, and did not get the same relief of their asthma as with ephedrine.

These results were disappointing, for it had been hoped that pseudo-ephedrine might be a valuable substitute for ephedrine in patients who had experienced the unpleasant side actions of ephedrine. Of the 21

patients in whom ephedrine had produced mild or severe side actions or had failed to give relief, only 4 preferred the action of pseudo-ephedrine. And of 6 patients, who were completely intolerant of ephedrine, only 1 was relieved by pseudo-ephedrine. The test to which pseudo-ephedrine was submitted in this experiment was severe, for the patients were selected by the criterion that they had experienced unpleasant reactions with ephedrine. Pseudo-ephedrine was therefore prescribed to a second group of 10 cases, of whom 7 had not previously used ephedrine or pseudo-ephedrine, and 3 had been relieved by ephedrine without reactions. The results in these 10 cases were as follows:—

- 4 were relieved without reaction.
- 2 were slightly relieved without reaction.
- 2 were entirely unaffected by pseudo-ephedrine.
- 2 were not relieved and experienced unpleasant reactions.

The number of our cases is too small for percentages to have any great significance, but it would appear that ephedrine gives relief in about 85 per cent of adult asthmatics and unpleasant reactions in 50 per cent; pseudo-ephedrine gives relief in about 60 per cent of adult asthmatics and unpleasant reactions in 20 per cent. The therapeutic efficiency of these drugs is rather closely correlated with their toxicity but in a few patients pseudo-ephedrine will relieve the asthmatic paroxysms when ephedrine has had to be abandoned on account of its unpleasant side actions.

CONCLUSIONS

- (1) Pseudo-ephedrine given by the mouth was more efficacious than ephedrine in lessening the frequency of attacks of asthma in children.
- (2) Pseudo-ephedrine was less efficacious than ephedrine in relieving the actual asthmatic paroxysm in adults.
- (3) Pseudo-ephedrine is less toxic than ephedrine, but in large doses it may produce the same unpleasant side actions.
- (4) Pseudo-ephedrine is worthy of further trial in the treatment of asthma in childhood, and in the treatment of adults who are unable to tolerate ephedrine.
- (5) Neither ephedrine nor pseudo-ephedrine is as effective as injections of adrenaline in the treatment of the asthmatic attack.

The Treatment of Profuse Bleeding from the Stomach and Duodenum

By R. S. AITKEN, M.B.N.Z., D.Phil. (Oxon.),
M.R.C.P. (Lond.)

(Abstracted from the *Lancet*, Vol. I, 21st April, 1934, p. 839)

THERE is no general agreement about the principles on which cases of profuse bleeding from the stomach and duodenum may best be treated. This is unfortunate, because severe cases, where the bleeding is grave enough to threaten life, often come under the care of hospital residents and practitioners whose individual experience of the emergency is not great. The main choice lies among three courses of action: purely medical treatment, medical treatment plus blood transfusion, and surgical treatment. The conservative teaching recommends medical treatment only, and in the absence of an extended experience of other methods the wise course is clearly to follow that teaching. It is usually coupled with the comforting assurance that very few cases so treated die. It is doubtful, however, whether the fatal cases are in fact few enough to offer much comfort, when it is remembered how common profuse bleeding is. Published figures vary from Hurst's 2½ per cent mortality among cases admitted to Guy's Hospital on account of hæmatemesis or melæna and not previously operated on, to Chiesman's 25 per cent mortality among cases admitted to St. Thomas's Hospital for gross hæmatemesis and melæna. Statistics on this subject are particularly difficult to appraise, because no exact limit can be set

to the degree and recency of bleeding that justifies admission of a case to a series, and because statistics take scant account of the very variable circumstances and features of different cases. Nevertheless, it does seem clear that approximately 10 per cent, at least of the moderately severe cases, die. This is no negligible minority. Hæmatemesis and melaena are so common that fatalities represent a considerable number of lives, and it is no credit to modern medicine that these are still lost from a cause so clearly understood and—in theory—so easily remedied as hæmorrhage from the stomach or duodenum.

The best use of the three methods mentioned above (medical treatment, transfusion, surgical treatment) is clearly to be found only by experience, for none is infallible, and each has its dangers. Bare statistics are an unreliable substitute for experience. On the other hand few observers, if any, have had adequate experience of all three methods, and if they have none has published an appraisal of them that has won widespread assent. The problem can best be studied, then, by collating the experience of a number of observers using these methods. This I have attempted to do, using the records of the London Hospital, which are in most cases sufficiently full for the course and the severity of the cases to be fairly accurately judged. The records chosen were examined from the point of view of estimating the value of medical treatment, transfusion, and surgical treatment, in dealing with uncomplicated urgent bleeding of the stomach and duodenum.

CASES TREATED MEDICALLY

There were 31 cases, with 17 deaths. The medical treatment consisted fundamentally in complete rest in bed, morphia, and by mouth either nothing at all or minimal quantities of water or ice. Some patients also received adrenaline or calcium lactate by mouth, saline solution rectally or hæmoplastin subcutaneously.

CASES TREATED MEDICALLY WITH THE ADDITION OF BLOOD TRANSFUSION

In this group there were 11 cases, with 3 deaths. The ages were from 15 to 64 (average 41). The sources of bleeding (judged usually from clinical evidence or subsequent x-ray examination) were: chronic gastric ulcer in 3 cases, chronic duodenal ulcer in 4, chronic jejunal ulcer in 1, acute ulceration in 2, and carcinoma of the stomach in 1 (non-fatal).

CASES TREATED SURGICALLY

There were 21 cases, with 7 deaths. The ages ranged from 24 to 62 (average 45). In all of them operation was undertaken with the object of *stopping bleeding*. The patients, many of whom had been referred by physicians, were all gravely ill from loss of blood, with the exception of the first two, in whom the bleeding was apparently somewhat less severe and transfusion was not given.

DISCUSSION

For the reasons mentioned in the introduction no valid statistical conclusions can be drawn from these case and mortality records. They do, however, broaden the outlook of anyone who has had some experience of similar cases. The attempted separation into less severe cases and grave cases throws into relief the fact that a large proportion of the latter (27 out of 63) died. Though the line of separation is not a hard-and-fast one, yet it is nearly always possible to say clinically whether a given case is grave or not. It is therefore well to know that 3 out of every 7 grave cases are likely to be fatal. This is obscured by the common method of expressing the mortality rate as a percentage of all cases. Whether the figure, 3 out of 7, obtained from this series holds exactly for other series does not affect the argument. Since this series has a general mortality rate of 11 per cent, it is probably a fairly typical series and justifies the inference that something between one-fourth and one-half of grave cases of gastric and duodenal bleeding end fatally.

There is no means of predicting with any accuracy which grave cases will die. Under purely medical treatment some go apparently very near to death and then recover; others die unexpectedly, or develop unforeseen respiratory or mental complications which turn the balance against them. Patients with a dyspeptic history suggesting chronic ulcer, and patients who have not had dyspepsia, as well as malignant cases, are found both among the recoveries and among the deaths. Any attempt therefore at further subdivision of grave cases with a view to individual prognosis seems useless.

It remains simply to review methods of treatment and to attempt to assess them empirically. In this series the mortality was heaviest among the cases treated medically; this remains true when the malignant cases and those at the extremes of age are excluded, and it definitely lays the conservative teaching of medical treatment in *all* circumstances open to criticism. The results of a surgical attempt to deal directly with the bleeding point, in a group of cases of similar severity, appear slightly better; they show at least that, in expert hands, operation on these exsanguinated patients is not necessarily a sentence of death. The middle group of cases, treated medically with the addition of one or more blood transfusions, deserves closer consideration. It showed—for what it may be worth—a lower mortality than the other two groups; and of its three fatal cases, one was already mentally deranged and another was moribund when the transfusion was given. Eight cases, however, were transfused while still bleeding, or shortly after the cessation of bleeding, and they recovered. This sets the evidence of experience against the theatrical view that transfusion, by raising the blood pressure, will merely increase the loss of blood from the bleeding vessel or vessels, and in that respect is in line with the experience of those who treated secondary hæmorrhage in war wounds by transfusion.

From a review of the whole series of cases studied in this paper the following recommendations emerge for the management of gastric and duodenal bleeding (hæmatemesis and gross melaena):—

(1) A distinction should be made, clinically, between grave cases and less severe ones. Recurrent bleeding is often but not always grave. Cases in which the red cells fall below 2,000,000 or the hæmoglobin below 40 per cent (on a scale on which the normal is 100 per cent) will usually be grave. The distinction is to be made, however, on consideration of the whole clinical picture.

(2) The less severe cases should be treated on the accepted medical lines.

(3) The grave cases should be treated medically, in bed, with sufficient morphia to ensure complete rest; and a transfusion of about 500 c.cm. of blood should be given, without moving the patient from his bed, after careful cross-grouping.

(4) If further bleeding is indicated by subsequent hæmatemesis or rising pulse rate, the transfusion should be repeated once or twice within the next 24 to 48 hours, or when necessary.

(5) If bleeding still continues and the patient's condition deteriorates, operation should be promptly undertaken, along with a further transfusion. The operation should probably be restricted to the minimum procedure necessary to find and secure the bleeding point.

These recommendations are substantially the same as those given by Hurst in his book on *Gastric and Duodenal Ulcer* in 1929. Bastedo in America and Tzanek in France agree in advocating transfusion in addition to medical treatment for grave cases, and in reserving surgery for those few cases in which the bleeding continues in spite of repeated transfusion. This course does not appear to have been widely practised in this country; it was not considered by any of the four opening speakers in a recent discussion on the

treatment of hematemesis in the sections of medicine and surgery of the Royal Society of Medicine.

The Modern Approach to the Problem of Human Sterility

By SAMUEL R. MEAKER, B.A., M.D., M.R.C.S.,
F.A.C.S., F.C.O.G.

(From the *Practitioner*, Vol. CXXXII, March 1934,
p. 326)

AMONG human beings the sex life is frequently unhygienic, 12 per cent or more of matings prove to be barren, 20 to 25 per cent of conceptions result in miscarriage, other abnormalities of pregnancy are common, childbirth borders upon the pathological, and the function of lactation is notoriously imperfect. It would be interesting to know how this unenviable record of reproductive achievement compares with the record of primitive humanity living under conditions less artificial than those of modern civilization. Certainly it compares ill with the average record of lower animals. Williams, writing on sex hygiene and reproduction in cattle, says, 'When a sexually sound cow, properly in heat, is bred to a genitally sound bull, she surely becomes pregnant'. Every one knows that such physiological perfection of the reproductive mechanism does not prevail in the human race.

If 100 human couples, young and apparently healthy, marry and have regular intercourse without contraception the results may be predicted with fair accuracy. In a small minority of cases pregnancy will occur at once, the wife missing her first period. Most of the wives will conceive after intervals ranging from a month to a year. Some few will have a first baby one to several years after marriage. A dozen couples of the hundred will remain permanently childless. Thus nearly 90 matings sooner or later prove conclusively that they are not barren, but at the same time they show the most obvious differences in the grade or degree of their fertility. Again one is led to conclude that, in relation to a standard of absolute perfection, the majority of human beings must be rated as more or less infertile.

This conclusion is further supported by direct clinical observations. To-day one recognizes a large number of disorders, some genital and some constitutional, which may operate to depress the reproductive function. If clinically fertile couples be subjected to a complete diagnostic study, the result is usually that one or two of these factors of infertility are discovered. In other words, there is objective evidence to demonstrate the fact that most non-sterile people possess a grade of fertility which is relative only, in the sense that it falls short of absolute perfection.

CAUSATION OF STERILITY

If the same methods of investigation be applied to clinically sterile couples, the principal difference in findings is one of degree. Each case shows, not one or two factors of infertility, but between two and nine, the average in my clinic being 4.86 factors per case. Thus it appears that, while Nature unaided often overcomes one or two obstacles to conception, four or five such obstacles commonly impose a barrier which she is unable to surmount. It is, of course, possible for sterility to be caused directly by one abnormal condition. Either a complete failure of spermatogenesis or of oogenesis, or a complete blockade in the male or female genital passages, is sufficient by itself to render absolutely sterile an individual, and hence any mating into which that individual may enter. Such absolute causes occur in about 30 per cent of clinical cases of sterility. Even then there are nearly always other causative factors in the background, which would become operative if the absolute causes were removed. In the remaining 70 per cent of cases the sterility is due not primarily to a single abnormality,

but to a summation or totality of multiple causative factors, of which any one alone might be of small importance. Moreover, these multiple factors are but seldom limited to one or the other partner. In my cases, some evidence of infertility has been identified in more than 90 per cent of the husbands and more than 95 per cent of the wives. The ordinary clinical problem, therefore, is not that of a definitely fertile man mated with a unequivocally sterile woman or *vice versa*.

It is rather the problem of two individuals, each possessing a somewhat lowered fertility, who together contribute a sufficient sum-total of factors to depress the fertility level of their mating below the threshold of conception.

In the past ten years one has learned to appreciate, with greater accuracy than ever before, the various factors which conduce to human infertility. A brief summary of these will here suffice. Local genital factors in the male play, altogether, a comparatively small part. The more serious disorders, such as testicular atrophy and epididymal blockade, are not common; while the pathological conditions more frequently encountered, such as varicocele and chronic prostatic-vesiculitis, seem to exert only a mildly depressing influence. Relative deficiencies in the semen are the rule rather than the exception among male partners to sterile matings; but the explanation of these subnormalities is to be found in states of constitutional depression far more often than in local disorders of the genital organs.

Local genital factors in the female are numerous and important. Rarities being excluded, there remain four groups of gynecological conditions which contribute frequently and notably to infertility. These are female genital hypoplasia, viscosity of the endocervical mucus, tubal obstruction or occlusion, and mechanical impediments to ovulation.

Constitutional factors influence the fertility of both sexes to an extent which medical men have only recently come to understand, though stockbreeders have long realized the importance of such conditions. Among human beings the reproductive capacity may be diminished by endocrinopathic states, chiefly those involving the anterior pituitary lobe or the thyroid; by any type of chronic intoxication, in particular that resulting from focal infections; by insufficient protein or other faults in the diet, together with a lack of enough exercise to insure good assimilation; and by a debility of whatever nature, especially the otherwise unimportant depression caused by slighter grades of anæmia.

Since the idea of constitutional factors causing human infertility is comparatively new, one might do well to cite briefly the principal evidences upon which it is based. First, there is the practical experience of the poultry yard and of the stock farm, in addition to the experimental work of the biological laboratory. While some caution must be exercised in applying to human beings conclusions drawn from the reproductive performance of lower animals, it nevertheless seems clear that subnormal constitutional states are likely to induce a deficient grade of gametogenesis in the genus homo, as well as in the other genera. Second, human patients who suffer from the constitutional conditions mentioned above, almost invariably show a lowered basal metabolic rate and other objective indications of depressed vital functions; and these measurements tend to become normal as soon as the underlying fault is corrected. Third, in male patients of this type the semen, when quantitatively evaluated according to standards of number, morphology, motility, and endurance of the spermatozoa, commonly proves to be deficient, but is seen to improve steadily under constitutional treatment. Fourth, the elimination of constitutional faults from one or both partners has now resulted in the clinical cure of sterility in cases so numerous that any likelihood of pure coincidence may be disregarded.

DIAGNOSTIC STUDY OF STERILITY

From the foregoing remarks upon the causation of human infertility it becomes evident that adequate diagnostic study of the sterile mating is necessarily a complex procedure. It must deal with the husband no less than with the wife, and must take into account the constitutional condition as well as the state of the reproductive organs. By tradition, the problem of sterility has been assigned to the gynaecologist. Actually it belongs in nearly equal degree to the urologist, the internist and the endocrinologist.

The essential feature of such an investigation is its completeness, in the sense that every possibility is routinely surveyed. Thus, and only thus, can one say in each case not only that certain causative factors are present, but also, and with equal assurance, that all other demonstrable factors are absent. In the past it was the fashion to accept the first discovered abnormality as the sole and only cause of sterility in any particular mating, the normality of all other items being most unwarrantably taken for granted. Such incomplete diagnostic study led to incomplete treatment, of which the results were, in general, notoriously unsatisfactory.

The gynaecological investigation of sterility should include history, abdomino-pelvic examination, measurement of the uterine index, trans-uterine insufflation of gas, hystero-salpingography, study of the endocervical secretions, and post-coital examination of the vaginal and endocervical contents. Some of these tests may require to be repeated before final conclusions are reached.

The urologist takes a history, makes a thorough examination of the male genital organs, and studies the prostatic-vestibular strippings. It is also his duty to examine the semen according to exceedingly critical standards, with a mathematical rating of the spermatozoa as to their number, morphology, motility, and endurance. The resultant figures may be accepted, broadly speaking, as a quantitative index of male fertility. If a specimen of semen is rated at less than 70 per cent of the normal, there is evidence of relative infertility on the part of the male. A specimen evaluated as low as 40 per cent indicates for practical purposes, complete sterility, since the same factors which cause the obvious depression usually operate to reduce, in a less obvious way, the fertilizing power of such spermatozoa as are present.

The medical histories and general physical examinations of husband and wife are expected to identify, first, any departures from the accepted standards of good general health and hygiene and, second, those special items which are known to have a direct influence upon fertility. Among these latter are included errors of diet, insufficient exercise, faulty hygiene, focal infections, other sources of chronic intoxication, diseases of the blood, and other debilitating conditions of whatever sort.

The endocrinologist must carry out an investigation of both partners sufficiently elaborate to diagnose even the milder grades of endocrine disturbance, and in particular the sub-functional states of anterior pituitary, thyroid, and ovary. The past ten years have brought many advances in the field of endocrinology, particularly along lines of biological experimentation. This work is basic research of the highest order, and without doubt the foundation of much future progress. It has already yielded practical results in the treatment of certain menstrual disorders, but as yet it has not contributed notably to the clinical management of infertility. At present, the endocrine aspect of sterility cases is still best evaluated by a discriminating use of the older methods. These include history, physical examination, physical measurements, determinations of oxygen, carbohydrate, and nitrogen metabolic rates, examination of urine and of blood, and in certain cases, other special tests. When each of the individual workers has completed his part of a sterility investigation, the final step is a correlation by conference, of

all the data obtained. Thus each problem is reduced to its simplest terms, a certain number of definite factors, and the way of treatment is clearly indicated.

TREATMENT OF STERILITY

The ideal treatment of the sterile mating would remove all obstacles to conception, thus bringing about a condition of perfect or absolute fertility. Actually, this can seldom be accomplished. The practical aim of treatment is to remove a sufficient part of the sum-total of depressing factors so that the fertility level of the mating may rise above the threshold of conception. This practical result is attained with a degree of ease which varies widely in different cases, according to the number and character of causative factors present. In some instances sterility can be cured by the simplest treatment; indeed, spontaneous cures are not uncommon, since there is constantly more or less fluctuation in levels of fertility. Matings relatively less fertile require more complicated procedures, while in those of lowest fertility all treatment may be unavailing.

In the ordinary clinical case, in which four or five factors are operative, the removal of any two or three of them may be sufficient to raise the fertility level into the range where conception becomes possible. Hence it is understandable that a given sterility might be clinically cured by any one of half a dozen different therapeutic programmes. For the same reason it is clear that any single item of rational treatment, however incomplete, will result in a certain number of cures.

In actual practice one naturally wishes to obtain the greatest number of successful results, and to do so in the shortest possible time. For that reason treatment should always be as nearly complete as possible. That is to say, it should be directed in each case against all of the causative factors which have been demonstrated, in order that the inhibiting sum-total may be broken down simultaneously on several different sides.

Medical treatment and endocrinological treatment are of the highest importance; indeed, their introduction has been mainly responsible for the great improvement in clinical results obtained in the past few years. Urological treatment should be carried out as indicated. I shall not attempt to discuss the details of these methods, since they come within the fields of my associates rather than within my own, but shall limit myself rather to certain observations on modern gynaecological treatment.

Female genital hypoplasia, as seen in the adult woman, is not directly amenable to treatment. After the age of 20 the developmental urge is dead, and ordinarily it cannot be revived. There seems to be a possibility that further advances in endocrinology may provide a means of dealing with this item, inasmuch as hormonal substances have already been found to stimulate follicular activity in the exceedingly immature ovaries of young animals.

Viscosity of the endocervical mucus can seldom be permanently corrected unless the os externum is large enough to allow free drainage. In cases of so-called pin-hole os, it is usually necessary to do a small dissection operation, since dilatation is inadequate and stems are dangerous. When the os externum is properly open, a course of depletion by glycerine or by heat will often rectify the abnormal condition of the mucus. If the viscosity has a background of infection, the quickest relief is obtained by the use of the cautery, or by removal of the diseased mucous membrane with the high-frequency electric current.

Tubal obstructions require as preliminary treatment that all necessary attention be given to chronic passive congestion and to chronic inflammation of the pelvic organs. Retro-displacements of the uterus should be corrected by manipulation and pessary. In many cases these simple measures alone are sufficient to restore tubal patency. For the more resistant obstructions, there are two possible lines of procedure. One of them

is the repeated therapeutic insufflation of gas and injection of oil, and excellent results are often thus obtained. The other method of treatment involves surgical operation. Salpingostomy is of relative little value except in fimbriated-cud occlusion; but in such cases it may be tried with considerable hope of success, especially if the operation be followed by therapeutic insufflation and injection for the purpose of maintaining patency.

Retention cysts in the ovaries and persistent corpora lutea are minor pathological entities of little or no general importance. In relation to sterility, however, they become items of the first magnitude, since they create an abnormally high intra-ovarian tension which interferes in a mechanical way with the maturation and rupture of normal follicles. Impediments of this type may be removed by careful ovarian surgery, of which a feature is the maximum possible conservation of normal tissue.

It has been suggested by friendly critics that my associates and I use methods which are unnecessarily elaborate. To these objections I would offer only one reply. Prior to 1927, working single-handed, I was able to obtain successful results in about 20 per cent of my sterility cases. The latest analysis of the results of our organized clinic, covering the years 1927-1931, shows that living babies have been born to 47 per cent of the couples who were investigated and treated according to present methods.

The cure, however, of established sterility will always remain a project less hopeful than prevention. There are five important items of preventive treatment; the greatest care should be given to the health and hygiene of adolescent children, particularly girls, with a view to forestalling genital hypoplasia. Faults of sex hygiene require attention, since they may lead to congestion of the female pelvic organs and so ultimately to cystic changes in the ovaries. Every effort should be made to eradicate venereal disease. It is important to avoid all unnecessary and harmful treatment of sterility, notably curettage of the endometrium, badly done plastic operations on the cervix, and operations for harmless retro-displacement of the uterus. Finally, childless couples should be encouraged to seek help without prolonged delay, since in any case some waning of inherent fertility begins during the fourth decade of life.

Backache

By V. B. GREEN-ARMYTAGE, M.D., F.R.C.P., F.C.O.O.
(Abstracted from the *Medical World*, 1st December, 1933)

It is not my intention to deal with gross lesions which cause backache, such as neoplasms or retroversion of the uterus with fixation, or of tubo-ovarian masses which may result from inflammation; I shall take, rather, those conditions which, as a rule, defy routine examination, the type of case which drifts from one doctor to another, or possibly finds its way to a quack, and eventually, no better but rather the worse, is wrongly labelled 'neurasthenia'.

Women, from a gynaecological point of view, may be divided into two great classes: the hypotonic, and the hypertonic. The hypotonic is the asthenic, and these form 30 per cent of all cases in gynaecological practice.

What are they like to look at? How can you 'spot' them in your consulting room? Usually, the face is long and mournful, they are flat-chested, the back is round, the scapulae project. The ribs are at an acute angle to the spine, and the abdomen below the umbilicus protrudes. As a rule these women suffer from dysmenorrhœa. They may live long, and intellectually are above the average. Those of them who become mothers frequently develop prolapse after their first baby, and those who are fortunate enough not to marry are generally to be found with various hypoplasias of the vagina and uterus and ovary, also with

high-arched palates, maybe spina bifida occulta, and maybe congenital prolapse.

The hypotonics are the women who drift from your practice, many of them seek consultants and are dilated here and stitched up there. Some undergo every type of pelvic engineering to cure them of their troubles. But the symptom of backache continues, for it is not of the pelvis, it is connected with the statics of the patient.

The line of gravity of the normal human being runs from the mastoid process directly down to the anterior junction of the cervical and dorsal spine, then in front of this junction it intersects the lumbar sacral articulation, midway between the sacro-iliac joints, to pass down just behind the head of the femur; it then cuts through the femur to run down in front of the knee joint, and reach the ground in front of the head of the astragalus. But in the kind of women of whom I am speaking the line of gravity is a different matter; it cuts the spine high up, above the dorso-cervical junction, giving the rounded back. It then passes behind the bodies of the lumbar vertebrae and behind the head of the femur. The result is that these women suffer from various morbid conditions of the spine, and the one that is most easy to detect is a marked lordosis or maybe scoliosis.

The normal person's erect position is maintained by the autonomic system, and that postural equilibrium is maintained by that system preventing the ligaments and muscles of the spinal column from getting tired. But if we sustain strain or become fatigued, or some accident occurs, then the autonomic system is put out of gear, and now postural equilibrium has to be maintained by the voluntary muscle system, and when that system tires, pain in the back ensues.

These asthenics or hypotonics either have some inborn abnormality, or they develop such, as a result of bad postures they are allowed to assume while at school, for naturally their mistresses do not understand the physics and biochemistry of the young girl nearing or achieving puberty. What are the effects of bad posture? or what may be causes of backache and the symptoms which these women suffer?

Backache in these people may be due to fusion of the transverse processes, or of one transverse process of the fifth lumbar vertebra to the sacrum. Sometimes the transverse process may be fused to the ilium. In other cases there may be hypertrophy and periostitis on one side; in another case bursæ may form and these inflame; in another there may be rotation of the sacrum, which can only be detected by a stereoscopic x-ray photograph. There may be a rotation of the fifth lumbar vertebra on its facets, or there may be a sinking of the fifth lumbar vertebra or sacrum. The pubic or ilio-sacral joints may show morbid changes.

But there are still other important changes, and they are the ones which occur in the main buffer or inter-articular disc, between the fifth lumbar vertebra and the first sacral. When a woman assumes the wrong posture and has obvious lordosis, or maybe scoliosis, what happens is that the buffers between the vertebrae become compressed to start with, and then, as a result of that pressure, they become thinned, and because the vertebrae are pushed downwards and forwards in the endeavour to maintain equilibrium, the discs tend to slide out between the bones, and the radiologist will tell you there is a lipping of the discs (most frequently the fifth), and these lips become perhaps ossified and press on the nerves which come out of the foramina of the lumbar vertebrae.

Another condition is that as a result of a descent of the vertebrae there may be an alteration in their 'facetting'. Any of these changes may occur in the women of whom I speak, who suffer from backache and have escaped diagnosis because a proper routine examination has not been carried out.

To do this the first necessity is, in the presence of a relative or nurse, to strip the patient and make her stand laterally, then look at her carefully from in front

and behind, noting how she stands, so getting to know how her line of normal gravity runs; and whether there is lordosis or scoliosis. Next, look for any rigidity or muscle spasm in the back while the patient is carrying out certain movements. With her hands on her hips, ask her to bend her body from side to side and backwards. Then find, if possible, the exact site of any acute pain she may feel. For instance, if you put your finger on the site of an inflamed bursa or periostitis, or a 'caught' nerve between the fifth lumbar transverse process and the wing of the ilium, she will have acute pain.

Next, carry out certain tests. First, get the patient to assume the knee-elbow posture, then ask her to hollow her back, then to arch it. With four fingers on either side of the vertebral column while she does this you will be able to tell whether there is localized rigidity or pain, which may place the origin of the backache, high up or low down.

The second test, known as Goldthwaite's test, is equally easy. Ask her to put one thigh and leg completely over the edge of the couch, keeping the other leg meanwhile straight out, then flex up the thigh which is on the couch, so causing rotation of the pelvis. If there is trouble in the sacro-iliac joint or symphysis she will have pain. This can be done in your surgery or a consulting room. Then put her other thigh and leg over the edge of the couch and test the other side. This will tell you whether the joint is inflamed, whether she has spondylitis or nerve involvement in its neighbourhood.

The third test is to put your hand under the back, and move the patient's thigh and leg upwards, to see if you can localize pain either in a high vertebra, e.g., in the third, or fourth, or in the pelvic joints.

Next, test the patient's knee jerks, because if she has developed some neuritis, or possible pressure which is causing destruction of nerve, there will be an alteration of the knee jerks, with probable obvious wasting.

Next have three stereoscopic x-ray photographs taken. An ordinary antero-posterior x-ray is not worth the celluloid on which it is rendered; it must be stereoscopic.

Having carried out the examination in this way and arrived at a tentative diagnosis, the next thing, and a very important one, is treatment. If you have a young girl who is at school, or who shortly after puberty has begun life as a stenographer or shop assistant, and has pain in the back, you will advise her on the following lines:—

First, there are the ordinary hygienic measures, which we need not waste time upon. Secondly, diet. These women are often very anæmic, with poor tone, and have acalcæmia: a shortage of vitamins A, B and D since they were born. Hence your aim should be to make good that shortage.

Next, you need to give the patient encouragement; please do not forget that; indeed your very thorough examination will help and impress her. Do not say, 'This is a bad business, but we must do our best'. Encourage her to do certain exercises herself, and put her into the hands of somebody who is capable of doing the proper manipulative massage and expert exercises.

Then we come to the subject of belts. I hate the word, because it spells something surgical, but it need not. You should be able to get corsets which will help these girls, in 99 per cent of the cases. These corsets should be so made that they lace from below upwards; many women are in the habit of wearing corsets which lace the other way. When they lace upwards they support the abdomen, which tends to protrude below the umbilicus. Such measures will cure over 90 per cent of your early cases, and no gynæcological operation will be necessary. But in a few cases you will need to provide plaster of Paris, or metal braces, or adhesive strapping, to assist in the immobilization of the structures in the neighbourhood of the fifth lumbar vertebra.

Having spoken of the chief extra-pelvic causes of backache in women, I will now refer to some intra-pelvic ones. The first of these is what I like to call 'pelvic flat-foot'. What is my reason for giving it that name? Some of you may have joined up for the war and, as recruits, had to march long distances. Your feet soon gave out, because you developed flat-foot. Nurses, policemen, and others who stand a great deal, are very apt to develop flat-foot, because the ligaments and muscles of the arch of the foot give way, and pain is caused in the back of the leg and foot. There is the same cause of pain in pelvic flat-foot. Such women have pain in the back because the muscles and ligamentous fasciæ of the pelvic diaphragm relax; they are, as a rule, anæmic multiparæ, but it may be met with in a woman who has had one large child or in one of the hypotonic type who has congenital weakness of the pelvic diaphragm and some prolapse. These cases may need operation, but at first rest, diet, and the ordinary hygienic treatment, associated with muscle atrophy, together with pelvic exercises, such as those of Stacey Wilson, will do more good. To operate without observance of these principles is to court failure.

But there is another condition, to which I give the name 'menopausal flat-foot'. When women are approaching the menopausal period of life they usually put on a good deal of fat around the waist, and suffer from fatty degeneration and wasting of the pelvic muscles and fasciæ. They do not complain of pain or backache until they reach the 'change of life'. Then they suffer from ovarian dysfunction, and, as a rule, from acalcæmia. What they need is the treatment of those who are hypotonic, together with small doses of thyroid gland and iodine.

The next big group we will speak of is the 'pelvic tonsil' group. What do I mean by that term? You who have had tonsillitis will know that it is accompanied by enlarged glands in the neck, which hurt when you turn your head or swallow. The 'tonsil' of the pelvis is the cervix, and when the cervix is inflamed, or torn, or lacerated, or may be is acutely infected with *B. coli* or gonococci, it is the same to the pelvis as the tonsil is to the throat: i.e., the lymphatics and glands are inflamed in the 'sacral bay', beneath the promontory of the sacrum. These glands may be inflamed with endocervicitis, just as they become involved in cancer. Therefore in the case of a woman complaining of backache always look with the speculum before you say there is nothing the matter with her. Endocervicitis is frequently a cause of pain in the back, just as tonsillar inflammation or enlargement causes pain in the neck. The treatment of each is identical.

Piles, constipation and varicose veins of the broad ligament go together: they are often merely a matter of cause and effect. A patient who is habitually constipated usually also has piles, and a patient with the latter often is constipated. The sigmoid colon runs on the left side of the pelvis, the left ovarian vein opens directly into the left renal vein and runs immediately under the sigmoid. Sir William Gull used to say, 'Every woman has a pound and a half of fæces in her sigmoid colon'. So remember that in the cases we are considering, this mass may press on the ovarian vein, and partially dam back the blood on the left side of the ovary and broad ligament and so produce varicosity of that ligament. Your patient may be a woman who does not take much interest in the action of her bowels or may be she is working all day cooped over a machine, and so this condition of varicosity of the pampiniform plexus of the broad ligament with tenderness and engorgement of the left ovary comes about.

The pain is referred to the back and the patient drifts from doctor to doctor. Often these cases are not diagnosed, because when the surgeon opens the abdomen the patient is in the Trendelenburg posture, and then one cannot see the varicose veins in the broad ligament.

How do you diagnose this condition? You can only diagnose it when the patient's pelvis is lowered into the normal position.

The next condition is the tension cyst of the ovary. These cysts in the ovary may defeat all attempts at diagnosis, even by the expert; the cysts may be scarcely larger than a walnut; they may be adherent; they may be prolapsed. These cysts may contain clear fluid, blood or chocolate-like material; one day they may be easily felt, the next seemingly they have disappeared. This illusive nature often causes argument. Because of the degree of tension in these cysts there is almost constant pain, though at times most severe between the menstrual periods. I think operation, together with removal of the appendix and ventro-suspension, is best for them if the pain is severe.

The next cause is in connection with the teeth, and flatulence and enteroptosis; they go together. Most of these women have heavy pouching below the umbilicus when they stand up. You should put a Curtis belt on to such a patient and get the bowels regularly open, make them do proper exercises, and eat and digest properly; have the attention of a good dentist, and then all their symptoms will probably disappear. This type of patient often has her appendix removed and œcum tucked up, but I doubt if they are benefited.

A Fourth Analytical Review of Reports from Pasteur Institutes on the Results of Anti-Rabies Treatment

By A. G. McKENDRICK, D.Sc., F.R.C.P.E., F.R.S.E.
LIEUTENANT-COLONEL, I.M.S. (Retd.)

(Abstracted from the *Quarterly Bulletin of the Health Organization of the League of Nations*, December 1933, Vol. II, No. 4)

[WITH the decentralization of anti-rabic treatment in India, the duty of giving a prognosis is falling more and more on to practitioners. As many will not have the facts and figures at their disposal we are giving a summary of Colonel McKendrick's analytic review on this subject.]

SUMMARY

In the adjoining table, certain of the percentage mortalities are contrasted with those of the previous reviews:

	First review	Second review	Third review	Fourth review
All patients ..	0.49	0.48	0.23	0.48
(a) Live vaccines ..	0.27	0.26	0.21	0.26
(b) Killed vaccines ..	0.65	0.80	0.28	0.66
Europeans ..	0.17	0.13	0.10	0.14
(a) Live vaccines ..	0.20	0.11	0.13	0.15
(b) Dead vaccines ..	0.10	0.14	0.10	0.12
Non-Europeans ..	0.84	0.88	0.78	0.83
(a) Live vaccines ..	1.02	0.82	0.71	0.74
(b) Killed vaccines ..	0.83	0.89	0.93	0.85
Biting animal:—				
Dog ..	0.42	0.44	0.24	0.47
Cat ..	0	0.07	0.04	0.06
Wolf ..	18.31	0	5.52	7.3
Jackal ..	1.58	1.64	5.56	2.2
Category:—				
A ..	0.29	0.34	0.47	0.44
B ..	0.18	0.38	0.31	0.34
C ..	0.60	0.57	0.25	0.62
D ..	0.10	0.05	0.02	0.01
Deep bites ..	1.18	1.06	0.74	1.10
Superficial bites ..	0.12	0.24	0.09	0.18
On bare skin ..	0.66	0.62	0.38	0.66
Through clothing ..	0.10	0.13	0.04	0.12
Locality:—				
Head ..	2.85	2.42	1.24	3.17
Arm ..	0.40	0.49	0.25	0.35
Trunk ..	0.42	0.11	0.10	0.31
Leg ..	0.30	0.40	0.11	0.30

	First review	Second review	Third review	Fourth review
Delay in commencing treatment:—				
0 to 4 days ..	0.35	0.46	0.18	0.53
5 to 7 days ..	0.59	0.46	0.16	0.38
8 to 14 days ..	0.64	0.49	0.28	0.40
More than 14 days ..	1.04	0.69	0.33	0.73
Post-vaccinal paralysis ..	0.025	0.009	0.027	0.021
(a) Cords ..	0.22	0.019	0.048	0.025
(b) Dilutions ..	0.03	0.03	0	0.105
(c) Killed phenol ..	0.006	0.003	0.026	0.008

It has been pointed out in previous reviews that, on account of the much greater risk run by the non-European as compared with the European, a high degree of heterogeneity exists in statistics in which the two race types are combined. In order to obviate this difficulty, it was suggested that the statistics of institutes which have to deal with the two race types should be submitted on separate schedules, one for each type. The response to this request has been gratifying and, as far as possible, the statistics of the two race types have been separately dealt with in the above analysis. The figures relating to non-Europeans are not as yet very large; but it is hoped that in future years, when this procedure of separation is universally adopted, results of greater precision than those given here will be obtained. The statistics of previous years have been re-examined, and such figures as relate to the two race types separately have been extracted. It has thus been possible to collect comprehensive figures from the series of four reviews, and to tabulate them. These combined figures form the data upon which the following conclusions are based.

Tables have been given which summarize the results obtained in the case of Europeans and in the case of non-Europeans, when the figures referring to each of the following fourteen factors are extracted from the whole data:

1. Categories A and B;
2. Category C;
3. Deep bites;
4. Superficial bites;
5. Bites on bare skin;
6. Bites through clothing;
7. Bites on head;
8. Bites on arm;
9. Bites on trunk;
10. Bites on leg;
11. Delay in arrival 0 to 4 days;
12. Delay in arrival 5 to 7 days;
13. Delay in arrival 8 to 14 days;
14. Delay in arrival more than 14 days.

The question is then asked whether, when one of these sub-groups is considered, there is any evidence of significant differences between the results of the various methods of treatment. It appears that there is no evidence of significant differences except in the case of deeply bitten Europeans, and deeply bitten non-Europeans ($P=0.029$ and 0.01 respectively). [The case of the sub-groups—Europeans bitten on the head and leg in which the P values are small (0.008 and 0.03 respectively)—has been discussed in section X, where it has been shown that it is not advisable to lay too much stress on these values.]

The evidence of heterogeneity in the deeply bitten is in accordance with the view that the definition of a 'deep bite' varies from institute to institute, and also with the view that, at some institutes, the proportion of excessively deep and extensive bites amongst those classified as deep bites is much higher than at other institutes.

If this be the full explanation of the heterogeneity amongst the deeply bitten, then, even in these large statistics, it has not been possible to detect any evidence which would indicate superiority of any particular method of treatment; and, further, no evidence has been found indicating that live vaccines are more

efficient immunizing agents than dead vaccines under the conditions of dosage, etc., in which they are employed in practice.

The mortality amongst non-Europeans is found to be 6.5 times as great as that amongst Europeans. This racial difference is *reduced* in the case of those who are bitten by animals which are certified to be rabid (i.e., those belonging to categories A or B); in the case of those who are deeply bitten; in the case of those bitten on the bare skin, and in the case of those bitten on the head. Thus, in general, the racial difference is reduced in the case of those who are presumably at a high degree of risk. The racial difference is *increased* in the case of those belonging to category C (for one reason because the non-European is better acquainted with rabies in animals than is the European); in the case of those bitten through clothing (presumably because the clothing of the European affords a better protection than does that of the non-European); in the case of those bitten on the leg (presumably because the legs of the European are more usually clothed than are those of the non-European); and in the case of those arriving late for treatment (possibly because the better educated European, if at risk, recognizes more fully the advantage of early arrival).

It would appear, then, no single one of the above-mentioned factors is sufficient in itself to account for the racial difference in mortality, but that they all participate in it. In fact, the results are in conformity with the view that, as compared with non-Europeans, the European populations who are treated are diluted with a much larger number of individuals who have not in reality been infected with rabies.

Evidence of the advantage of early arrival appears to emerge with definiteness from the non-European statistics, but not from the figures relating to Europeans. The ratios of the non-European to the European mortalities for the successive periods 0 to 4 days, 5 to 7 days, 8 to 14 days, more than 14 days are respectively 5.9, 6.0, 8.0, and 12.1. Thus, the relative mortality increases progressively with lateness of arrival. It would thus seem that the relatively greater risk to

which the non-European is exposed becomes progressively more marked in the case of those who delay in coming for treatment. The absence of evidence of the advantage of early arrival in the case of Europeans is difficult to understand. It has been pointed out that the influences which come into play are very complex, and depend upon a number of secondary factors. For instance, as mentioned above, the European who considered himself to be seriously at risk would take steps to ensure early arrival. Whatever be the explanation, it would seem that the influences at work obliterate evidence of the advantage of early arrival in the case of the European, whereas in the case of the non-European they do not. Of course, the alternative view might be advanced that the rise in mortality in the non-European statistics might itself be due to one of these secondary factors. For example, there would probably be a tendency for trivial bites occurring at a great distance from an institute to be neglected, but for deeper and more extensive bites to cause such concern that a long journey to an institute would appear advisable. This would result in a tendency for those arriving late to be more seriously at risk, and thus for the mortality amongst late arrivals to be higher. The evidence at present available does not seem to indicate that those who arrive late are more seriously bitten than those who come early.

Further light on this matter could only be obtained if more detailed information were available, so that the causes of late arrival at the different institutes and the relation of late arrival to severity of bite could be ascertained. The matter is important because, if a knowledge of the factors at work were available, an estimate might possibly be arrived at as to the absolute and not merely the relative efficiencies of the various methods of treatment.

From figures relating to 290,337 persons who were treated by the various methods, it appears that the liability to post-vaccinal paralysis amongst those treated by 'live' vaccines is 4.4 times as great as amongst those treated by 'killed' vaccines, and 11 times as great as amongst those treated by 'heated' vaccines.

Reviews

THE MEDICAL ANNUAL: A YEAR BOOK OF TREATMENT AND PRACTITIONER'S INDEX. Fifty-second year, 1934.—Edited by H. L. Tidy, M.A., M.D. (Oxon.), F.R.C.P., and A. R. Short, M.D., B.S., B.Sc., F.R.C.S. John Wright and Sons Ltd., Bristol. Pp. ciii plus 644, with 192 text illustrations and 69 plates, plain and coloured. Price, 20s.

THE arrival of the *Medical Annual* each year is a matter of no little importance to medical readers in this country, as it probably is to those in all other countries where the English language is the common medium of expression of scientific men. We will not say that this year it is 'bigger and better' than ever, because the remark is suggestive of a formula, though in actual fact it is larger by one *forme* and, if it is not better, it has certainly maintained the very high standard set by its fifty-one predecessors (the reviewer is speaking from personal experience of only nineteen of these).

Again, the year has not been remarkable for any outstanding advances, but there is abundant evidence in these pages that in none of its branches is medical science threatened with stagnation. However, in the space of the column allotted for this review, only the briefest reference can be made to a small percentage of the many subjects dealt with.

Further work with supra-renal cortical extract in the treatment of Addison's disease is reported, but this

hormone extract seems to be a long way from playing insulin to the diabetes of Addison's disease. Agranulocytic angina, a comparatively new disease, still continues to attract attention, but contrives to maintain its high mortality; pentose nucleotide K.G.96, intramuscularly administered, offers the best chance of relief. Some of our preconceived ideas regarding anæmia having been badly shaken a few years ago, the subject is undergoing complete reconstruction, so that few years pass without an 'authoritative' reclassification; some confusion is certain to be the result and we pity the medical student of the present day, but as there appears to be little acute divergence between different authorities, we assume that the matter will soon sort itself out. Anæmia, in its many aspects, is given a number of pages, which not only give one a good summary of the year's work on this important subject, but show clearly the modern trend; this is very definitely towards the effect of dietetic deficiencies in this condition. New premedicants and basal anæsthetics come into favour each year, though they do not always oust their predecessors; sodium soneryl, a barbiturate, but less toxic than many allied compounds, seems to be finding considerable favour. (This reminds us that we found no reference to the 'battle of the barbiturates' in these pages.) A successful method of artificial respiration, for employment on the operating table, the inflation of the lungs by blowing through the face-piece of an ether

inhaler, is described and illustrated. Blood transfusion still continues to be popular, but more particularly with the surgeon and the gynaecologist than with the physician; valuable hints on the technique of this operation are given. Interest in lymphogranuloma inguinale has been stimulated by the introduction of Frei's test and the publication of Stannus' book on the subject, but this is not sufficient justification for the subject being dealt with in two places, particularly as this appears to have been done at the expense of granuloma venereum, reference to which we could find under none of its common pseudonyms. The radium treatment of cancer is becoming a more important and a more complicated subject each year; it has long since ceased to be the last resort in inoperable cases, but it is being used more and more in early cases in combination with surgical removal of new growth. But we must go faster; though we have missed many important sections we are still in the C's and our space is nearly exhausted.

Surgeons will find many new operations and new methods of doing old operations described. They have been given the giant's share of the illustrations; these are all clear and make detailed descriptions of technique unnecessary.

Readers who have to treat tropical diseases have again been well served; this section has been done, as hitherto, by Sir Leonard Rogers. We hope that when he retires from active work his successor in office will replace him here. Under the amebiasis reference is made to carbasone (*sic*) treatment; the error is possibly a printing one, and it is the only one we noticed.

The editors will perhaps forgive us if we add the sauce of criticism to our review; the introduction, which is by way of being a summary of the book and for that reason very useful to the indolent reviewer, is not quite up to its usual standard; further, the taint of cynicism, so inappropriate here, has been allowed to creep in, *e.g.*, the paragraph on asthma.

The *Medical Annual* still maintains its very high standard and continues to be the best value for his money that the medical man, be he physician, surgeon or gynaecologist, general practitioner or specialist, can hope to get.

L. E. N.

PRINCIPLES OF GYNÆCOLOGY.—By W. Blair-Bell, B.S., M.D. (Lond.), F.R.C.S. (Eng.), F.C.O.G., F.A.C.S. (Hon.), LL.D. (Glas.). Fourth Edition. 1934. Baillière, Tindall and Cox, London. Pp. xiv plus 848, with 16 coloured plates and 507 figures. Price, 35s.

THIS is the fourth edition of this book of which the first appeared in 1910. It has been largely revised and rewritten by M. M. Datnow, of the University of Liverpool, and Arthur C. H. Bell, surgeon to the out-patient department, Chelsea Hospital for Women.

The work of revision has been very complete and several sections have been entirely re-organized. The book has been brought up to date by the inclusion of chapters on physiological phenomena (internal secretions) and pathological lesions (endometriomata and ovarian neoplasms). The portion on the nature and treatment of malignant disease, with which work the author is specially identified, has been almost completely rewritten. In the treatment of innocent neoplasms, a considerate attitude is recommended and it is advised to approach their treatment 'in a physiologically reverent and conservative spirit'. It is emphasized that 'the complete removal of both ovaries for neoplasms during the reproductive period is rarely necessary'. One is glad to find this point stressed in view of the spate of unnecessary surgical interference which has deluged this field of gynaecology in the past.

The author very modestly devotes a brief page and a half to the place of lead therapy in malignant disease. It is pointed out that local treatment of malignant lesions cannot fill the mark, and that some general systemic mode of attack is essential. He is of opinion

that a chemical preparation which has a specific action on the chorionic epithelium with its syncytium should exert the same lethal influence on the cancer cell.

He has shown that lead fills this rôle.

The method of administration is briefly outlined and also the use of H_{228} (lead salt of benzenesulphonylglycinate) and H_{213} (lead potassium complex of o-thiobenzoic acid).

A fuller account of the end results of treatment might have been included in this section.

Many new illustrations and some coloured plates have been added; these are excellently carried out and convey their meaning in the clearest form.

Part II, which comprises history taking and the examination of the patient, is very comprehensive and will be of considerable value to the student and the practitioner.

It is difficult to single out any case of omission in this excellent volume. The section on contraception is rather brief and contraceptive methods might have been more freely emphasized and more fully dealt with. The whole book bears the impress of the author's personality and this personal note is an added interest. The subject-matter in each section is very clearly expressed without redundancy and with all essentials fully discussed. The historical instruction is valuable and will act as an incentive to embryo practitioners to follow in the illustrious path of the great exponents of gynaecology. The question of where obstetrics ends and gynaecology begins is always a moot point and this book makes more than a successful attempt to solve this knotty problem. The radiographs reproduced are excellent. The illustrations in the section on operative procedures are lucid and the details are always well defined.

Appendix 1 gives a list of post-operative exercises and these are of special value, as references to the necessary sequelæ of treatment in other textbooks on gynaecology are very scanty.

Appendix 2 is devoted to the ætiological classification of the cause of certain gynaecological symptoms and manifestations, and forms a most convenient and compact arrangement of basic principles which should be of the utmost value to readers.

The publishers are to be congratulated on the general formation of the book which is free from printing errors and omissions.

The volume can be thoroughly recommended to the general practitioner and the student as an up-to-date, clear and concise treatise on gynaecology. It has few superiors, if any, in the domain of gynaecology amongst English textbooks. The section on evolution of the female genital organs in vertebrates is very excellent and a useful introduction to the general study of gynaecology. The book should be a most useful addition to the library of the practitioner and the senior medical student, and, at such a moderate price, should be accessible to all who are interested in this branch of the healing art.

D. M.

TREATMENT IN GENERAL PRACTICE.—By H. Beckman, M.D. Second Edition. 1934. W. B. Saunders Company, Philadelphia and London. Pp. 889. Price, 45s.

THIS is a well-arranged and eminently practical book. In his preface to the first edition the author described himself as an editor of the true authors of the book who are represented by the extensive bibliography which he gives. While accepting this definition of his functions, the reviewer feels that he must congratulate the author on his editorial capacity, for he has the faculty of selecting only essentials from the mass of literature he has consulted in the preparation of the book, and, where he does not directly quote from an authority, his own writing is clear and his facts are presented in an admirably condensed form. Another valuable character of the book is that it is remarkably up-to-date, considering the amount of ground covered,

for all the important advances well into the year 1933 are included.

There are a few errors in printing, for example in the top line on p. 108, 0.2 should be 1.2, but the author is probably not responsible for mistakes of this kind.

Written as it is by a pharmacologist, it is perhaps natural that drug treatment somewhat overshadows that of general management and diet, and the book might be improved if the latter aspects of treatment were somewhat enlarged upon.

On the whole the most modern opinions available on treatment are given fairly, and if the author at times is led to disagree with certain statements of his authorities he supports his contentions by urgent arguments drawn from his own wide experience of the action of drugs. It is a book that can be recommended equally to the beginner and to the experienced physician, for it can safely be taken as an authoritative guide by the former, and by the latter as a reference book in which he will find available the most up-to-date information on therapeutics.

P. A. M.

TREATMENT OF THE COMMONER DISEASES MET WITH BY THE GENERAL PRACTITIONER.—By Lowellys F. Barker, M.D. 1934. J. B. Lippincott Co., London and Philadelphia. Pp. vii plus 319. Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 9-6

THIS book is based upon ten lectures delivered by Dr. Barker, Professor Emeritus of Medicine, Johns Hopkins University, to the Academy of Medicine of Lima and Allen Counties, Ohio. The book, as its title indicates, deals with the management of some of the internal diseases that are generally encountered by the physician in his general practice. In the preface the author says:—'Medical research has in recent years been making prodigious progress; original contributions to knowledge have been made in every diagnostic and therapeutic domain. Even in the great teaching centres, no single man any longer lays claim to complete acquaintance with the newer facts in all branches. Before the task of keeping pace with all of the advances of practical significance in connection with infectious diseases and with disorders of the respiratory, the circulatory, the hæmopoietic, the digestive, the urogenital, the locomotor, the nervous, the mental, the metabolic and the endocrine systems the most encyclopedic type of mind must falter'. The object of this book is, therefore, to present brief 'synopses of achievements' in the treatment of some of the commoner diseases in order to enable the busy practitioner to keep pace with progress made in medicine in recent years. This purpose has been fulfilled by Professor Barker in a very satisfactory manner. In this small but scholarly volume he has presented the 'whole welter of medical literature' in so condensed a form and in a delightfully readable manner. At the same time the information contained in the book will be found satisfying and instructive not only to the general practitioner, but also to a wide range of advanced research workers. The book is replete with references to the original authorities in practically every page, and the frequent references to the author's own long experience extending over forty years forms a valuable feature of the book.

In the ten chapters which comprise this book a very wide field is covered by the author. No attempt is made to discuss fully or completely the treatment of any particular disease, nor does the author deal with the ætiology or other aspects of the diseases. Chapter I contains some general considerations in the method of studying patients and is divided into the four groups, the pyknic, asthenic, athletic and dysplastic; chapter II deals with some of the commoner infectious diseases. The next two chapters are devoted to disorders of the respiratory and circulatory systems, and chapter V to commoner diseases of the blood and of the blood-building organs; chapters VI to VIII describe

some of the diseases of the digestive apparatus, kidney and urinary passages and the locomotor system. A short but interesting account of the commoner nervous and mental diseases is given in chapter IX, and in the concluding chapter an excellent survey of the diseases of the metabolism and the endocrine system is presented. The section of the principal vitamin deficiencies is up-to-date and contains references to the work of Szent-Györgyi on the isolation of vitamin C and other very recent work on the subject.

In a book of this character it is manifestly impossible to deal with all the 'ills that flesh is heir to'. But after reading the book one feels that the treatment of some of the commoner tropical diseases has received scant attention at the hands of the author. For instance, there is not a single reference in the book to leprosy, kala-azar, or filariasis. A section on the treatment of some of these major tropical diseases would be welcomed by physicians practising in these regions, and make the book more complete. It may be hoped that for the next edition of the book the author might consider this suggestion.

The book contains useful and practical information for the physicians and can be confidently recommended to them.

S. S. R.

THE BIOLOGY OF THE PROTOZOA.—By Professor G. N. Calkins, Ph.D., Sc.D. Second Edition. 1933. Ballière, Tindall and Cox, London. Pp. xii plus 607, with 3 colour plates and 223 figures. Price, 37s. 6d.

THIS book is a second edition of Professor Calkins' well-known work of 1926, and is a very great improvement on the first edition. The chapter on the 'Chlamydozoa' has disappeared, and these supposed organisms are only referred to once (on p. 360) as 'the questionable Chlamydozoa'. The other chapters have been rearranged, and a new one added on general ecology, commensalism and parasitism.

The book is not an easy one to review. In the first place it contains an amazing amount of information collected during almost a lifetime of study of the Protozoa, chiefly of the free-living forms, and especially of the Ciliata. The medical protozoologist is apt to take far too narrow a view of his subject, and to consider only such forms as are endoparasitic or entozoic in man. From this point of view the book should be read *in extenso* by all laboratory students of the parasitic protozoa of man, for its wide and comprehensive presentation of the biology and bionomics of the Protozoa. Such subjects are considered as reproduction, fertilization, sex differentiation, growth, vitality, maturity, senescence and organization. The medical reader of this book will glean here something of the general principles underlying the science of protozoology and of the organization and development of the Protozoa.

The arrangement of the book, however, is confusing, whilst the style is extremely scrappy and inadequate. No pages are given in it, only the date and volume references being given. The author appears to be very familiar with German, and, of course, American protozoology, but rather ignores the work done by British and French protozoologists. The chapters on taxonomy will be most useful to all students of the science. The English reader will shy at some of the nomenclature; such words as 'fiber', 'cecum', 'ameba', 'endameba', and 'skeptics' are annoying to anyone with a classical upbringing. Mr. Clifford Dobell is incorrectly referred to in the bibliography as C. C. Dobell. The bibliography gives only one reference to Sir Ronald Ross, this dealing with *Leishmania donovani*; and only two to Dr. Wenyon's work.

When one comes to the medical aspects of the book, frankly the reviewer is appalled. There are two colour plates of the malaria parasites; one is an absolute travesty of the beautiful and accurate originals in

Wenyon's *Protozoology*; the other, of the development of the gametocytes of *Plasmodium falciparum*, after Aragão, is not very much better, the erythrocytes showing a fine stippling which is not true to life. The accounts of leishmaniasis, malaria, and trypanosomiasis are brief, rather confused, and not too accurate. The section on amebiasis would be better deleted. On page 51 an organism, which is apparently *Entamoeba coli* in its motile, trophozoite phase is depicted and called '*Endamoeba intestinalis*'. This apparently refers to Aragão's attempt in 1917 to rename *Entamoeba coli* as *Endamoeba intestinivulgaris*, and later in the same year as *Endamoeba intestino-vulgaris*, both of which names Dobell has shown to be invalid. The parasite of amebic dysentery becomes *Endamoeba dysenteriae* to Professor Calkins, and is illustrated in a very poor plate after Cleveland and Sanders on p. 394, including a very atypical octonucleate cyst containing chromatoid bars. (If other authors are to be borrowed from, there is no excuse for ignoring the beautiful and accurate plates in *The Amœba living in Man*.) What the figure on page 62 (after Hartmann) represents, it is difficult to say; but it is alleged to show stages in the metamorphosis of the 'endosome' and 'endobasal body' in *Endamoeba dysenteriae*.

Some amazing statements are made. On page 361 it is alleged that Wenyon records the occurrence of *Trichomonas* from the toe-nails. The reviewer is fairly familiar with Dr. Wenyon's work, but he can find no such statement in any of Wenyon's publications. Reichenow (no reference given) is reported as stating that members of the genus *Giardia* 'are frequently present in great numbers in the blood'. On pages 112 and 113 one finds resurrected the binuclearity hypothesis of Schaudinn and Hartmann, which one hoped was dead. An amazing account of the parabasal apparatus of *Leptomonas ctenocephali* is given on page 119, after Lwoff.

The reviewer has read Professor Calkins' book with very great interest, with much appreciation, but with some irritation. Minchin's *Introduction to the Study of the Protozoa* was a classic for decades, but it is now completely out of date. There is a real need for a simple and clearly written book on the general biology and taxonomy of the Protozoa, as apart from the much narrower science of medical protozoology. Professor Calkins' book, however, is neither simple nor clearly written; it is often both confused and obscure. Even with its defects, however, it is a volume which every serious student of the Protozoa should read for its valuable wealth of information.

R. K.

DIETETICS FOR THE CLINICIAN.—By M. A. Bridges, B.S., M.D., F.A.C.P. 1933. Henry Kimpton, London. Pp. xvi plus 666. Price, 32s.

THE interest displayed in diet by the medical profession is subject to the usual law of 'cycles'; without tracing the history back very far, one can say that dietetics had reached the ebb stage during the last century and that there is every indication that the tide is now flowing strongly. This inflowing tide is bringing in the flotsam of the patent food advertisements, but at the same time some valuable jetsam that had been prematurely thrown overboard to make room for the scientific advances (bacteriology in particular) of the last century. Although the study of dietetics is as old as medicine itself, the recent advances in chemistry and biochemistry which have taken place during the time that this field of medical science has been lying fallow have introduced so much that is new that an entirely new literature is demanded. This demand is being supplied, but, as yet, the medical library is not rich in books on dietetics; this remark applies particularly to clinical dietetics, though we do not share the extreme pessimism of the writer of the book under review, regarding all other books on dietetics. However, this book does undoubtedly fill a want.

The introductory sections on the physiology and mechanics of digestion will usefully refresh the memory of the reader. Section III provides a very good essay on vitamins and gives a few facts regarding the vitamin needs of the organism and the vitamin content of certain foods, but it leaves a number of gaps.

In the next section are given diets of food articles, rich and poor, respectively, in various food constituents, e.g., foods rich in calcium, and foods with low calcium content. The value of these tables are limited by the fact that many of the articles are peculiar to America and in some cases foreigners will not know what they are. The reviewer must plead ignorance in a few instances, and, though he feels confident that he will be able to avoid 'Zwieback' with its high carbohydrate content, he is afraid he may have to give up the idea of taking 'Graham bread' or even 'Swiss chard' to obtain sufficient 'roughage'; however, in the last instance there are thirty-two familiar alternatives from which to choose.

The second part of this book is devoted to diets in various diseases, the principles of the diet are discussed and then a number of menus are given; these of course will be of only limited value in this country, but will serve as a guide even if they cannot be strictly adhered to.

Part III is on infants' and children's diets, in health and in various states of ill-health, e.g., malnutrition, acidosis.

The practitioner in this country will find the book very useful, despite the fact that it is not written from an Indian point of view; it might well serve as a model for a book on clinical dietetic in India.

SURGICAL PATHOLOGY OF THE MAMMARY GLAND.—By A. E. Hertzler, M.D. 1933. J. B. Lippincott Company, Philadelphia and London. Pp. xviii plus 283, with 240 illustrations. Price, 21s. Obtainable from Messrs. Butterworth and Company (India), Ltd., Calcutta. Price, Rs. 15-12

THIS is one of a series of monographs on surgical pathology from the University of Kansas. The outstanding features of this work are that it appears to be based entirely on personal experience, and that the author has made a special study of the subnormal, as a link between the normal and the definitely abnormal.

One of the most interesting and instructive chapters in the book is on pre-clinical carcinoma of the mammary gland; nevertheless we think that it would not be very wise to allow the paragraph entitled 'When no lump can be felt' to be broadcast amongst the laity. The stabbing pains which the author considers should be taken as serious warnings are surely very common experiences. The caution that these should be overlooked if a relative has recently died of cancer appears paradoxical but is of course sound. On the other hand the advice that the evidence should be similarly discounted if the woman has a morbid fear of cancer presents difficulties. How many women do not possess some trace of this fear, the extent to which it is evident depending on their temperaments and circumstance (v.s.)?

The point of view of the writer is quite definitely that of the clinician, or surgeon, if one can draw the distinction, and it is to him that we specially recommend this book. There are altogether 240 illustrations of clinical, morbid anatomical, and histological subjects, and we cannot speak too highly of the way they have been reproduced. The book is well up to the standard of its predecessor in this important series.

RECENT ADVANCES IN SEX AND REPRODUCTIVE PHYSIOLOGY.—By J. M. Robson, M.D., B.Sc., F.R.S.E. 1934. J. and A. Churchill, London. Pp. x plus 249, with 47 illustrations. Price, 12s. 6d.

THIS book gives a concise résumé of the vast amount of work that has been carried out during recent years on the investigation of those endocrine secretions that

have a bearing on menstruation, pregnancy and the menopause. The general impression gained from its perusal is that, although an enormous number of facts has been accumulated in recent years regarding the internal secretion of the ovaries, the pituitary and other glands, and their effect on woman's sexual life, very little is yet really known about them, and that much more must be done before this knowledge can be of much use in its clinical application. Another impressive fact that emerges from the perusal of this book is that all types of animal that have so far been used for experiment differ widely from each other and from human beings in their reactions to these hormones, so that conclusions based on the findings in animal experiment are liable to be quite misleading when applied to man. The result is that at first sight the book appears to be of little use to the practising medical man, but it will be of a definite negative value to him and as such is well worth reading. By this the reviewer means that practitioners will learn from the book that the use of hormones with an action on the sexual functions of women has at present a very limited application and that their empirical employment is quite unjustifiable.

The final chapter is devoted to this aspect of the question and it is especially recommended to the serious attention of 'up-to-date' practitioners (of which there are many) who appear to think that the greater number of new and expensive gland extracts that they prescribe for their patients the more 'scientific' they are.

ANNALS OF THE PICKETT-THOMSON RESEARCH LABORATORY. Volume IX. Influenza. Part I.—By D. and R. Thomson. 1933. Published for the Pickett-Thomson Research Laboratory by Baillière, Tindall and Cox, London. Pp. xvi plus 640, with 28 plates. Price, 42s.

THE industry of John Stuart Mill, the writer of *Principles of Political Economy*, and the dogged persistence of his friend Thomas Carlyle, when he faced the re-writing of the first volume of his *French Revolution* after the manuscript had been burnt, appear as very ordinary human qualities in the presence of these examples of almost superhuman effort displayed by David and Robert Thomson; after having completed five volumes on the streptococci which entailed reference to about ten thousand papers in this subject, they now turn to essay an attack on influenza and its literature, actuated, we surmise, partly, by a desire for personal revenge, but mainly because it was the most colossal problem that they could envisage.

The present volume is only part I, a mere introduction to the subject, of 640 crown octavo pages and twenty-eight of the usual superb plates that are a character of these *Annals*. But perhaps we are over-emphasizing our point; this is actually one of the two volumes in which the subject is to be completed, and the second volume is promised for this year.

A number of sections are devoted to the history of influenza epidemics, epidemiological features, clinical varieties, symptomatology, the age, sex, race, etc. incidence, the mortality statistics, immunology, and other such aspects of the disease, before the main subject, its bacteriology, is faced. The rôle of Pfeiffer's bacillus is the first bacteriological problem tackled; the authors' conclusion gives one an excellent summary of the two hundred and fifty pages which are devoted to the subject. They take the view that the bacillus is probably not the causative organism but that it is a very constant concomitant and that it plays an important part in the pathology of the disease, especially in the severe cases. They point out that it is a difficult organism to grow and that very often workers who report their failure to find it, fail because of their technique. This, they consider, is often because workers attempt to study far too many cases. One is rather horrified to hear that the proper bacteriological study of one plate from one case of influenza takes

about three weeks; whilst we entirely agree that the modern tendency to study large numbers, obviously in a slipshod manner, is to be deplored, there is surely some danger in drawing conclusions from the intensive study of a very few cases, especially of influenza, in a non-epidemic period. In a rapid investigation of a hundred cases in an epidemic, the *positive* findings must be important; what must be guarded against is drawing any conclusions from the *negative* findings, and we agree with the authors that such conclusions are too often drawn.

In the remaining hundred pages of the book the literature on the rôles of other micro-organisms, streptococci, pneumococci, *M. catarrhalis*, *Bact. pneumosintes*, Friedlander's bacillus, and others are reviewed.

Finally, there are two interesting sections, on the rôle of filterable viruses and on animal influenza. It is distressing to think that the pig is a martyr to influenza, but it is some compensation—to us—to think that from this fact we have obtained an important clue to the ætiology of influenza in man.

We can add nothing to what we have already said in praise of these extremely important publications. They should certainly be in the possession of every medical school and research institute library in India.

L. E. N.

A SHORT HISTORY OF THE EPIDEMIC INFECTIOUS DISEASES.—By E. W. Goodall, O.B.E., M.D. 1934. John Bale, Sons and Danielsson, Ltd., London. Pp. 113. Price, 3s. 6d.

It is on the whole very much easier to write a long book on a subject than a short one; into the one you put all you know, or can find out, but for the other you require just as much knowledge, which has to be supplemented by just as thorough research, and in addition you have all the trouble of selection of the most important points. That is to say, these are the conditions imposed if the book is to be as successful as Dr. E. W. Goodall's *Short History of the Epidemic Infectious Diseases*.

There are four chapters; the first two and the last can be read as a continuous essay on the subject; the third chapter is on specific infectious diseases, and, though here the continuity of the essay is necessarily broken, it was the only way the subject could have been treated.

The author is very insistent that the Laws of Moses were designed to combat endemic rather than epidemic disease; certainly many of them were intended to prevent the spread of bowel diseases and these can surely be epidemic.

It is a book that will be read with pleasure and profit by sanitarians and by all students of medical history.

L. E. N.

TUBERCULOSIS (IN HINDI), VOLUME I.—By S. L. Gupta, M.B., B.S. 1933. Hindi Mandir, Allahabad. Pp. xix plus 432, with 115 illustrations. Price, Rs. 6

THIS book is a most comprehensive exposition of the subject in the Hindi language, harring treatment of the disease which we presume will be given in the second volume. The book is divided into twenty-two chapters. Chapter I gives a definition and a brief history of the disease. Chapters II and III are devoted to its bacteriology and give a concise and clear description of the classification, characters, methods of staining and cultivation of the tubercle bacilli. In chapter IV is reviewed the prevalence of the disease in general and in chapter V its spread in India. The author quotes a mass of statistics and shows that, while in Europe and America with the better knowledge of the disease and the application of the modern methods of prevention the mortality from tuberculosis has very much decreased, it has considerably increased in this

country. He states that places which used to be considered as immune have shown within the last 40 years a considerable mortality from this complaint, making due allowance for the greater accuracy in diagnosis attained during recent years.

Chapter VI deals exhaustively with the etiology of the disease and in chapter VII the question of immunity is discussed and the following points are brought out. In all races nearly all men and women are infected with tubercle before adult age is reached. The infection takes place in childhood and the tubercle bacilli remain in the body in a quiescent state for years but, when from any cause the protective power of the body is reduced or the virulence of the micro-organisms is intensified, reinfection takes place giving rise to the active disease. If a child recovers from a severe attack of acute tuberculosis his immunity is increased and a majority of such subjects remain immune against reinfection, either from within or without, throughout their lifetime.

Chapters VII and IX treat of the pathology and morbid anatomy of the disease. They are quite full and exhaustive. The morbid appearances are shown in a large number of well-executed plates and other illustrations.

Chapters X to XVI are devoted to the clinical course and symptoms and chapters XVII to XXII to the diagnosis of the disease. They are all remarkably complete and up to date.

The book is an example of wide reading and the most painstaking labour, and as such will be of immense benefit to Hindi medical practitioners not acquainted with English.

B. J. S.

PSYCHOPATHOLOGY: A SURVEY OF MODERN APPROACHES.—By J. E. Nicole, L.M.S.S.A., D.P.M.R.C.P. & S. Second Edition. 1934. Baillière, Tindall and Cox, London. Pp. x plus 284. Price, 12s. 6d.

THOSE who are acquainted with the first edition of Dr. Nicole's *Psychopathology* will extend a warm reception to this second edition, now revised and enlarged by the addition of four new chapters as well as certain additions to existing chapters. As Dr. W. H. B. Stoddart observes in the foreword which he has contributed to the book, there is such a mass of informative material compressed into so small a space that some readers may run a risk of becoming confused by losing perspective. However timely be Dr. Stoddart's warning, it should not deter anyone, more especially a student of mental disorders, from paying the closest attention to every word Dr. Nicole has written. Starting with a short historical introduction, Dr. Nicole proceeds to outline, always with almost startling brevity, the psychological hypotheses of Morton Prince, Freud, Adler, Jung, Rivers, Watson, Kempf. He then reviews Breman's endocrine theories and the principal 'gland personalities'. Chapter X, one of the new additions to the book, deals with the biochemical and physiological contributions to the theories as to the causation of mental disease, besides including such factors as basal metabolism, cholesterol, blood bromide, blood urea, water balance, the hæmolytic crisis and the psychogalvanic reflex. Dr. Nicole discusses the recent work of W. Burridge of Lucknow who has advanced the theory that, in all excitation processes of nerves and muscles, two factors are concerned, namely, (a) ionic concentration and the action of electrolytes, and (b) states and degrees of colloidal aggregation depending upon hormonal activity. The ionic factor appears to depend largely on calcium metabolism while the 'colloidal' one is related to affectivity. From the biochemical approach Dr. Nicole passes on to the constitutional approach, wherein he reviews the work of Kretschner, Rodalje Willemse, and Stockard. He touches on the work of the Italian school of de Giovanni, Viola and Pende, who have recognized a so-called

microsplanchnic type in which the vertical diameters are excessively developed compared to the horizontal ones and a macrosplanchnic type with the opposite characteristics. In chapter XII Dr. Nicole reviews the accumulation of ethnological and sociological evidence in regard to the theory that individual mentality is nothing but a compressed edition of racial development. Dr. Nicole, very rightly, deplors the absence of correlation between the various schools of modern psychology and psychopathology, and attributes to this absence of correlation a good deal of the confusion to be found in modern textbooks on these subjects. He considers very briefly, but with commendable clarity, the modern position of psychology as a science and touches on the points of contact between psychology and philosophy. In the chapter entitled 'Applied Psychopathology', Dr. Nicole reviews the application of psychopathological findings to general medicine, crime, delinquency, law, education, child guidance, vocational and industrial psychology. Dr. Nicole concludes his remarks on the application of psychopathology to the law and its administration, with the very cogent observation that as the law is itself the result of collective mental factors that may contain as much of the pathological as those of the individuals it is meant to control, the validity of its concepts are open to the gravest objections. There is an interesting discussion of the concept of the 'ego' in psychiatry as well as of the so-called herd instinct. The book contains an admirable bibliography of over nine hundred books of reference in English or translated into English.

O. B.-H.

PSYCHOLOGY AND PSYCHOTHERAPY.—By William Brown, D.M. (Oxon.), D.Sc. (Lond.), F.R.C.P. Third Edition. 1934. Edward Arnold and Co., London. Pp. vii plus 252. Price, 12s. 6d.

THERE is a naïveté about Dr. William Brown which, if it figures in his lectures at Oxford, must render him a perpetual source of amusement to his pupils. The nebulousity of this book with its arithmetical appendices, evokes the mental image of a comet rather than that of a conventional textbook, which, one is led to presume, it is meant to be. Dr. William Brown begins with a paucity of psychology in which the names of Freud, McDougall, Myers and Spearman figure prominently. (Professor C. Spearman is no longer 'of London University' as Dr. Brown states, but let that pass.) Without wishing to belittle the admiration Dr. Brown displays for these four eminent men, it is nevertheless pertinent to observe that however great strides psychology has made in recent years, it can never rid itself of its fundamental defect, namely, that the object observed is identical with the instrument of observation. Further, more leisurely reflection would have shown Dr. Brown that a prerequisite of investigating the problem of intelligence and skill is some understanding of the root-problem of anxiety. As a practising psychotherapist, it should be clear to him that 'tests' of the nature described by him must function as anxiety-investigators, so that the phenomena he tries to measure with the help of mathematics are either residual or the result of auxiliary reaction formations. In other words, he is measuring the apparent flexibility of anxiety-defences. Dr. Brown is a great upholder of religion, though what he means by 'religion' is not at all clear. He maintains that everyone is at heart 'religious' but omits to define the term. He states that 'science needs to be supplemented by philosophy and religion', a rather remarkable pronouncement from so ardent an admirer of Freud! The book deals with a multiplicity of subjects, including war neuroses, psychical research, 'Buchmanism' and the relation of mind to brain. It ends finally with a mass of highly obtruse mathematical calculations which not one reader in five hundred could hope to understand.

O. B.-H.

MENTAL DEFICIENCY NURSING (SIMPLIFIED).— By O. P. N. Pearn, M.R.C.S., L.R.C.P., D.P.M. 1934. Baillière, Tindall and Cox, London. Pp. vii plus 281, with 21 figures. Price, 5s. 4d.

THIS little book is, as its author proclaims, with commendable candour, a cram book and nothing more. In India, where the care and custody of mental defectives is still the concern of private enterprise and then only on a very small scale such a book as this cannot expect to have a wide reception. Not until the problems of public health—mental as well as physical—have become for the *intelligentia* of India as fascinating as politics, can the problem of mental deficiency expect to receive any serious attention. When that time comes, if it ever does, works of this description will doubtless receive the attention that is their due.

O. B.-II.

PHYSIOLOGY. PART I (CATECHISM SERIES). Fourth Edition. E. and S. Livingstone, Edinburgh. Pp. 86. Illustrated. Price, 1s. 6d. Postage, 2d.

THIS handy little volume has presumably been designed for students as a book of ready reference, and has very well fulfilled its purpose. It should be especially useful to students preparing for their oral examination.

The book is quite small in scope, but has a good deal of new material in it and has been brought up to date. The information is accurate, well stated and brief. It is an useful contribution to the Catechism Series, and it is hoped that in the subsequent three volumes the whole subject of physiology will be thoroughly dealt with. The paper and printing are good and we congratulate the publishers for their attempt to place such useful little books within the reach of every student.

P. D.

THE WAR OF THE HUMANS AND THE MOSQUITOES OR THE STORY OF DOCTOR, HEALTH AND THE PRINCE'S HAPPINESS.— By Lieut.-Col. G. Jolley, C.I.E., M.B., Ch.B., D.P.H., D.T.M. & H., I.M.S. 1934. Macmillan and Company, Limited, London. Pp. 77. Illustrated

THIS small booklet is written in the form of a fairy tale in which mosquitoes, other insects and fish are given personalities and endowed with powers of conversation. It outlines briefly the main facts about malaria transmission and the commoner methods of prophylaxis that are employed.

The language is simple and there are numerous illustrations, but the latter are somewhat crude, and some of the statements would probably not find the approval of the scientific malariologist.

Nevertheless, this little publication will be read with profit by children, as the method of presenting the facts will be sure to impress themselves on the memory even of infants.

HOUSING CONDITIONS AND RESPIRATORY DISEASE: MORBIDITY IN A POOR-CLASS QUARTER AND IN A RE-HOUSING AREA IN GLASGOW.— By C. M. Smith. Medical Research Council: Special Report Series, No. 192. 1934. Published by His Majesty's Stationery Office, London. Pp. 36. Price, 9d.

THE reading of this report will be of special interest to research workers, as few have not had the similar experience of finding that the figures they have so laboriously collected do not prove what they hoped they would prove. Uncritically examined the figures suggest that the inhabitants of the re-housing area are more liable to respiratory disease than those of the slum area. Which, as Euclid would say, is absurd!

The report will be valuable for those who propose to undertake a similar enquiry, as it demonstrates the difficulties and the fallacies of work of this kind. We

should say that the main fallacy depends on the fact that people who live in slum areas appear to like living in them and attempt to conceal any ill-health they suffer. Anyone attempting a similar enquiry will do so with his eyes open. Let him avoid all the fallacies—if he can.

THE CHEMISTRY OF FLESH FOODS AND THEIR LOSSES ON COOKING.— By R. A. McCance and H. L. Shipp. Medical Research Council: Special Report Series, No. 187. 1933. Published by His Majesty's Stationery Office, London. Pp. 146. Price, 2s. 6d.

THE results of this very practical investigation will be of great interest to many people outside the medical profession, as well as to those within it. There are fashions in cooking, and these fashions are often engineered by persons commercially interested in the sale of cooking apparatus. Also in connection with cooking there are many 'old wives' tales', which have been blindly accepted by succeeding generations of housewives; such traditions usually have a sound foundation, but sometimes conditions have so altered that they are no longer applicable. An unprejudiced investigation of this kind is therefore very welcome.

The enquiry was a limited one: it was confined entirely to flesh foods and mainly to beef and fish. It was a purely chemical investigation, only proteins, fats, carbohydrates, salts, and water being taken into consideration. The question of vitamins was not within the scope of the enquiry.

Naturally, we cannot detail the results of these investigations; we will, however, give two examples of popular theories that have been upset. There appears to be no foundation for the 'pellicle' theory; that is, that if a joint is put into a hot oven a pellicle forms on the surface which prevents the loss of salts by evaporation. There is no difference in the loss whether the joint is placed into a hot oven, or into a cool one that is subsequently heated up. Secondly, the relative loss of salts is as great in a closed oven as in an open one.

The report is an important contribution to the science of cooking which is so closely allied to the science of medicine.

DIET AND THE TEETH: AN EXPERIMENTAL STUDY. PART III. THE EFFECT OF DIET ON DENTAL STRUCTURE AND DISEASE IN MAN.— By May Mellanby. Medical Research Council: Special Report Series, No. 191. 1934. Published by His Majesty's Stationery Office, London. Pp. 180, with numerous plates and text illustrations. Price, 5s.

MRS. MELLANBY'S work on dental caries, first published in 1918, in which she demonstrated that a sufficient supply of vitamin D was necessary in a child's diet to ensure the metabolism of calcium and phosphorus for the proper formation of the teeth, has had a revolutionary effect on the study of dental caries throughout the world. Her two previous reports, published in 1929 and 1930 respectively, dealt with dental caries in experimental animals and the effect of diet. In this report the subject is dental caries in children from different social groups.

It was naturally not possible to apply the same experimental methods in investigating dental caries in man as were employed with animals, but she has been able to show that certain structural defects in teeth are associated with dental caries, that these structural defects are dependent on deficient dietary in mother and child, and that by correcting this dietary these defects can to a large extent be overcome. Generally speaking, a properly-formed tooth does not decay; pre-natal and early natal nutrition are therefore factors of the greatest importance, but it has been shown that secondary dentine plays a considerable part in preventing decay, so that continuance of a suitable diet is also

important, and further there is evidence that under a suitable diet caries can even be checked after its onset.

An observation of importance, and one of special interest in this country, is that in countries where vitamin-D deficiency is uncommon, *e.g.*, in the tropics, where the sun's rays playing on an uncovered skin provide this, and in the Arctic regions, where oil is a

constant constituent of the dietary, dental caries is also comparatively uncommon.

The report is supplemented by a series of photomicrographs of histological sections of teeth, in forty-six full-page plates, all very well reproduced.

The whole constitutes a publication of primary importance to the medical, as also to the dental, profession.

Abstracts from Reports

TRIENNIAL REPORT ON THE WORKING OF THE RANCHI INDIAN MENTAL HOSPITAL, KANKE, IN BIHAR AND ORISSA, FOR THE YEARS 1930-32

DURING the triennium under review this hospital continued to receive patients as in the previous years from the provinces of Bengal and Bihar and Orissa.

The accommodation of the hospital remained the same as in the previous years, *viz.*, 1,014 for males and 272 for females, total 1,286.

Ever since the inception of this modern mental hospital the question of treatment of patients has always engaged our serious attention and we introduce many of the newest western methods of treatment with due regard to eastern conditions. On my return from leave in 1930, I introduced many forms of new treatment which I had picked up during my second study tour in Europe and America.

Drugs.—*Sulphur injections in mental disorders.*—An experimental study of 100 cases with sulphur injections was fully described in my last annual report (1931). Since then we have experimented with another 40 cases; 17 cases recovered and were discharged as cured; 57 cases improved, out of which 25 have since relapsed and 32 have still maintained the improvement; 66 cases did not show any improvement. This shows that the results of our experiment were quite encouraging and the sulphur injections in my opinion are well worth a trial in all fresh admissions. It gives better results in early cases of psychosis as well as in the psychoneurosis while its effect is not discouraging even in chronic cases. This therapy is now a routine treatment in this hospital in all newly admitted cases.

Hydrotherapy.—During the triennium under report 407 cases were given this treatment—the average number of hours of emersion per patient was 63.

There was a great rush on this department throughout the period under report and many patients were denied this useful form of therapy for want of accommodation. Hydrotherapy is chiefly instrumental in allaying excitement and insomnia in highly refractory cases. The scheme of building a hydrotherapy ward could not be taken up for want of funds.

Occupational therapy.—This therapy still remains as the sheet anchor of our treatment. A very brief outline of works done in this department is as follows:—

Weaving, cane and bamboo work, smithy, carpentry, tailoring, cobbling, mending clothes, mattress and pillow making, lace making, knitting, embroidery work, durrie making, gardening, domestic and office work, Joss stick making, etc.

It is our policy to make the occupational therapy departments of this hospital, which serve as excellent therapeutic agents, to be useful both to the patients as well as to the State.

Approximately 200 patients attend daily the temporary amusement hall of both sections and play various indoor games. As heretofore the hospital band continued to entertain the patients in the amusement hall, and the gramophones were used in the wards for the amusement of those patients who were unable to attend the amusement halls. During the triennium, many football and hockey matches were played with outside

teams of Kanke and Ranchi and the hospital team won many such matches. The annual sports of the hospital were held every year during Christmas week and many patients of both sexes took part in it and carried away many prizes. On New Year's eve we arrange a display of fireworks every year which the patients look forward to and enjoy immensely.

During the period under report the hospital staff staged 17 theatrical shows, and 6 vaudeville shows were staged by the combined efforts of patients and staff. Moreover when any theatrical, magic and variety show of repute visit Ranchi we always try to engage them for the patients.

Cinema.—I am happy to be able to record that the Government on the recommendation of the managing committee sanctioned the purchase of a cinema machine at a cost of Rs. 2,120-5-6.

The reference clerk of the hospital voluntarily offered to operate the cinema machine. He was trained and now works the machine as well as a regular cinema operator.

Band.—The hospital band which was organized in 1928 continues to maintain progress under the conductorship of Naik Shib Charan, one of the hospital attendants. The band now numbers 12 performers, all members of the staff.

Dietetics.—As in former years great attention was paid to the diet of the patients. A well-balanced nourishing diet largely helps the recovery rate. All patients are weighed once a month and those who steadily lose weight are segregated in the infirmary with a view to ascertaining the cause and are fed on special diet until they regain their original weight. The weight charts of patients showed a general rise.

Feasts.—During the period under report several special feasts were given to the patients on festive occasions such as the Pujas, Holi, Christmas, Id, etc.

Religion.—Due respect is paid to the religious beliefs of the patients and arrangements are made for the observance of their respective religious festivals. They are allowed to go out on these days to attend prayers, *pujas*, *kirtans*, etc. The Muhammadan patients regularly attend the *Juma* prayers under the maulavi who is one of the jamadars of this hospital.

The Hindus attend the *kirtans* whenever a pandit calls at Kanke and the Christian patients attend divine services under the Roman Catholic and Anglican chaplains.

Picnics.—Picnics are a notable feature of amusement for the patients and provide a change in surroundings which is much appreciated by the patients.

Parole.—Throughout the triennium many patients were granted local as well as Ranchi parole with or without attendants. Patients seem to enjoy this liberty and the privilege is not abused and it has a salutary effect on their general health.

Motor drives.—The hospital cars were kept busy throughout the triennium on drives. Patients of both sexes go out daily for drives by turn and are also allowed to shop at Ranchi on their return journey from drives.

It will be seen from the above abstract that the treatment of patients in the Indian mental hospital is

Parasites and fever tend to disappear rather earlier from the quinine-treated cases, but the number treated to date is small and the differences are within the limits of probable error. In all cases treated, careful records were kept of symptoms suggesting intolerance towards the drugs, and in so far as these symptoms afford an index of toxicity, here again there would appear to be no significant differences between totaquina and quinine.

In none of the cases treated to date has it been necessary to administer quinine or totaquina by intramuscular injection. Cases unable to tolerate oral treatment are not uncommon in hospital practice, and attempts have been made to develop a preparation of totaquina suitable for injection. Two such preparations are under trial, a ten per cent suspension of totaquina in olive oil, and a fifty per cent filtered solution of totaquina bi-hydrochloride. The preparation of the oily suspension was prompted by the supposition that the tissue necrosis which follows the injection of strong solutions of acid salts of the cinchona alkaloids may perhaps be due not so much to the alkaloids themselves as to their acidity.

Preliminary experiments on guinea-pigs have not been encouraging. Oily suspensions were found to be difficult to work with; in adequate concentration they do not easily pass through a suitably sized needle, while unabsorbed oil has been recognized as long as 11 days after injection. The tendency to necrosis and ulceration appears, however, to be appreciably reduced.

The necrotic effect of a fifty per cent solution of totaquina bi-hydrochloride following subcutaneous injection into guinea-pigs has not appeared greater than that produced by quinine bi-hydrochloride in similar concentration, but further work on the varying effects of a wider range of doses is necessary before totaquina in solution can be exhibited in this manner to human cases.

In addition to the above investigations on the treatment of malaria, extensive laboratory tests on the subject of culture of malaria parasites as an aid to diagnosis have been carried out, as well as examination of the nature of Mayer's reagent as an indicator of the excretion of quinine. Mosquitoes have also received a great deal of attention and the various Malayan anophelines have been studied from the point of view of infectivity by malaria, trapping and identification, larval surveys, feeding habits and the larvicidal effects of various mineral oils. Although a considerable amount of the information on the above points that is contained in this report is necessarily of special value to workers in Malaya, it may be read with profit by malaria investigators anywhere in the world.

The work on tropical typhus has been continued and a great deal has been done on elucidating its various problems, not the least important of which is the apparent proof of the identity of the 'K' type of tropical typhus and Japanese river fever. A full report of this work is promised in the near future and it will be awaited with interest. Numerous other investigations including attempts at transmission of leprosy to rats, epidemiology of diphtheria, investigation of vaccine lymph, the bacteriology of milk, extract of rice polishings, typing of pneumococci, and the study of skin diseases, have been carried out.

An interesting case of infection of a human being with *Trypanosoma lewisi* of the rat is reported, and although the parasites disappeared five days after their discovery in the blood of the patient this record is of considerable interest as indicating that this widely distributed rat parasite may become established in man.

The latter part of the report contains an account of a large amount of routine work on bacteriology, pathology, water examination, medico-legal, and chemical reports. Once again we congratulate the director in producing a record of hard work and progress which it would be difficult for any institute of similar size to equal.

REPORT BY THE DEAN ON THE WORK OF THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE FOR THE YEAR ENDED 31ST JULY, 1933

This report is difficult to summarize, because, in the form in which it is presented, only the essentials are included.

Its perusal, however, shows that the expansion of the activities of the London school, to which we referred last year, still continues and considerable further progress has been made. In spite of the fact that the staff have to spend so much time in teaching, a large volume of original work is turned out and in appendix I, which is a list of papers and reports published during the year, there are over 120 publications.

The probability of the absorption of the Ross Institute by the London school is alluded to in the report, and we understand that this has since become an accomplished fact. This will still more enhance the work of the school, because as a result of this amalgamation they have acquired a body of men who are principally interested in field work in malaria.

The manner in which the London school is growing from year to year indicates that before very long it will be the chief centre of public health work (in its widest sense) in the Empire, if it has not already reached that position.

Correspondence

ACRIFLAVIN IN CEREBRO-SPINAL MENINGITIS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—May I venture to suggest the trial of intravenous injection of a one-per-cent solution of acriflavin or trypaflavin in cases of cerebro-spinal meningitis?

The writer had given two injections of five cubic centimetres each of this solution to a case with success, and, though one swallow does not make a summer, it would be well worth trying, as it will be harmless and might do some good at least before the serum becomes available.

Yours, etc.,
J. B. VAIDYA.
LIEUTENANT-COLONEL. I.M.S.

NIRVAN,
ALTAMONT ROAD,
BOMBAY,
2nd May, 1934.

Service Notes

APPOINTMENTS AND TRANSFERS

THE Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal staff:—

Colonel W. T. McCowen, *vice* Colonel G. C. L. Kerans, D.S.O., retired, to be Honorary Surgeon. Dated 23rd April, 1934.

Lieutenant-Colonel J. A. S. Phillips, Director of Public Health, Bihar and Orissa, is appointed to officiate as Inspector-General of Civil Hospitals, Bihar and Orissa, with effect from the 8th April, 1934, until further orders, *vice* Colonel H. C. Buckley granted leave.

Lieutenant-Colonel F. J. Anderson is appointed as Professor of Clinical and Operative Surgery, Medical College, Calcutta, *vice* Mr. L. M. Banarji appointed Professor of Surgery.

Lieutenant-Colonel R. E. Wright, C.I.E., Professor of Ophthalmology, Medical College, Madras, and Superintendent, Government Ophthalmic Hospital, Madras,

has been duly nominated by the Government of Madras as a member of the Medical Council of India, *vice* Lieutenant-Colonel Clive Newcomb, D.M., F.I.C., resigned.

In exercise of the powers conferred by paragraph 4 (a) and (b) of Section C of Schedule II to the Indian Aircraft Rules, 1920, the Governor-General in Council is pleased to approve Major S. M. A. Faruki to act, until further orders, as a Medical Officer for the purpose of carrying out the medical examination of candidates for the grant or renewal of Pilots' and Navigators' licences under Sections B, C, D, E and F of Schedule II to the said Rules.

Major R. S. Aspiuall is appointed to be Civil Surgeon, Simla (West), with effect from the 16th April, 1934.

The services of Captain S. Smyth are placed temporarily at the disposal of the Government of Punjab, with effect from the 1st April, 1934.

Captain S. M. K. Mallick, an officer of the Medical Research Department, is appointed as Officiating Assistant Director, Central Research Institute, Kasauli, with effect from the date on which he assumes charge of his duties.

The undermentioned Lieutenants (on probn.) are restored to the establishment:—

23rd April, 1934

W. M. E. Anderson.
J. W. D. Goodall.
P. I. Franks, with seniority 23rd April, 1933.
H. B. Wright, with seniority 23rd April, 1933.
J. M. David.
D. P. Dewe.
M. G. Lenne.
G. E. S. Stewart.

LEAVE

Colonel H. C. Buckley, Inspector-General of Civil Hospitals, Bihar and Orissa, is granted leave on average pay for 8 months, with effect from the 8th April, 1934.

Lieutenant-Colonel A. D. Stewart, C.I.E., Director, All-India Institute of Hygiene and Public Health, Calcutta, is granted leave on average pay for 1 month and 11 days, with effect from the 16th July, 1934. He is also permitted to prefix to that leave the Institute vacation from the 27th April to the 15th July, 1934.

RETIREMENTS

Brevet-Colonel J. McPherson, C.I.E., K.H.S. Dated 16th October, 1933.

Lieutenant-Colonel A. D. White. Dated 26th February, 1934.

Lieutenant-Colonel C. R. O'Brien. Dated 4th April, 1934.

PROMOTIONS

Majors to be Lieutenant-Colonels

Dated 5th May, 1934

B. Z. Shah.
V. R. Mirajkar.
A. J. D'Souza, M.C.
Dated 23rd May, 1934
B. C. Ashton.
Dated 26th May, 1934
M. M. Khan.
E. R. Daboo, M.C.
B. G. Mallya.

Captains to be Majors

F. R. W. K. Allen. Dated 5th April, 1934.
M. Taylor. Dated 18th April, 1934.
W. Lawie. Dated 28th April, 1934.
The King has approved the following promotion:—
The seniority of Lieutenant (on probn.) J. Edis-Myers is antedated to the 5th February, 1933.
The seniority of Lieutenant (on probn.) W. G. Kennedy is antedated to the 19th February, 1933.

Notes

FICHERA 365

A NEW ATTEMPT IN THE TREATMENT OF CANCER

HITHERTO, attempts to establish a chemotherapy of cancer have to be considered more or less as failures. Experiments with lead and other heavy metals have shown that only in doses toxic for the organism itself, did such metallic compounds have any influence on the tumour cells. Again, researches into the peculiar metabolism of cancer cells, *viz*, increased glycolysis, failed to suggest any remedial measure.

Professor Gactano Fichera, Director of the Surgical Clinic in Pavia University, Italy, and Director of the National Research Institute, Vittorio, Emanuele III, however, realized as early as 1910 that the real cause of cancer must lie in disturbances of oncogenous equilibrium in the organism. By studying the results of implantations of a great variety of tissues in cancerous organisms, he learned to differentiate between the organs containing cancer-growth-promoting substances and those containing the cancer-growth-inhibiting substances; the organs containing cancer-growth-inhibiting substances, he designated as 'antiblastic organs'. In the course of the last twenty-five years, Professor Fichera has succeeded in making extracts out of the antiblastic organs, and these extracts seem to restore the defensive bodies of the organism against tumour cells.

Injection of such extracts in a good number of cancer patients have been found to bring about specific lysis of cancer cells, without, however, any effect on the normal epithelial and mesenchymal cells. Further, it has also been found that these extracts, injected in high dosage, do not produce any by-effect and are completely harmless to the patient. In certain patients, again, injections have led to the disappearance of relapsing and metastatic tumours, unsuitable for surgical or irradiation treatment. In still other cases, cancerous growth has been altogether arrested and there has been no relapse during a period of 2 to 3 years. In primary cases no more fit for surgical or irradiation treatment, Fichera succeeded in getting a regress in 9 per cent of the total cases and a complete arrest in a further 8 per cent of the cases. All these cases have been under clinical observation during the last three years. It is expected that this treatment will have still better results when applied in early cases or as supplementary to operation or irradiation treatment.

The first communication to the medical profession was made by Professor Fichera himself at the last International Congress of Cancer Research in Madrid, Spain, October 1933. A further lecture by the author was given in the Ministry for Public Health, Berlin, in December 1933.

In his first trial he employed extracts prepared by himself, and the stability of which, however, was very limited. In co-operation with the scientific laboratories of the I. G. Farbenindustrie, he has now succeeded in preparing the extract into a stable and sterile form. The preparation is at present put on the market by Messrs. Bayer-Meister Lucius, under the name of 'Fichera 365', further details of which can be had from Messrs. Haverro Trading Co., Ltd., P. O. Box 642, Commerce House, Bombay. References to the scientific publications of Professor Fichera, which have been published mostly in the Italian and German languages, can also be had from Haverro Trading Co., Ltd.

PROPELLERS TESTED BY MEANS OF X-RAYS

'METALIX' x-ray apparatus have for some time been in regular use in German aeroplane factories, where various parts of aeroplanes are subjected to x-ray examination. This method of examining aeroplane parts is also being generally adopted in America, as is

indicated by the following recent statement in the *Chicago Daily News*:—

'The experiments of Professor George S. Clark at the University of Illinois in Urbana-Illinois have shown that x-rays constitute the simplest, quickest and most effective means of examining aeroplane propellers. In the course of one of these tests a propeller was dismounted, examined and remounted in the brief space of 45 minutes. It is expected that in the near future an x-ray apparatus will form part of the regular equipment of airports and aeroplane workshops'.

'VELOX' DISINFECTORS

THE essential point in disinfection is penetration. No matter what quantity of steam be used, or how hot it is, without the act of penetration that steam is useless. Therefore in using a disinfectant that lacks the power of penetration, one is not taking the precaution that is necessary to ensure against the spread of infectious disease.

Seldom do we hear of a firm of manufacturers who have been willing to carry out well-planned and extensive tests and experiments on the subject of sterilization and disinfection. But in the case of the manufacturers of the Velox disinfectant this has been done.

The Velox disinfectant employs the Geneste Herscher principle which is considered to be equal in efficiency to any, and mechanically the most adaptable for disinfectors in modern practice. These machines are lined longitudinally with solid drawn-copper tubes; the steam thus surrounds the inner chamber, which can be far more easily examined than in the ordinary jacketed machine. A high vacuum is obtained and maintained, a temperature of 249°Fahrenheit is continuous during disinfection as the steam inside the surrounding tubes is kept at fifteen pounds per square inch pressure, and the articles are thus produced perfectly dry and disinfected.

Velox disinfectors are finding places in prominent institutions in India, and we are informed that plants are being used at the King Edward VII Pasteur Institute and at the Khasi Mission Hospital, Shillong; at the Pasteur Institute, Kasauli; by the Port Health department, Calcutta; by the Ootacamund and Ahmedabad municipalities; on the G. I. P. railway; and in many other institutions and departments in the country.

Messrs. Balmer Lawrie and Company, Limited, are the agents in India.

Further particulars on page lxii.

THE DOSE OF SOLGANAL B OLEOSUM

THE commencing dose of the above preparation recommended by the manufacturers is 0.01 gramme not 0.1 gramme, as, through a printing error, it appeared in a letter we published in our June issue.

'HYPOLOID' BISMUTH OXYCHLORIDE

BISMUTH OXYCHLORIDE is a water-insoluble salt for the injection treatment of syphilis.

'Hypoloid' brand bismuth oxychloride, suspended in a sterile isotonic saline solution, is prepared by Burroughs Wellcome and Company, and issued in rubber-capped bottles of 25 c.cm. containing 0.1 gramme of the medicament per cubic centimetre. It satisfies the most stringent tests for the effective introduction of bismuth into the tissues. It is well tolerated in respect of pain and nodosities and is absorbed at a uniform rate, which, without causing toxic symptoms, produces effective anti-spirochaetal effect.

THE VALUE OF DIFFERENT GOLD PREPARATIONS IN THE TREATMENT OF PULMONARY TUBERCULOSIS

SUMMARIZING their results in a paper in the *Patna Journal of Medicine*, Dr. Kesava Pai and his colleagues

at the Government Tuberculosis Hospital, Madras, give the following table:—

	Cases treated	Cases benefited
Sanocrysin	84	49
Solganal	65	42
Solganal B oleosum ..	11	9

Whilst they consider that the number of cases treated with the last-named drug are too few on which to base any conclusions as to its greater efficacy, they point out that Solganal B oleosum is injected intramuscularly, is absorbed more slowly, and therefore gives rise to fewer reactions than do even smaller doses of the intravenous drugs.

SANOCRYSIN AND OLEO-SANOCRYSIN

WE are notified by H. R. Napp, Limited, 3 and 4, Clements Inn, London, W.C. 2, that, as from the 1st April, they have been appointed sole distributors of Sanocrysin and Oleo-Sanocrysin in the British Empire (excluding Australia, New Zealand, Canada, Gibraltar and Iraq).

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

MALARCAN IN THE TREATMENT OF INDIAN STRAINS OF MALARIA

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

B. SEN, B.Sc., M.B.

and

S. K. GANGULY, M.B.

(Department of Pharmacology, School of Tropical Medicine, Calcutta)

UNTIL recently quinine was the only drug employed in the treatment of all forms of malaria, but Acton (1920) showed that, while it cured 90 per cent of malignant tertian infections if properly given, in benign tertian infections the primary cures were not more than 25 to 30 per cent even after a two months' course. Cinchona febrifuge which contains all the alkaloids of cinchona bark gave a cure rate of about 50 per cent (Acton *et al.*, 1921) so that it could be reasonably concluded that there must be alkaloids other than quinine which are responsible for this enhanced rate of cure. These other alkaloids were tested by him individually. Cinchonine and quinidine in 10-grain doses twice daily gave a cure rate of 60 per cent of benign tertian infection after a short course. Fletcher (1923) tested the action of different cinchona alkaloids individually in the treatment of malaria and testified to their having well-marked anti-malarial properties. The anti-malarial action of these alkaloids, however, varied in potency; quinine and quinidine, for instance, were more powerful than cinchonine and cinchonidine. It would appear from this that not only do the different cinchona alkaloids vary in their anti-malarial activity generally but that their action on different species of the plasmodium also varies. Attempts have, therefore, been made by workers to develop compounds of these alkaloids by altering the side chains round the main nucleus and by combining them with other substances, such as aniline, acridine or other suitable compounds. In this way it is hoped that compounds with enhanced anti-plasmodial activity against one or other species may possibly be produced which will act on both the sexual and the asexual cycle, or that perhaps such compounds will even have a destructive action on the sporozoites injected by the mosquito bite and in this way act as true prophylactics.

'Malarcan' appears to be a product which has been prepared with this end in view. It was supplied to us through the courtesy of Dr. P. Rezak of Vienna in order that we might test its therapeutic efficacy against malaria in India.

The drug is sold in the form of tablets which have a bright yellow colour. The makers recommend two tablets to be given every four hours day and night, i.e., 12 tablets within 24 hours, till the patient no longer shows any signs of fever. This is often not feasible and in our trials we gave the requisite amount of the drug in 3 or 4 divided doses daily. They recommend that tablets should be swallowed after a meal or light refreshment, with water. After the fever has subsided it is advised that two tablets be taken three times daily. The total dose necessary varies according to the severity of the attack from 80 to 120 tablets. In children smaller doses are recommended according to age.

The makers also recommend the drug as a protective against malarial fever, two tablets being taken daily after any meals during the period the patient is exposed to infection and two tablets every other day for three weeks after leaving the malarial zone. The method of administration advised in itself shows that the drug is not claimed to be a true prophylactic, inasmuch as it is not expected to destroy the sporozoites injected by the mosquitoes, but to act as a curative in the same way as quinine does. The drug, it is said, produces no toxic or untoward symptoms and does not precipitate blackwater fever, like quinine does in susceptible patients.

'Malarcan' is said to be a compound of a stereo-isomeric base of methyl-cupreine with methyl-acridinium-chloride and hydrocholic acid. It is thus probably a derivative of quinine or quinidine and, in high dilutions, it shows fluorescence under ultra-violet light.

The anti-malarial properties of Malarcan on the Indian strains of malaria were tested by us in a series of 29 patients in the Carmichael Hospital for Tropical Diseases. Patients were admitted under the senior author and soon after admission thick and thin films from the peripheral blood were examined. In some cases a parasite count was also made. Except in urgent cases the anti-malarial treatment was withheld for a few days in order to identify correctly the species of the infecting parasite as well as to make sure that there was no chance of spontaneous recovery. The patients were then put on Malarcan, and no other drugs except purgatives were given. After the completion of treatment the patients were kept under observation in the hospital for a fortnight, daily examinations of the blood were made for 15 consecutive days, and a blood culture for malarial parasites was taken in many patients before discharge. It would undoubtedly have been advantageous if the patients could have been kept under observation for a longer period after treatment, but as soon as the temperature settled down they wanted to leave the hospital and it was with great difficulty that they could be persuaded to stay for a fortnight. Besides, in an endemic

area like Calcutta it is very difficult to distinguish between a relapse and a reinfection, but by this procedure it was hoped that an idea could be formed regarding the efficacy of the drug. During these trials regard was paid to the effect of the drug :

(a) on the temperature and other symptoms met with in the disease,

(b) on the sexual and asexual forms of the parasites and the time taken for their disappearance from the peripheral blood, and

(c) on the splenic enlargement and relapse;

(d) on the relapse rate;

note was also taken of any untoward effects produced.

In the table opposite details of 29 patients on which this drug was tried are given.

In case 1 two tablets thrice daily up to 34 tablets were given, and, in case 2, six tablets in 24 hours. In these patients the effect of the drug was only observed on the sexual forms of *Plasmodium falciparum*; these patients had crescents in the blood and suffered from no other symptoms. It will be observed that no effect whatsoever was produced and the crescents persisted in the peripheral blood after administration of Malarean.

The drug was then tried in smaller doses than those recommended by the makers in order to see what effects were produced on the malarial parasites circulating in the blood as well as on the symptoms produced. In cases 3 to 15, the patients were mostly given two tablets of Malarean three times a day for 5 to 6 days. They were suffering from either *Plasmodium falciparum* or *Plasmodium vivax* infection and in one patient there was a mixed infection with these two species. A perusal of the table will show that in cases of *Plasmodium falciparum* infections the asexual forms generally disappeared within three days of the administration. The crescents were not touched in any case. As regards the infections with *Plasmodium vivax*, both the sexual and asexual forms disappeared from the peripheral blood within 3 to 4 days, that is to say, the parasites of this species took somewhat longer to disappear than those of *Plasmodium falciparum*. Further details of the treatment are given below :—

Case 3.—He had been given 6 tablets of Malarean and 4 doses of plasmochin, 0.01 gm. each, a fortnight ago; this time 6 tablets a day for 6 days; left hospital on the eighth day.

Case 4.—Two tablets thrice daily for 5 days. No parasites found for 9 days.

Case 5.—One tablet b.d. up to 7 tablets; scanty crescents on the fourth day; rings and crescents on the eighth day.

Case 6.—Had been given 7 tablets 9 days before; 2 tablets b.d. up to 17 tablets and plasmochin for 2 days; crescents persisted and scanty rings found on the fifteenth day.

Case 7.—Half tablet b.d. for 5 days; parasites reappeared on the eleventh day.

Case 8.—Two tablets t.d.s. for 5 days, no parasites for 15 days, culture sterile.

Case 9.—Two tablets 4 times a day for 5 days; no parasites for 15 days; culture sterile.

Case 10.—Two tablets b.d. for 5 days; no parasites for a week.

Case 11.—Two tablets t.d.s. for 5 days; no parasites for a week; culture sterile.

Case 12.—Two tablets t.d.s. for 5 days; no parasites for 15 days; culture sterile.

Case 13.—Two tablets 4 times a day for 5 days; left hospital.

Case 14.—Two tablets 4 times a day for 5 days; had a course of atabrin 5 months ago.

Case 15.—Two tablets t.d.s. for one day then b.d. for 4 days; no asexual forms seen for 10 days; crescents disappeared after 4 days.

Out of this series of 13 patients, 4 (30 per cent) showed no signs of recrudescence of the attack while under observation for the fortnight following the treatment, while 3 (23 per cent) apparently relapsed and showed the same species of parasite which they originally carried. The remaining 6 unfortunately left the hospital before the period of observation expired, but all of them were parasite-free on the date of discharge.

Of the remaining, 10 patients received 12 tablets of Malarean daily for 7 to 8 days, that is, the full dose advised by the makers. Of this series, 6 (60 per cent) were apparently cured, and three relapsed while still under observation in the hospital; one left hospital before the expiry of the period of observation. These patients suffered from either *Plasmodium falciparum* or *Plasmodium vivax* infection except two patients who had mixed infections.

Case 16.—Four tablets t.d.s. up to 80 tablets; no asexual forms for 15 days; crescents persisted.

Case 17.—Two tablets 4 times a day up to 40 tablets; again 16 tablets a day up to 64 tablets; no parasites for 17 days; culture sterile.

Case 18.—Four tablets t.d.s. up to 80 tablets; no asexual forms seen for 15 days; culture sterile; crescents persisted and were removed with plasmochin.

Case 19.—Four tablets 4 times a day till 80 tablets; no parasites for 5 days.

Case 20.—Twelve tablets a day till 80 tablets; parasites disappeared from the fifth day of treatment; parasites reappeared on the fifteenth day; then treated with atabrin.

Case 21.—Twelve tablets a day up to 80 tablets; parasites on the tenth day.

Case 22.—Two tablets 4 times a day up to 80 tablets; no parasites from the sixth day of treatment for 15 days.

Case 23.—Two tablets 6 times a day up to 80 tablets; parasites on the fourteenth day and treated with atabrin.

Case 24.—One tablet t.d.s. up to 15 tablets; parasites still present, then 2 tablets t.d.s. up to 30 tablets; no parasites for 12 days.

Case 25.—One tablet t.d.s. up to 15 tablets; parasites on the fourth day. Two tablets t.d.s. up to 30 tablets; parasites disappeared from the second day of treatment for 12 days; culture sterile.

Case 26.—Two tablets t.d.s.; treatment stopped on the third day on account of a reeling sensation which continued for 5 days.

Case 27.—Had been given 8 tablets a day for 5 days three weeks ago; this time 12 tablets a day; treatment stopped in the middle of the course on account of a reeling sensation.

Case 28.—Two tablets thrice daily till 7 doses.

Case 29.—Two tablets in 24 hours.

TABLE

In every case the parasites, except the crescents, disappeared from the blood within four days. Of the three patients who relapsed one suffered from benign tertian and two were cases of mixed infections. That the drug had no action on the sexual forms of *Plasmodium falciparum* (ereseents) is shown by the fact that in case 1 they were only scanty ereseents, no asexual forms being present before treatment; 34 tablets produced no effect on these parasites. In case 2 six tablets were given without any decrease in the number of ereseents. Case 15 was peculiar in that the ereseents could not be found four days after the treatment. As the patient had only scanty ereseents before the treatment was begun, their disappearance was probably spontaneous and not the result of the treatment. In case 16, the drug appears to have stimulated the growth of gametocytes and stopped that of the asexual forms.

A careful study of these cases shows that the action of Malarean closely resembles that of quinine in that it is equally effective against the asexual and sexual stages of *Plasmodium vivax* and *Plasmodium malarie* and has no action on the sexual forms of *Plasmodium falciparum*. Its action is also somewhat stronger on the asexual forms of malignant tertian than on those of benign tertian. The effect of the drug on the splenic enlargement is practically the same as that of quinine. After treatment with Malarean, there was a great reduction in the size of the spleen where this organ was soft. The drug produced no appreciable effects on the blood pressure, pulse or respiration.

Certain untoward symptoms were met with during the treatment with Malarean which, however, were not serious. Cases 26 and 28 had a reeling sensation which gradually disappeared when the drug was stopped. In two patients flatulence, abdominal discomfort and insomnia developed, but they were temporary and were got rid of with a dose of carminative or a bromide mixture.

Summary and conclusion

(1) Malarean is said to be a compound of a stereo-isomeric base of methyl-eupreine combined with methyl-aeridinium-chloride and hydrochloric acid. It is probably a derivative of quinine or quinidine.

(2) The effect of Malarean on Indian strains of malaria closely resembles that of quinine. Its action on the asexual forms of malignant tertian is rapid, while on the crescents it has no action whatsoever. On the sexual and asexual forms of benign tertian and quartan the drug has an action similar to that of quinine.

(3) The action of the drug on relapses is also very similar to that of quinine.

GLABELLAR PRESENTATION, ITS INCIDENCE AND TERMINATION

By A. L. MUDALIAR, M.D., F.C.O.G.

(Second Obstetric Physician and Gynaecologist, Government Hospital for Women and Children, Madras)

VARIATIONS in the degree of flexion in cephalic presentations have been noted for a long time by obstetricians and different names have been given to various presentations depending upon the degree of flexion of the head. Thus we have vertex, brow and face presentations; and among vertex presentations, we have the sub-classifications, posterior fontanelle and anterior fontanelle presentations, depending upon whether the head is fully flexed, hyper-flexed, flexed to the normal extent, or slightly under-flexed. That such variations in the degree of extension might also occur cannot be denied. So far, however, the literature has got but few references to any definite types that have occurred, and no nomenclature has been suggested to these variations. It will be seen from a description of cases given below that variations in the degree of extension occur with sufficient frequency to justify this nomenclature.

My attention was first drawn to this abnormality about a couple of years ago, and since then there have occurred ten other cases which seem to me to justify the suggestion that a definite nomenclature should be introduced for these abnormal presentations. They deserve a separate description in the literature and hence the new nomenclature suggested.

Glabellar presentation.—This is a presentation wherein the head lies in a position of extension

(Continued from previous column)

(4) Malarean is not a toxic drug and in the doses recommended by the makers it produced no serious untoward symptoms.

(5) The drug is about 4 to 5 times more expensive than quinine and appears to have no advantage over that drug.

midway between a brow and a face. The diameter of engagement may be said to be the mid supra-maxillary bregmatic diameter which is the distance between the mid-point of the superior maxilla and the posterior point of the bregma. On actual measurement of a large number of cases, it has been found that this diameter varies between 4 and 4½ inches. The following cases give the details of glabellar presentations conducted at this clinic within the last two years :

Case 1.—A II-para, first child delivered naturally; patient was admitted in labour, the membranes having ruptured 12 hours before admission. A vaginal examination made after admission revealed the fact that the cervix was nearly fully dilated, an incompletely extended face was presenting, and the head was still fairly high at the brim of the pelvis. Fœtal heart—126, mother's pulse—68. Axis-traction forceps was applied without effect. Internal podalic version was then performed and an asphyxiated female child weighing 6 pounds was extracted and revived by the usual methods. The examination of the face revealed the fact that the caput that had formed on the presenting part was seen over the upper lip, the malar eminence, the supra-orbital ridges and a portion of the frontal eminence.

The striking fact about it is that the lower jaw does not share in the caput formation; nor is there any trace of caput formation near the anterior fontanelle. The mid-point in this presentation is the glabella, and it is for this reason that the suggestion is put forward that these presentations should be called 'glabellar' presentations. They are often mistaken for a face presentation, because if the finger is passed fairly high up, the mouth can be easily reached and even the lower jaw. The other cases which occurred during this period were :

Case 2.—A III-para, first two children delivered naturally; diagnosed by abdominal palpation as a right occipito-posterior presentation. Membranes ruptured prematurely. Twelve hours after the rupture of membranes a vaginal examination was made and it was found that the os was a little more than two-fifths dilated; the head was engaging transversely; the upper lip and nose and supra-orbital ridges could be easily felt. A 'glabellar' presentation was diagnosed. Patient was put under deep anaesthesia, cervix dilated, internal podalic version performed and a live male child weighing 6½ pounds was extracted. The caput was well marked over the forehead, nose and upper lip.

Case 3.—A II-para, first child delivered by forceps; was admitted in labour and was diagnosed by the house surgeon on duty as a case of face presentation. The os was four-fifths dilated and the presenting part in the mid-cavity. An hour afterwards, on examination, it was found that the presentation was really midway between brow and face. The fœtal heart was 156. Axis-traction forceps was applied after promoting slight extension of the presenting part and a male child was extracted slightly asphyxiated, which was revived by the usual means.

Case 4.—A VII-para, all other children born naturally; diagnosed by the house surgeon on duty as a brow presentation. Admitted with a temperature of 103.2°, pulse 130, fœtal heart inaudible. Axis-traction forceps applied and with much difficulty, a dead female child was extracted. The caput formation over the

forehead, eyebrows, nose and upper lip, revealed the fact that this was also a 'glabellar' presentation.

Case 5.—A primipara, admitted with the os fully dilated, medium-sized caput present on the forehead, supra-orbital ridges and the upper jaw. Patient had been in labour for over 24 hours and was exhausted, the tongue being dry and coated. Presenting part was not fixed and was felt above the brim. Os was fully dilated; membranes were absent; uterus not tonically contracted. Internal podalic version was done and a deeply asphyxiated child was extracted weighing 6½ pounds which could not be revived.

Case 6.—A primipara, admitted with a history of having been in labour for over 12 hours, and membranes ruptured 6 hours prior to admission. Measurements of the pelvis—normal; general condition—good; uterus—full-term and acting; diagnosed as left mento-anterior by the house surgeon on duty. Fœtal heart nearing 160; mother's pulse—88. Axis-traction forceps applied and a deeply asphyxiated child weighing 5 pounds was extracted with considerable difficulty, but revived by usual methods. The caput formation revealed that this was a 'glabellar' presentation as well.

Case 7.—A V-para, other labours natural. In labour for nearly 20 hours; membranes ruptured more than 12 hours previous to admission. Uterus was full-term, acting strongly, the head was fixed. Vaginal examination revealed that the os was fully dilated, cephalic presentation; the superciliary ridges, eyes, nose and the upper lips could be felt. Fœtal heart—120, mother's pulse—100. Axis-traction forceps applied and a live male child weighing 7 pounds delivered. Presentation: 'glabellar'.

Case 8.—Primipara, admitted with a history of having been in labour for 15 hours. On examination, temperature—101°, mother's pulse—120, slight œdema of the feet, tongue coated, uterus—full-term, acting slightly; position of the fœtus—right occipito-anterior?; head—fixed; fœtal heart not heard; pelvic measurements normal. Diagnosed as a face presentation by the house surgeon on duty. On further examination, this was found to be a case of 'glabellar' presentation. Axis-traction forceps applied and a dead female child weighing 5 pounds was extracted with much difficulty.

Case 9.—A primipara, admitted with a history of labour for 3 hours; pelvic measurements—normal; uterus—full-term, acting slightly; head engaging; membranes ruptured 3 hours after admission. As the os was only two-fifths dilated, patient was given a draught and allowed to rest. Eight hours later the os was fully dilated, fœtal heart nearing 160. Axis-traction forceps applied and a female child weighing 5½ pounds was extracted without difficulty. The caput formation revealed the fact that this was also a typical case of 'glabellar' presentation.

These nine cases show that there is an intermediary position between a face and a brow, which presents definitely and where the difficulties of delivery through natural powers are considerable. The best method of delivering these cases would seem to be by performing internal podalic version, if the conditions permit; or by extending the presenting part, converting it into a face presentation and delivering by the application of forceps. It may here be stated that internal podalic version has been the method of choice in the delivery for some time past, with gratifying results, in those cases where, with a fairly normal pelvis and no marked degree of disproportion, the cause of delay has been due to the presenting part not

being flexed, and being fairly high up above the brim of the pelvis.

On looking up the literature, I find that Professor Dougal of Manchester has also referred to a very similar case before the Royal Society of Medicine in 1929, and suggested that the presentation was due to an extended lower jaw. Professor Dougal called it an unusual variety of face or brow presentation, but we think that the term 'glabellar presentation' is more appropriate. The description given by Professor Dougal is as follows:—

'The patient was having violent pains, but her general condition was perfectly good. On holding back the perineum with the fingers, it was possible to see the orbital ridges, eyes, upper lip and open mouth of the child and the caput was well marked over the eyes, nose and upper lip, the last being much swollen and resembling a large polypus. Careful examination under anæsthesia showed the head to be lying in the right mento-anterior position, with the lower jaw firmly caught above a little to the right of the symphysis pubes.

He inserted his hand into the vagina, pushed up the presenting part and flexed the lower jaw which came down with a distinct click. The presentation was now a simple face, and he was able to complete the delivery with forceps quite easily. The child was alive and weighed 6½ pounds. Its appearance was not prepossessing, as there was a large caput over the face and the lower jaw was so much displaced backwards that the child appeared completely devoid of chin. (The mother's pelvis was apparently normal).'

This description exactly coincides with the description of our own cases, and there can be no doubt that this was a similar case, better styled a 'glabellar' presentation. The drawings* (plate VIII) make this quite clear.

Orbicular presentation.—Here the face is over-extended and the mouth presents. One case of this description was encountered within the last two years. It is naturally indistinguishable from a face presentation, but a careful vaginal examination reveals the fact that while the nose, mouth, and lower jaw are easily felt, the supra-orbital ridges and malar eminences are not easily within reach. The caput formation is distinctive, the eyebrows not being affected in the caput. The management of this particular case was similar to that of a face presentation and does not call for any remarks. Plate VIII, figure 5, makes the position clear, as to the abnormality in the face presentation, and as the orbicularis oris is so pronouncedly prominent, it is suggested that this may be styled 'orbicular presentation'.

The drawings showing the caputs in cephalic presentations in the varying degree of flexion and extension are given in plate VIII.

(Continued at foot of next column)

*Photographs from which these drawings were made were sent to us by the author. The drawings are such accurate copies of these photographs that the reproduction of the latter would be superfluous. The only excuse for thus duplicating the illustrations would be to establish the *bona fides* of the draughtsman; readers must accept our word for this.

TINEA IMBRICATA (TOKELAU) IN BENGAL

By H. W. ACTON, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

and

L. M. GHOSH, M.B., D.T.M. (Liverpool)

School of Tropical Medicine, Calcutta

History

THE disease was first described by Dampier in 1789. Tilbury Fox described it as 'Tokelau' ringworm in 1874, but he considered the fungus to be identical with that of the European ringworm. Manson (1879-82) in China was the first to describe the disease in any detail and he gave it the name *tinea imbricata*; he considered the fungus a non-cultivable *Trichophyton*, to which Blanchard gave the name *Trichophyton concentricum*. Castellani in Ceylon (1910-11) was the first to cultivate the fungus, and he proved it to be the causative agent by successful inoculation in human volunteers.

Geographical distribution

The home of the disease is certainly the Malay Peninsula whence it has spread to the Pacific islands, China, Java, Borneo, New Guinea and Ceylon. As far as is known there is no record of this disease occurring amongst Indians in this country. Although Castellani and Chalmers (1919) mention two cases from South India, they give no details as to the race of these patients, the locality they came from, or whether they had ever been in an endemic area for any sufficient length of time. However, one of our colleagues at the Calcutta School of Tropical Medicine, Dr. N. C. Dey, who spent some time working amongst the aboriginal hill tribes of Assam in the districts of Kamrup, Goalpara and Nowgong, is quite definite that *tinea imbricata* occurs amongst the aboriginal hill tribes there and in the adjacent Abor hills. But the disease is very rare amongst the Indian immigrants from the plains.

It would seem from the nature of the geographical distribution that the disease is spreading

(Continued from previous column)

I wish to express my thanks to Mr. P. H. Vital Rao, M.B., D.G.O., house surgeon, for drawing up notes of these cases and for other help rendered.

REFERENCE

Dougal, D. (1929). *Journ. Obstet. and Gyn. Brit. Emp.*, Vol. XXXVI, p. 245.

very slowly from its original focus to the adjacent countries.

The disease has not the wide distribution of the ordinary ringworm and only infects people who have come in close contact with sufferers, frequently or for long periods of time, because the fungus has very little, if any, saprophytic existence in nature, like the ordinary dermatophytes, the epidermophytons and the trichophytons, which grow readily on wooden bath-mats, on leather, on coir matting and even in mud and in the dung of animals; the fungus of *tinea imbricata* would not grow in any of these.

In the laboratory also the cultivation of this fungus is very difficult. The scales must be very fresh—that is, inoculated on to the medium immediately they are scraped off from the lesion.

The case reported (*see* protocol I) is a Bengali who comes from Mymensingh, a plains district of Bengal. He had never left his native district until a short time ago. He acquired the disease in childhood. The Mymensingh district is bordered by the Garo Hills and Goalpara district. The members of the hill tribe amongst whom the disease is reported to be common are constantly visiting the plains for purposes of trade, etc. It is quite possible this man acquired his infection by direct contact from the infected visitors from the hills.

Symptomatology

The disease begins usually with one or more small round or oval patches, slightly raised and very irritable. Soon a ring of flaky scales is formed. This ring increases in size and in the meantime another ring starts in the centre inside the first and so on until a very large roundish patch is formed containing several concentric rings. Manson has very aptly compared this concentric ring formation with ripples produced by a stone thrown into a pool of water. If early treatment is not given other areas become infected and several systems of concentric rings appear which overlap one another and gradually the whole body is covered with these rings.

The scales are greyish or brownish in colour, flaky and thin, resembling tissue paper. Sometimes large portions of the scales can be removed by pulling with a pair of forceps. A well advanced case may suggest the appearance of a case of exfoliative dermatitis, the patches being very diffuse and the rings discerned with difficulty.

The fungus does not affect the hair follicles and infection of the scalp has never been reported. The general health is not affected, but the patient complains of severe itching at intervals.

Diagnosis

Diagnosis is usually easy the lesion being very typical. Scraping from the patches treated with

Diagnosis is usually easy, the lesion being very the scales.

Treatment

In the early stages this is satisfactory, but when the whole body is involved it is very difficult as the lesions are very apt to recur, being reinfected from other parts of the body.

The patches should be treated twice daily with the following paint until every sign of the disease has disappeared; after this the area should be painted once daily to obviate recurrence.

Fiat pigmentum

Culture.—The fungus of *tinea imbricata* was regarded as non-cultivable prior to 1910 when Castellani first grew it. However, Castellani (1928) holds that the primary culture is not possible on solid medium and advises primary cultivation on liquid glucose broth, followed by sub-culture on solid medium. We never had any difficulty in obtaining a primary growth on solid medium (especially on Czapeck's synthetic medium) directly from the scales, and all our attempts, including hanging-drop culture, were successful. Fresh and non-desiccated scales must be used and several tubes inoculated at the same time.

Animal and human experiments

We failed to produce the disease on guinea-pigs both by intradermal inoculation of a saline emulsion of the culture and by rubbing the culture on a scarified area.

One experiment on a human volunteer was successful. The intradermal inoculation of a saline emulsion of the culture failed to produce the disease, but by rubbing an emulsion on a scarified area on the forearm a typical lesion from which the fungus was recovered was produced (plates IX and X, figures 2), the incubation period being about ten days. After three weeks the patch was cured with the paint (*v. s.*) within four days (for further details *see* protocol IV).

Mycology

The growth of the fungus in all the common laboratory medium is faviform, that is, of the *Achorion* type. The end-organs are only arthrospores—single or in chains—and chlamydospores, intercalary and terminal. There are no fuseaux, no free conidia, and no aleurospores. The mature chlamydospores have double walls. The rate of growth, the nature of the colonies, the colour and the *duvet* formation varies with the nature of the medium and the oxygen supply

(see protocols II and III). There is so much variation in these that it is impossible to classify the species by colour variation alone in laboratory media.

Classification

Castellani created a separate genus *Endodermophyton* (Castellani, 1909), for fungi affecting the skin between the superficial and deep layers of the epidermis, such as *tinea imbricata*, and mentions four species:

End. concentricum Blanchard, 1901.

End. tropicale Castellani, 1914.

End. indicum Castellani, 1911.

End. mansonii Castellani, 1914.

Castellani admits that the growth is faviform in all the four species and this is verified by Sabouraud and Pinoy (Castellani and Chalmers, 1919). The character of the growth and the nature of the end-organs indicate that botanically this fungus belongs to the genus *Achorion* (Remak, 1845), and we cannot find sufficient grounds for the creation of a separate genus to add to the confusion already existing in the classification of the dermatophytes.

We cannot express any views regarding the species *concentricum*, or *mansonii*, as we have had no opportunity to study these two species of Castellani, but the species we have grown shows the typical characters of both the other two species of Castellani—*tropicale* and *indicum*. As the *duvet* formation and colour variation depends on the composition of the medium and can easily be controlled, we think it likely that these two latter species are one and the same. We venture to conclude that the fungus causing the disease *tinea imbricata* should be named, provisionally, *Achorion indicum* Castellani, 1911. However, we consider it possible that all four are but a single species, and if this can be proved the species must be named *Achorion concentricum* Blanchard, 1901, according to the rules of nomenclature.

Summary

Tinea imbricata, a disease not uncommon in the Malay Peninsula, has hitherto not been reported as occurring in an Indian in this country; a case is described.

It is a disease with a limited geographical distribution because the causative fungus does not appear capable of living a saprophytic existence as do other ringworm fungi. In this case the infection may have been acquired through contact with Assam hill tribesmen, amongst whom the disease is rumoured to be common.

Primary growths of the fungus from scales can be obtained on both solid and liquid media, provided the scales are fresh.

Cultural characters: The growth is faviform. End-organs—arthrospores, single or in chains. Chlamydospores—terminal or intercalary.

The faviform growth and the arthrospores as end-organs justify the inclusion of the fungus of the *tinea imbricata* in the genus *Achorion*, and a separate genus *Endodermophyton* is not necessary.

As the colour of the growth and *duvet* formation vary in the same species according to the medium in which it is grown, separation of species on these characteristics is not justified and in our opinion the fungus of *tinea imbricata* should be named *Achorion concentricum* Blanchard, 1909, until further investigation justifies differentiation.

Protocol I

CASE

A. G., MOHAMMEDAN male, 20, resident of Mymensingh, a plains district of Bengal; gives a history of infection from childhood. He had never been in any hill district, nor outside Bengal.

When he first presented himself in the skin clinic he was thought to be a case of exfoliative dermatitis affecting the whole body except the scalp, the palms of the hands and the soles of the feet. The scales were very thin, tissue-paper-like and exfoliating. On pulling the free margins long pieces could be drawn out. Careful examination showed the lesions to be arranged in concentric rings, this was especially distinct over the back, sides of the chest and upper part of the abdomen. The rings were of a brown colour; very fine, raised and gyrate. On some areas, namely the arms, forearms, thighs and legs, the eruption appeared as a diffuse scaly dermatitis the circular arrangement being practically impossible to make out. Exfoliation was abundant and the scales were easily scraped off with a blunt scalpel.

Scrapings.—Scales show mycelia in abundance, septate and interlacing freely. No free conidia were seen.

Culture.—Positive both in solid and liquid media.

Character.—Faviform; growth brownish (in Sabouraud's maltose peptone media) covered with white powdery surface. Colour varied according to various media and different oxygen supply. Grows aerobically, anaerobically, or under partial aerobic conditions.

End-organs.—Arthrospores in chains, chlamydospores, both intercalary and terminal, no free conidia seen.

Biochemical reaction.—Not hæmolytic. Slightly proteolytic in serum. Does not ferment sugars.

Animal experiments.—Not successful.

Human inoculation.—Successful.

Fig. 4a

Fig. 4b

Protocol II

Culture medium	1st week	2nd week	3rd week	4th week	5th week
1. Sabouraud's maltose peptone agar.	Very slight growth, white downy, 4 mm. diam.	Growth very slow, white, about 6 mm. diam.	Achorian-like growth, dirty brown, raised cerebriform in the centre and white-powdery over the surface. About 7-8 mm. diam.	Achorian-like growth, dirty brown, raised cerebriform. White-powdery surface. Margins—no radiations. End-organs—no free conidia, no arthrospores, only chlamydo-spores.	Like 4th week. Achorian-like growth, dirty brown, very slow—surface powdery, roots not seen. End-organs—chlamydo-spores, intercalary and terminal (plate IX, figure 9).
2. Synthetic (Czapeck's) solid.	Very slight white downy growth radiating from centre about 6 mm.	Very slow growth, white smooth about 1 cm. One sub-culture made in same medium (plate IX, figure 6).	Primary growth smooth colourless, growth 1 cm. in diam., thick downy roots, sub-culture same type of growth.	Primary—smooth, colourless growth, little over 1 cm.—very slow, radiating from the centre of the scale. Thick woolly roots growing deep down. Sub-culture—same type of growth.	Primary—smooth colourless growth radiating from the scale—fluff with the surface of the media—roots thick cotton-plug-like (plate IX, figure 8). Sub-culture—growth slow like the primary culture. End-organs—chlamydo-spores—in chains (intercalary and terminal).
3. Synthetic (Czapeck's) viscoid. Agar 0.2 per cent.	Very slight.	Very slight growth, roots woolly; in abundance.	Slow growth; muffy white roots all round.	White woolly growth from all sides of the scales, some floating on surface, some in the middle of media, some sticking to the sides.	Like that of 4th week. Fine segmented mycelium. End-organs—chlamydo-spores both intercalary and terminal (plate IX, figure 4).
4. Synthetic (Czapeck's) liquid.	Growth not perceptible.	Growth hardly perceptible.	Very little growth, only one scale looks like a tiny little shining spot radiating from the centre, which is scale.	Growth fair this week, flaky or woolly growth lying at the bottom and floats on shaking, many colonies.	Growth like that of powder-juff. End-organs in plenty. (plate X, figure 3), chlamydo-spores in chains (arthrospores), the terminal spores are big and have double septa.
5. Whey agar.	Growth not perceptible.	Very slight.	Growth very slow, and smooth.	Very slow growth like Sab. (1), colour dirty brown or sand; achorian-like raised.	Achorian-like growth, dirty brown or sand; powdery surface like that on glucose agar; End-organs—chlamydo-spores.
6. Glucose agar.	Slight growth.	Growth like Sabouraud's (1), but very slow.	Achorian-like growth, dirty brown, raised and cerebriform with white-powdery surface, downy margins.	Raised, rough cerebriform growth like achorian—growth fair, colour dirty brown covered with white powder.	Raised cerebriform, like achorian, surface powdery. End-organs—chlamydo-spores. Colour—dirty brown covered with white powder.
7. Glycerine agar.	Not perceptible.	Very slight.	Very slow growth, white smooth colonies.	Growth very slow, sand colour; smooth with colourless radiating margins.	Very slight growth, like 4th week. Sand colour; margins almost colourless radiating.
8. Saccharose agar.	Do.	Very slow, white and smooth.	Very slow like glycerine agar.	Growth very slow, small sand coloured colony, snuff-colour powdery.	Growth like that of 4th week.
9. Glucose broth.	Do.	Small flaky mass, floats on shaking.	Small flaky mass about 4 mm. diam., floats on shaking.	White woolly flaky growth, floats on shaking. Photomicrographs show terminal and intercalary chlamydo-spores in chains (arthrospores).	Woolly, like powder-puff. About 5 mm. diam., floats on shaking (plate IX, figure 3). Arthrospores in chains.

Protocol III

	Medium	Conditions	Growths
10 11	Sabouraud's medium } Synthetic medium }	Complete anaerobiasis.	More downy surface. Colour—grey, with beaded appearance (plate IX, figure 7).
12	Sabouraud's (sub-culture).	Partial anaerobic condition.	Less pigmentation; white radiating surface runners; less downy and less cerebriform; colony smooth.
13	Glucose agar with rubber cap.	Oxygen tension constant.	Colour—salmon pink; usual growth (plate IX, figure 5).
14	Sugars.	None fermented in fifteen days.
15	Serum.	Liquefied slowly.

Protocol IV

ANIMAL AND HUMAN EXPERIMENTS

(a) Guinea-pig no. 1 was given an intradermal injection of saline emulsion of a culture on a shaved area on the back.

Result:—1st week—slight swelling.
2nd week—swelling still present.
3rd week—swelling subsiding.
4th week—no swelling.

(b) Guinea-pig no. 2 was inoculated by superficial scratching (vaccination method) on the shaved skin of the shoulder, dressed with saline gauze and strapped.

Result:—1st week—slight swelling, area raised about 1 cm. in diam.
2nd week—area smooth, no hairs grown as yet.
3rd week—condition the same.
4th week—hairs growing, no infection.

(c) Ramu—intradermal injection of saline emulsion. Left forearm in front—slight swelling.

Result:—1st week—swelling still present.
2nd week—no swelling, no infection.

(d) Ramu—inoculation by rubbing the culture on the back of right forearm (vaccination method).

Result:—1st week—slight swelling.
2nd week—swelling still present.
3rd week—distinct rings appeared with swelling of the part (plates IX and X, figures 2); mycelia found in the scales and recovered by culture.

HOT WEATHER EAR—A CLINICAL ENTITY*

By F. J. PALMER, F.R.C.S.I.

LIEUTENANT-COLONEL, R.A.M.C. (Retd.)
Hoogrijan, Upper Assam, Bengal

THE writer first made the acquaintance of this condition shortly after first landing in India. He was then stationed in Meerut, a very hot station, where the soldiers made free use of the swimming baths in cantonments. There were several admissions to hospital with a condition which was diagnosed in accordance with the nomenclature of diseases as 'Inflammation of the external auditory meatus'. The condition was generally attributed to contaminated bath water entering the meatus and setting up inflammation there. A medical officer of experience, I think belonging to the Indian Medical Service, informed me that he had seen the condition in Bombay where he had heard it called 'monsoon ear'.

The treatment consisted in syringing with antiseptic lotions, and as far as I can remember after the lapse of years, was not brilliantly successful in all cases.

Subsequently I came across several cases of this affection in a company of soldiers who had been engaged in musketry practice rather later in the season than usual; but whether the infection—which one inferred—was dust-borne or water-borne is not quite certain. I was rather inclined to believe this affection to be really a ringworm of the external meatus.

The following is a brief description of a typical case of the disease:—A medical man is generally first consulted because of pain in the ear, sometimes slight in early cases, and often agonizing in later ones. On inspection the

* Being a paper read at the Annual General Meeting, Assam Branch, British Medical Association, 1934.

* Other references will be found in this paper.

meatus is found more-or-less blocked by a swelling of its walls. In a marked case this swelling almost completely blocks the channel, and any attempt to introduce an auriscope to see what is the condition causes such pain that it has to be abandoned. In a case where the swelling is less marked, a portion of the drum can sometimes be seen through a chink formed of the swollen lining of the meatus which is red and inflamed, and from which hang tatters of dead white skin. In cases where the meatus has been patent from the first, or becomes so later, after syringing such fragments of dead skin may come away in what seems to be an annular skin cast of the meatus.

In some cases the tympanum is covered by a purulent-looking membrane, almost exactly simulating a perforation with pus overlying the remains of the drum. I have several times in such cases, after a course of treatment, seen a blue absolutely healthy and intact tympanum emerge when the membranous shroud had disintegrated.

I can still recollect quite clearly the indignation of a London ear specialist who was examining cases in the hospital of which I had charge in Mesopotamia, and who had asked me to look at a case of what he considered bad perforation, when I replied 'I am not quite certain, I shall tell you after I have treated him for a week'. At the end of that time I was able to show him an intact drum appearing, and to explain why I had hesitated to accept his diagnosis.

The condition is usually unilateral, but it is fairly common in such cases to find the same inflammatory process existent to a lesser extent in the opposite ear.

The cases in which the meatus is not completely blocked respond to antiseptic syringing and slowly improve.

In the cases in which blockage of the meatus is complete, syringing is of no avail. It never gets round the corner where the trouble is. Such cases, after a spell of severe pain, often exude a little watery semi-purulent fluid and the swelling slowly subsides and the pain disappears. They are then usually diagnosed as boils of the meatus.

The method of treatment that I have evolved, after some experience of these cases, gives quick relief in even the most marked of them. The cardinal point in treatment to remember is that, to be successful, the medicament must be applied to the affected inner portion of the meatus beyond the obstruction.

The following may be used in treatment :

(1) *Glycerine* one drachm, to which one small drop of sanitol is added and thoroughly mixed up. If this seems to cause undue irritation, the amount of glycerine may be increased.

It is probable that other varieties of cresol would prove equally efficacious, and years ago when I saw most of these cases, I used any kind

of cresol which came to hand. It must be remembered, however, that these vary much in the amount of irritation which they are capable of causing, and the dilution of cresol may have to be increased in such cases.

(2) *Ichthyol and glycerine*, equal parts, or if this mixture is not sufficiently liquid in cases where the meatus is tightly blocked, one part of ichthyol to two of glycerine.

These medicaments are introduced in the following manner :—The patient lies upon his side with the affected ear uppermost, and the meatus is filled with the medicaments. A no. 2 or 3 Jacques rubber catheter is then taken, and, held very lightly, is worked up and down past the obstruction, with the greatest gentleness, carrying with it the application to the place where it is wanted.

Used in this way, by anyone endowed with good tactile sensibility, there is not the slightest danger of damaging the tympanum. A careful estimation is of course made of the depth to which safe penetration may possibly be made.

Owing to the small size of the instrument used, the application does not, as a rule, cause severe pain. Should it do so, a strong solution of cocaine, as used for mucous membranes, may be first applied, but such is seldom necessary. This manœuvre should be carried out twice daily.

This treatment is rapidly followed by a lessening of the pain, and it must be remembered that, in some of these cases, the pain is extremely severe.

Whilst the medicament is taking effect, pain may be relieved by hot fomentations. It was formerly my custom to give opium in cases with severe pain. This should now be unnecessary, and I would use Compral or Novalgin instead.

The effect of this treatment is, firstly, relief of pain. Some days later the swelling decreases, and a little later an auriscope can be introduced, and an estimation of the condition made. As soon as the meatus is sufficiently open, syringing can be commenced. I generally use the cresols in weak solution, but eusol may be alternated. In the returned lotion may often be found the skin flakes so characteristic of the disease.

Treatment must be continued for weeks, until with the auriscope no flakes are seen, and the tympanum and the lining of the inner half of the meatus appear normal.

Though I have called the condition 'hot weather ear', as most of the cases I have seen occurred during that time, one of the two cases I have seen in Europeans since I have been in Assam occurred during the cold weather.

My own impression is, that the condition is most probably a ringworm, with or without a superadded, secondary, probably bacillary, infection; but I have been unable to demonstrate

'BACKDOOR DRAINAGE', AN ANTI-MALARIAL MEASURE DESIGNED TO MEET A PARTICULAR PHYSIOGRAPHICAL SITUATION IN SYLHET DISTRICT, ASSAM

By C. STRICKLAND, M.A., M.D. (Cantab.)

Professor of Medical Entomology, School of Tropical Medicine, Calcutta

and

D. GIBSON, M.B., Ch.B. (Glas.)

Medical Officer, Dholoi Valley Tea Estates

Physiography of Sancherra garden

A RIVER has a regimen like that of a pendulum; in its course it oscillates from side to side, and the consequence is that it moves in a series of curves, these having an amplitude depending on the gradient and a wave-length depending on the width of the river. The phenomenon however is influenced in its manifestations by such static factors as the heterogeneity of the earth—for instance if the banks of a stream that would naturally swing in curves be rigidly protected it is compelled to follow a straight course—or it is biased by such a dynamic matter as the deposition of alluvium by another stream approaching it—and so when one observes that two streams pursue independent courses for some distance down a valley plain, one may be sure that the oscillation of each has been biased by the resistance offered by the alluviation of the other, the resultant course of the streams being the state of equilibrium between the apposing forces.*

An example on a grand scale of the influence of a stream on the course of a second one, even when the latter is the greater of the two, is seen in the Ganges Valley, where the great river has been for various reasons pushed over to the south against the peninsula by the deposits of its tributaries the Gogra, Gandak, and others; while on a small scale such factors doubtless have determined the courses of the Dholoi River and the Legata River in the Dholoi Valley of South Sylhet, the scene of this report, the two rivers running down the valley independently for some distance before joining (see map 1).

Now not only do two apposing streams influence the oscillation of each other, but the

result may even proceed to the length of the larger stream choking, as it were, the smaller; if this indeed cannot escape elsewhere, for it stands to reason that if the alluviation of a stream be powerful enough to influence another in its course, the deposit may go so far as to invade the latter grossly, the first effect of the choking of the lesser stream* by the deposition of silt in its bed being that the stream is raised, thus reducing the gradient of its course behind the obstruction. Consequently the stream swings more from side to side and its valley is thereby further widened by erosion: while it more readily overflows its banks, and a permanent swamp, or even a broad expanse of water may be the result. The stream at the obstruction meanwhile becomes more exiguous as it is choked by the deposit, so that the outflow from the lake or swamp that may have been formed behind it becomes a mere trickle, and indeed if the outflow be no more than can get away by percolating through the barrier of silt it entirely disappears underground.

Such a strangulation of a stream emerging from a valley in the hills, and the physical consequences as described above, were observed by us in 1923† in the Sancherra garden of the Ali-nugger Tea Company in the Dholoi Valley of Sylhet in Assam. Here the 'lines' of the tea-garden labourers had been built on a spur of hilly ground to the south of a shallow *bhil*, or lake, which had originated in the way described and been deepened by the local fishermen who had erected a bund for this purpose. The valley in which the *bhil* was confined had been naturally widened by the swinging of the stream in its attempt to escape from the obstruction at its mouth and the area provided a sump for the local rainfall, from which at the height of the rains there was only a very exiguous outlet, or spill (see map 2); over higher ground‡ to the west, a high bank of alluvium deposited by the Sancherra River (see levels in map 2 and figure 1): while during the drier months the only outlet for the lake was by percolation through this bank of deposit. The *bhil* was shallow, covered with aquatic plants, and bred innumerable mosquitoes, of which *Anopheles funestus* (*minimus*), *aconitus* and *philippinensis* may be mentioned.

(Continued from previous page)

any fungous elements, possibly owing to defective technique.

The exfoliation of the epithelial lining definitely suggests ringworm, but on the other hand, the treatment used may increase this.

I believe that a certain proportion of the cases diagnosed as furunculosis of the meatus belong to this category.

* Actual junction of two streams will be effected if the bigger stream when swinging can overcome the resistance due to deposition of alluvium by the other.

Malaria in Sancherra garden

In 1923 the spleen-indices were as follows:—

'Lines'	Spleen-index
East	58.8
Bazar	52.5

* The choking may even completely block up the mouth of a tributary valley.

† When one of us (C. S.) surveyed this garden in connection with a general malaria survey of the Assam Tea Estates.

‡ A very common phenomenon in South Sylhet.

In 1926 Messrs. Duncan Brothers of Calcutta accepted a scheme for the amplification of the survey of 1923 and allowed us to organize some anti-malarial work on this garden with others in their agency, to see whether measures based on the findings of the survey would be effective.

with it. Careful consideration of the sequence of events resulting in the formation of the *bhil* indicated that its artificial drainage by cutting through the bank of silt obstructing the outflow was not feasible, as more silt from the original source would immediately dominate the drain

MAP 1

The Dholoi River Valley (taken from the Survey of India sheet, 1 mile to the inch scale).

As it had been concluded that the *bhil* was an undesirable feature in the malariageny of the place, discussion arose as to what to do

and fill it up. It would be comparable to expecting a prick in the skin to remain open. Among various alternatives it was ultimately

Fig. 1.—A high bank of alluvium deposited by the Sancherra River planted with paddy.

Fig. 2.—A *kunji*, an exiguous valley the bed of which has been levelled off by years of paddy planting.

indeed possible that on taking levels the northern route would be found to be unsuitable and the southern suitable.

The following were the relative levels at important points. The average water-level in the *bhil* was 31.40 feet* with soundings of the bottom everywhere of less than 3 feet. The levels taken along the *kunji*† to the north into which the cutting was to be made were 40.40 feet; 35.30 feet; 31.30 feet; 30.60 feet; 27.20 feet; and at the Hagricherra they were 20.00 feet (average water-level) and 16.70 feet at the bed of the stream. There was therefore ample fall from the *bhil* bed the lowest point of which was 28.80 feet, to the *kunji*, but between these

Fig. 3—The cutting looking east toward the *bhil*, in 1930

two points the bank of the tea garden, on which tea was being grown and which would have to be cut through, rose to 43.10 feet at the datum level. In the end the necessary cutting‡ through this bank was made down to the 28 feet level, so that the deepest part of the cutting was about 15 feet (figures 3 and 4) and it was continued as a drain along the eastern edge of the *kunji* to the north to the 27.20 level, from which point the drainage was to run away over the general surface of the land, see Section for diagrammatic section of work.

*The datum utilized was 43.10 feet shown at X on map 2. It corresponded approximately with the 123.10 feet contour in the Survey of India maps

†Exiguous valley, the bed of which has been levelled off by years of paddy planting (see figure 2). This *kunji* is to be called the Johnstone *kunji*.

‡Named the Wilson Cutting.

Physical results

The effect of this earthwork was to dry up almost completely the great expanse of water in the *bhil* (figures 5 and 6). Mr. Aitken's and

Fig. 4—The same as figure 3, in 1934, well settled and now overgrown with jungle to support the sides and prevent anopheline breeding

Fig. 5.—The *bhil* near the cutting before completion; water at the cold-weather level: the line of bushes delimits the rains level.

Mr. Wilson's notes on results are appended. A few depressions remained, but the garden labourers filled most of them in and levelled them off for the purposes of paddy cultivation (figures 7, 8 and 9). No deleterious effects on the Hagricherra have since been noted. A

Fig. 6.—The same as figure 5 after draining off the *bhil*: the 'nullah' was formed by the flow-off and has since been levelled away.

side-issue however has been that the ryots on the lands adjoining the *bhil* have entered a protest against their loss of fishing-'rights' on the estate land.

Fig. 7.—The bed of the *bhil* levelled up and planted with paddy.

The levels on the bed of the *bhil* after the main work was completed are shown in the map, the lowest point as already stated being 28.80, not too low for drainage through the cutting, but too low for rapid drainage. This and other such places have therefore been filled in, and further to facilitate drainage a contour-drain graded from 29.30 to the cutting at 28

feet has been dug on the western side of the *bhil* (figure 9).

Results to health

As for the result to the malaria endemicity, this as stated above was noted by one of us

Fig. 8.—The southernmost arm of the *bhil* below the bazar cooly lines: a contour-drain protects it, as seen on the left.

Fig. 9.—The arm of the *bhil*, at the apex of which the cutting was made: the contour-drain on the left is shown on map 2, on the west of the *bhil*.

(C. S.) in 1923 and has been recently taken again by him in 1934 as follows:—

'Lines'	East	Bazar	South	TOTAL
1923	58.8	52.5
1934	25.71	11.62	17.24	17.75

It is not within our purpose to discuss here the causes of the residual endemicity.

Conclusion

The lessons to be learnt from these observations are:—

(1) That it is essential to understand what Nature is doing, otherwise one may be tempted into measures opposed to her infinitely greater power: thus the common practice of the 'straightening out of rivers' by cutting by-passes is folly, because, as explained above, rivers are curved in their courses in obedience to dynamic laws:

(2) That in areas of great alluvial deposition one may commonly find big streams not

only influencing the course of lesser streams but actually blocking them with silt so that they cease to exist above ground and swamps and lakes are formed behind the obstruction:

(3) That on no account should open drainage through recent alluvium be resorted to, but such areas of deterioration may perhaps be drained out by the 'backdoor method', thus defeating Nature by a stratagem:

(4) This 'backdoor' drainage is very often impracticable, as a cutting to an active stream at a suitable level would be too costly:

(5) That Man, represented in this case by tea-garden labourers, may be, though unintentionally, an important factor in altering the physical features of the surface of the land by filling in depressions for the purpose of planting paddy.

Acknowledgments

We are indebted to Messrs. Duncan Brothers and Company in the first instance for their kindly placing this estate at our disposal for the conduct of this sanitary experiment, and, as for the executive work, we have received a great deal of assistance from Mr. H. Aitken, the consulting engineer, who after confirming the survey levels concurred in the scheme, Mr. John Forbes, general manager of the Ali-nugger Tea Company gardens, whose influence was a great inspiration for success, Mr. Wilson, the manager of the Sancherra garden, who discovered the best line for drainage and carried out the main scheme, for which reason we would like the big cutting to be named the Wilson Cutting, and finally Mr. Johnstone, who more lately has taken out the levels again to enable us to see what changes there have been.

We would also wish to thank our assistant Dr. Paul for his careful malariological data enabling us to control the scheme.

APPENDIX

Details of executive work, and cost supplied by Mr. Wilson.

WORK			
Total length of cutting through bank and the <i>kunji</i> on the north	690 ft.		
of which the cutting through bank may be taken to be	350 ft.		
and the outlet drain	340 ft.		
Cutting—			
greatest depth	15 10 ft.		
greatest width at top	15 ft.		
greatest width at bottom	3 ft.		
Outlet drain—			
width	3½ ft.		
depth	1½ ft.

ANTI-MALARIAL WORK ON A GROUP OF TEA ESTATES IN SOUTH SYLHET

By R. A. MURPHY, L.R.C.S.I., L.R.C.P.I., L.M.

Medical Officer, Luskerpore Valley Medical Association, South Sylhet

THE anti-malarial work here reported upon was initiated in 1926 under the auspices of Messrs. Duncan Brothers of Calcutta, the agents for three of the tea gardens in the group of which I was in medical charge. Later on, other companies decided to adopt the same measures, so that in the end the estates of the Amo, Deundi, Chandpore, Teliapara, Luskerpore, and the Imperial Tea Companies were included in the scheme of work, the results of which are reported below.

In 1926 practically no anti-malarial work had been attempted in the tea districts in India, so that the scheme—which was based mainly on the findings of Dr. C. Strickland of the Calcutta School of Tropical Medicine during an extensive malarial survey of the tea districts in 1922 and 1923 and was carried out in collaboration with him—was really an experiment in sanitation.

The results of the initial work in the gardens of Messrs. Duncan Brothers' agency have been

(Continued from previous column)

Cost

The capital cost of the executive work for 1930-31 was as follows:—

	Rs.	As.	P.
1930. The big cutting cost ..	347	4	6
Infilling depressions ..	149	7	9
	496	12	3
1931. Contour-drain dug round <i>bhil</i> , big cutting deepened ..	60	0	0
Infilling holes ..	160	0	0
GRAND TOTAL 1930-31 ..	716	12	3

APPENDIX

Note by Mr. H. Aitken, Consulting Engineer to Messrs. Duncan Brothers and Co., on the executive work, dated 29th March, 1934:—

I inspect the *bhil* annually and can assure you the works are a complete success.

I take this opportunity of letting you know, in connection with contour seepage drains round the foot of *tillahs*, that during the past three cold weathers I have had miles of these drains cut and existing ones deepened resulting in most effective drainage in low narrow *kunjis* under tea cultivation, most profitable work.

Note by Mr. Wilson, 23rd August, 1933:—

What was previously waste *bhil* land is now excellent *khet* land while outside our boundary a greater area is being cultivated by *bustee* people.

To the garden coolies every acre under cultivation means anything from Rs. 100 to 175 per annum, and this for a capital cost to the garden of about Rs. 100 an acre, plus a little for necessary upkeep.....

(Sd.) D WILSON.

lately reported upon by Dr. Strickland and myself (1932).

The operations were particularly difficult because of the nature of the terrain; this is dominated by alluvial deposits obstructive to drainage on the estates, which lie on the low hills bordering the flood plains. However, various means have been adopted to overcome the difficulty, and two new methods in anti-malarial work have been evolved, one '*bhil-silting*', the other '*backdoor drainage*'.*

In the earlier work the problem was to deal with the extensive anopheles-breeding marshes or *bhils*. These *bhils* on the gardens originally joining the scheme have for the most part been rendered innocuous by *bhil-silting*, but the numerous highly-dangerous drains remain to be treated. Thick shading of drains is essential, and it is unfortunately more difficult to start and maintain this growth of vegetation than to make the drains, as it requires more supervision and generally has to be done at a more inconvenient season of the year. Cattle do much damage to drains, but even more to the growth of shading, and the only satisfactory solution is to fence them off.

Further progress now depends almost entirely on this drain shading, and this will have to be undertaken intensively.

The mosquito catchers visit each garden approximately once a month, and the assistant, Dr. Chakravarty, after examination of the captures, sends to the manager a report regarding the dangerous species and where they have been found. This enables the managers to know exactly what place requires attention, and they are now aware of what steps to take to right matters, unless the conditions are exceptional.

Tanks were oiled periodically.

The maintenance of drains requires constant supervision, and where there is a tea-house assistant it is a good arrangement to put him in charge of them. It is work that he is not tied down to do at a definite time, and that can be done as opportunity offers. It interests him, being a change from factory routine, and allows of fresh air and exercise.

The effect of the anti-malarial measures on the health of the labour forces.—On the whole the results to health have been very satisfactory. The case of garden B, where the August sickness rate has dropped from 19.6 per cent to 2.5 per cent, may be claimed as fairly typical of the results obtained, but apart from such figures the managers affirm that the working capacity of the coolies has enormously improved.

The population on any one tea estate, or even group of estates, is too small to enable definite conclusions to be drawn from vital statistics covering only short periods, except in the case of gross variations or exceptional circumstances. A favourable infant death rate in any year, for instance, may be spoilt by the unavoidable deaths of a pair of premature twins. All diseases fluctuate naturally in their incidence over varying periods. In this report therefore the figures for several years have been grouped together, so that a truer perspective may be obtained. The tables and graph show the figures for malarial incidence and infant deaths before and after the scheme was instituted. The graph illustrates the drop in malaria cases better than does the table, as the latter takes no account of the increase in population, which has risen from 14,398 in 1929 to 17,656 in 1933, so that the drop in cases from 6,596 to 2,101 is more significant than at first it appears to be. Further this additional labour has been largely recruited from Tipperah gardens and from the local *bastis* and the disease thus imported tends to lower the general health, also, as is well known, immigrants may intensify malaria.

Infant-mortality rates are given, as, although a non-malarial garden may from one or other cause have a high rate, a badly malarious garden will never have a low one. Most of the infant death rates are very good and prove the control of malaria. The garden with the highest rate has only recently joined the scheme, and already there is an improvement, which as work progresses is certain to continue. The coolie infant enjoys the advantages of natural feeding and sunlight, and, were malaria to be eliminated, the death rate here should be very low.

In 1933 the percentage of cases as a whole showed little change from the previous year. A substantial decrease would have been shown had there not been an unusually large number of

A FORM OF GENERALIZED OEDEMA ATTENDED WITH MALNUTRITION WHICH IS BECOMING INCREASINGLY COMMON IN RANGOON

By M. L. KUNDU, M.B. (Cal.), F.R.F.P.S. (Glas.),
L.M. (Dub.)

General Hospital, Rangoon

DURING the last two and a half years that I have been posted in Rangoon, a peculiar disease,

(Continued from previous page)

cases in the latter half of October and November, a time when malaria here is usually becoming quiescent. This, it may be surmised, was due to exceptional climatic conditions, but owing to lack of facilities, it is not possible to define these. The meteorological records available are of little value for scientific purposes as temperatures taken with thermometers hung on bungalow walls are subject to many errors.

‡ From 3 and 6 years, as records were available.

In spite of the scheme having been handicapped by the financial stringency, and in some cases by difficulties in supervision due to attenuated staffs, considerable success has been attained, and if further work is now carried on energetically the loss due to malaria should after a few more years be trivial.

My thanks are due to Dr. Strickland of the Calcutta School of Tropical Medicine for his collaboration in the initiation of the scheme and for his continued interest and advice during its development.

apparently of the deficiency group, characterized by a rapidly progressive general anasarca, moderate anaemia, normal or increased urinary output, and malnutrition, has come under my observation more frequently than when I was in this city fourteen years ago. The disease differs from the type of beri-beri which is prevalent in Burma, and also from epidemic dropsy, which occurs almost exclusively amongst the Bengalee residents of the city and which is clinically a different entity from beri-beri, though many authorities presume that it is only another manifestation of this disease. It may be similar to cases of famine dropsy or war oedema, described by Sir John Megaw (1930), as, undoubtedly, on account of the increasing trade depression in this city, there are large numbers of the labouring class people who are unemployed and who have to subsist on a diet verging on starvation. However, the price of rice being very favourable, a sufficient quantity of food can easily be made up for a few pice with white rice and leafy vegetables; it is the quality of the food of all the patients that came under my observation that was at fault; it was ascertained by questioning them that their diets were particularly poor in fat, and articles rich in vitamin B.

The cases suggest chronic glomerulo-tubular nephritis, but it soon becomes apparent that there is hardly any cardiovascular change; the blood pressure is low or normal, and the urine is not scanty, and contains neither albumen nor casts. They have none of the symptoms of either beri-beri or epidemic dropsy, and with rest, a diet of milk, eggs, germinating pulses and red rice or good bread, and with only a little iron and aperients by way of medicine, they improve fairly rapidly, except in cases where the oedema is of long standing and the skin has become hardened with continued waterlogging; in these cases hypodermic injections of strychnine seem to be of great value.

The following cases are typical of the disease; and a brief description of their condition and result of clinical investigation will give a better idea of this ailment:

Case 1.—N., Hindu male, aged 40, gardener by occupation, was admitted in Rangoon General Hospital on 31st January, 1933, for treatment of anaemia and general anasarca of 10 months' duration. He had been mostly out of employment and often had to subsist on charity. Two months ago he was admitted into hospital once and was treated for ancylostomiasis and discharged relieved. He had to return very soon as he quickly deteriorated for want of proper nourishment.

Examination of blood on 2nd February:—Total white blood cells—5,400 per cubic millimetre; total red blood cells—3,930,000 per cubic millimetre; haemoglobin—55 per cent.

Urine—nothing abnormal; stools—no ova, no protozoa, no cellular exudate.

Blood pressure—120/75; Wassermann reaction—negative.

Chloride content of tissue fluids:—On 7th, 8th and 10th February these were respectively 622, 613 and 613 milligrammes NaCl per 100 cubic centimetres.

There was no tenderness of the calf muscles, no loss of knee nor ankle jerks, and no paresis of the legs and hands. Except for slight enlargement of the superficial cardiac area to the right, there was nothing abnormal in the heart. He was put on food rich in vitamin B, and an iron-ionic mixture containing sulphate of iron with arsenic and magnesium sulphate, and a course of ten injections of strychnine (1/60 grain) given daily. Patient showed marked improvement and was discharged cured on 7th March.

Case 2.—M., Hindu male, aged 65, hawker of vegetables by occupation, admitted on 24th January, 1933, for general anasarca. On examination, there was moderate anaemia, but not enough to cause such an amount of anasarca that he had had for the last two months. Food consisted mostly of leafy vegetables, tamarind water and white rice.

General examination :—Gums—pyorrhœa alveolaris present. Heart—superficial cardiac area slightly enlarged to the left and below, and a soft systolic murmur could be heard in all the areas with equal intensity.

Blood pressure—130/70 on admission.

No tenderness of the calf muscles. Knee and ankle jerks present.

Urine—normal.

Stools—nothing abnormal found.

Blood picture.—Total white blood cells—6,600 per cubic millimetre.

Polymorphonuclears 72 per cent.

Lymphocytes 20 " "

Large mononuclears 2 " "

Eosinophiles 6 " "

Red blood cells—3,150,000 per cubic millimetre.

Hæmoglobin 55 per cent.

Wassermann reaction—negative.

Blood urea—26 milligrammes per 100 cubic centimetres.

Urine urea—0.4 per cent.

Chloride content of tissue fluids :—On 7th, 8th and 10th February these were respectively 613, 585 and 613 milligrammes NaCl per 100 cubic centimetres.

Blood pressure after treatment—140/90.

He made no improvement with diuretics, but when he was put on food rich in milk and fats, and given a course of strychnine injection, grain 1/60 daily for ten days, and an iron-ionic mixture, he made rapid improvement and was discharged cured on 11th May.

Dr. Kahali of the physiological department of the Rangoon medical college very kindly estimated the tissue chlorides from the fluid obtained by puncturing the œdematous extremities with a Southey's trocar and cannula; Folin's and Whitehorn's method was employed. The results all fell within the normal range, which is 560 to 620 milligrammes NaCl per 100 cubic centimetres.

The cause of the general anasarca therefore was neither cardiac nor renal inefficiency, nor alteration of tissue fluids, but the diminished vitality of the epithelium of the capillaries, which were unable to carry on the normal osmosis. Rest, food rich in fats and vitamin B, and strychnine and iron quickly make them recover, whereas if they are treated as cases of chronic Bright's disease or ancylostomiasis they do not show any improvement.

DIAGNOSTIC SIGNIFICANCES OF URO-BILINURIA IN CASES OF PYREXIA

By J. R. DOGRA, M.D.

CAPTAIN, I.M.S.

Officiating Deputy Assistant Director of Pathology
Waziristan District, Razmak

Introduction

THE present investigation was carried out at the Indian Military Hospital, Rawalpindi. The remarks apply to men of the Indian Army admitted to this hospital for treatment.

Diagnosis of the fevers in the Punjab present much difficulty, particularly in the Army, where an endeavour is made to label diseases accurately. A sepoy is a fairly intelligent individual, and usually knows all about quinine and its efficacy in mild pyrexia, particularly during the period when the so-called seasonal fever is prevalent. He is protected against the enteric group of fevers by regular prophylactic inoculations and against smallpox by regular vaccination. The result is that a physician in the Army sees cases of varied pyrexia which are atypical. Further, our knowledge with regard to fevers like sandfly fever is hardly adequate. It becomes, therefore, in some cases, very difficult to arrive at a correct diagnosis. Amongst the Indian troops it is difficult to exclude the question of malarial infection, as most of them get infected during the early days of their life in the villages and from time to time when they visit their homes on leave. Malarial infection thus, in these cases, greatly complicates the picture.

Although, the detection of malarial parasites in the peripheral circulation is the final and most definite means of diagnosing this infection, those who deal with cases will admit that it is not always possible to find the parasites in the blood, particularly when it is known that the number of malarial parasites per cubic millimetre of blood in benign and malignant tertian infection when they first produce symptoms may only be 200 and 600, respectively.

Further, a preliminary dose of quinine, which may be insufficient to stop an acute attack of malarial fever, is sufficient to reduce the number of malarial parasites in the peripheral blood circulation, thus making their discovery impossible.

Endeavours are made, therefore, from time to time, to discover some means of diagnosing malaria when the peripheral blood shows absence of parasites.

Jamiat Singh (1930) pointed out the importance of the presence of excess of urobilin in the

(Continued from previous column)

REFERENCE

Rogers, L., and Megaw, J. W. D. (1930). *Tropical Medicine*. J. and A. Churchill, London.

urine in cases of malarial fever,* this excess of urobilin being due to enormous red-cell destruction by the malarial parasite.

Urobilin in urine

Urobilin in the urine occurs normally in small quantity but is not enough to give a positive reaction with the tests employed for its detection. It is only when this substance is present in large quantities that it can be detected in the ordinary way.

Urobilin is a non-threshold substance and is excreted in urine as urobilinogen which, on exposure to air and light, becomes urobilin.

In liver insufficiency, urobilin enters the systemic circulation in large amounts and may be readily demonstrable in the urine.

Similarly, when there is excess of red-blood-cell destruction, as for example, in malaria, hæmolytic anæmias, internal hæmorrhage, or in certain cases of poisoning, again urobilin appears in the urine in large amounts. It has been suggested that, in the tropics and especially in the Punjab, the presence of excessive urobilin in urine in cases of fever, in the vast majority of cases, is indicative of malaria.

This, being a reasonable hypothesis, prompted the present investigation. Endeavour was made to investigate all cases of pyrexia admitted to the Indian Military Hospital, Rawalpindi, from time to time. The cases were not selected in any way. Cases thus studied can be divided into (a) cases of malaria, and (b) non-malarial cases.

Procedure adopted in investigation of cases

All fever cases admitted or detained in the hospital were studied; notes taken of clinical and laboratory findings, particularly in the cases of pyrexia of unknown origin. Special note was made of the exact time and date of onset of the disease to enable one to find out how long it takes before urobilin appears in urine after the onset of fever in the case of malarial fever particularly.

Collection of urine.—Every patient, on admission, was provided with a small glass tumbler on which was pasted a label with the number, name, unit and the ward number of the patient. This was placed by the bed-side and the patient instructed to collect his own urine specimen daily. Those admitted in the morning were ordered to collect all urine passed up to 4 p.m. These specimens were examined the same day at 5 p.m. All the tumblers were then re-distributed to patients

at 8-30 p.m. with instructions to collect all urine passed from 9 p.m. to 6 a.m. the following morning. These were then examined at 10 a.m. daily. Daily examination of urine was done in all cases during their stay in hospital. It will be noted that specimens examined were a whole night's collection.

Tests employed to detect urobilin in urine

Test no. 1. A 3 per cent solution of para-di-methyl-amino-benzaldehyde in 50 per cent hydrochloric acid results in straw-coloured solution. Five drops of this reagent are added to five cubic centimetres of urine: a red colour indicates presence of urobilin in excess. Intensity of colour and the time taken to develop indicate, roughly, the quantity of urobilin present. The following reactions occur:—

(a) *Immediate reaction*, where the urine turns red within five to thirty seconds of adding the para-di-methyl solution.

(b) *Delayed reaction*, where maximum intensity of colour developed 1 to 3 minutes after adding para-di-methyl solution.

A rough method of quantitative estimation of urobilin was adopted by comparing the intensity of colour with three shades of red used as standards. Standard one was labelled '+'; slightly but definitely pink; standard three, was labelled '+++'; intensely red colour; standard two, was labelled '++', intermediate between one and three. This was found to be the most useful and practical method. The quantitative method of estimation by treating urine with an equal quantity of saturated solution of zinc acetate in absolute alcohol, after adding a drop of Lugol's iodine, and then comparing the filtrate with a standard solution of acriflavin (1 milligram of acriflavin in 30,000 cubic centimetres of distilled water, representing one unit) with the help of a Cole's comparator, though more accurate, is very cumbersome and was not found to be practicable.

This test is simple and easily done by the bed-side. It was noticed that a normal urine will show a reddish-brown colour after addition of the reagent when left overnight; to avoid any mistakes the reaction should be read within five minutes of performing the test.

When this test is carried out in a large number of cases, as in the present investigation, the use of drop bottles was very helpful in obtaining uniformity and saving time.

Test no. 2. Add two drops of Lugol's iodine solution to five cubic centimetres of urine and then add five cubic centimetres of saturated solution of zinc acetate in absolute alcohol, filter: the filtrate shows a green fluorescence when urobilin is present in excess. The fluorescence can be intensified by adding a few drops of zinc acetate solution in absolute alcohol. The intensity of green fluorescence again indicates the quantity of urobilin present in the urine. This was also standardized by comparing the three shades of green. The results are noted as +, ++, or +++.

This test is not simple and hence not a suitable bed-side test. It is, however, a simple laboratory test and is, in addition to being a confirmatory test, a reliable one.

In the present investigation both these tests were performed in every case. It was found that in every case both were positive or were both negative, except in a very few cases when the first test gave a positive, +, after some time, i.e., after three minutes, the second test gave a negative result. It is important, therefore, that in cases of doubt both the tests should be performed and more reliance placed on the second test. There was no occasion when the first test was negative and the second one positive from the same specimen of urine.

[* *Note.*—The writer conveys the impression, perhaps unwittingly, that the observation is a comparatively recent one. This is not so; it was made many years ago, and in 1913, Acton and Knowles (*Indian Journ. Med. Res.*, Vol. I, p. 167) investigated the urobilin in the urine in a number of cases of 'latent' malaria.

We take this opportunity to draw the attention of our readers—particularly of those who live in a locality where it is endemic—to the fact that in kala-azar there is nearly always excess of urobilin in the urine; Napier and Sharma (*Indian Med. Gaz.*, Vol. LXVIII, p. 545) found a definite increase in 82 per cent of cases of this disease. The test is therefore of no value in differentiating kala-azar and malaria.—EDITOR, I.M.G.]

Cases investigated

(a) *Malaria cases.*—In this group are included :—

(i) Proved malaria cases, where the malarial parasite was found in the peripheral blood (100 cases).

(ii) Cases diagnosed as 'malarial cachexia', where no parasites were seen in the peripheral blood, but patients were chronic malarial subjects with enormously enlarged spleens (5 cases).

(iii) Clinical malaria cases, where no parasite was discovered in the peripheral blood, yet they were undoubtedly cases of malaria (9 cases).

Of the 100 proved malarial cases, under study, it may be said that they were all mild cases. The different varieties of malarial parasites occurred as under :—

(1) Malignant tertian: 39 per cent.

(2) Benign tertian: 57 per cent.

(3) Mixed infections: 3 per cent (benign and malignant tertian).

(4) Quartan: 1 per cent.

Fever started with a rigor in 94 per cent of cases. Constipation was a very constant symptom, being present in 90 per cent of cases.

Enlargement of the spleen ranged from being palpable on deep inspiration to about three fingers below the costal margin. It was only present in 39 per cent of cases. Enlargement of the spleen occurred in 42 per cent of cases when cases of malarial cachexia and clinical malaria are included.

Although much is said about the enlargement of the liver in malaria, the present series did not exhibit this symptom even in cases of chronic malaria where the spleen was enormously enlarged.

Examination of blood films.—In every case blood films were examined daily during the first and second days of stay in the hospital or till a positive result was obtained. Both thick and thin films were examined in each case.

Results of urine examination

Urobilin in excess occurred in all cases. It did not however occur in a regular manner. It was due to regular daily examination that one detected its presence at some stage of fever. This is to be expected as the appearance of urobilin depends on so many factors. Severity of infection and its duration, liver function and the rather obscure mode of excretion of urobilin by the kidneys will effect the presence of urobilin in urine. Although the number of cases is not large enough to draw conclusions there seems to be sufficient data to draw attention to the following points of interest :—

(1) *During the first 24 hours urine is negative for urobilin or, at best, weakly positive after 12 hours.*—In the present series 33 per cent of cases came to the hospital on the first day of disease; of these 70 per cent gave a negative

result and the other 30 per cent a weak positive, i.e., +. In no case was a positive reaction obtained within 12 hours of the onset of symptoms.

(2) *Positive reaction remains till the temperature comes down.*—The reaction increases each day the fever continues and begins to decrease as the temperature comes down. In one case the reaction became negative a day before the temperature became normal.

(3) *Urobilin lasts up to six days after the temperature becomes normal.*—The disappearance of urobilin from the urine is very irregular; the average period for the 100 cases was 2.33 days.

(4) *Amount of urobilin appears to be in proportion to the severity of infection.*—In the cases of heavy infection, i.e., where a large number of parasites was seen in blood films, marked urobilinuria occurred. This is to be expected, as the greater the number of parasites the more red-cell destruction is likely to occur. There seems to be no relationship between the height of temperature and the amount of urobilin excreted.

Jamiat Singh (*loc. cit.*) states that urobilinuria does not occur in afebrile malaria; I found it otherwise. In order to investigate the high incidence of malaria in a particular unit I examined all men for enlarged spleen; 5 per cent of the total strength had enlarged spleens. None of these men had suffered from an acute attack of malaria during that season, but 66 per cent of them showed urobilinuria. None of them showed any malarial parasites in the peripheral circulation. Both thick and thin films were examined on two occasions. These men were placed on quinine treatment. Fifteen days later their urine were all negative for urobilin, although some of them still had enlarged spleens.

This appears to indicate that malarial infection, even when an acute attack is not produced, causes red-cell destruction resulting in profound anaemia and debility.

(5) *Maximum reaction occurs on the morning following the day on which quinine is administered.*—It is definitely known that quinine *per se* does not cause any hæmolysis of red cells in the blood, but quinine, when given in the presence of hæmolysing agents such as the malarial parasite, increases the marked hæmolysis.

It is unnecessary to dilate on this subject, but I wish to point out that this observation may be utilized in the diagnosis of cases suspected of malaria by giving quinine and examining the urine the following morning for urobilin. Latent malarial infection *plus* quinine will give excess of urobilin in the urine.

(6) *Whole night's urine essential.*—Although a 24-hours' specimen is ideal, a 12-hours' specimen and particularly the whole night's urine is sufficient. Specimens of urine collected after the

first urine in the morning had been voided, in several cases, gave irregular results.

Urobilin curve

The accompanying chart shows details of a case. The dark line indicates the urobilin curve, showing its absence on the first day, maximum rise on the fourth day, and disappearance three days after normal temperature. This may be taken as a typical case.

Non-malarial cases

The practical utility of the foregoing investigation in regard to urobilinuria in malaria is largely dependent on the frequency of occurrence of the same phenomenon in other diseases. It has been pointed out before that urobilinuria occurs in several other conditions (*v. s.*), but in most of these conditions the means of diagnosis are numerous and comparatively easy. Difficulty, however, arises in more common conditions like sandfly fever, the enteric group of fevers (particularly in the atypical ones), tuberculosis, and pyrexia of unknown origin. It is here that the exclusion of malarial infection, a matter of great practical importance, is difficult. Absence of malarial parasites in the blood is not sufficient, but this test, intelligently performed and interpreted, is very valuable.

In the present investigation of the conditions mentioned above, only sandfly fever has been investigated in a sufficiently large number of cases. More work on similar lines is being carried out, and will be communicated at a later date. Suffice it to state that urobilinuria has not occurred in cases of pulmonary tuberculosis, enteric group of fevers and cases of upper respiratory catarrh.

Sandfly fever

Up to date a little more than 100 cases have been investigated. Absence of malarial parasites from the blood and continuous fever of 3, 5 or 7 days' duration seem to be the only diagnostic signs. In the present series 66 per cent of cases started with fever with rigor. Body pains were equally common. Congestion of the conjunctivæ is hardly of any diagnostic significance. The urobilin test, however, is of considerable assistance. In my cases 100 per cent negative results have been obtained, a point of considerable importance.

During the season when these fevers occur together, it was very striking how frequently one saw two patients in the same ward, lying side by side with identical symptoms, one showing urobilinuria and malarial parasites and the other neither of them: the former would get better with quinine therapy, which had no effect on the latter.

I admit that in a mixed case where both conditions are present urobilinuria will occur. It will also occur in the case of a chronic malarial subject who gets, say, sandfly fever. Such a case of sandfly fever, if diagnosed or at least treated for malaria, will be considerably benefited.

Conclusions

1. Excessive urobilin occurs in all cases of acute malaria and in some cases of chronic malaria. In all cases of chronic malaria on the day following that on which quinine is administered.
2. In the Punjab malaria constitutes the commonest cause for positive reactions in cases of pyrexia.
3. The reaction is not specific to or diagnostic of malaria, as it also occurs in many other conditions, both febrile and afebrile.
4. In malaria (a) the tests should be multiple, and (b) they may be expected to become positive on the second or third day of disease, and certainly on the day following the quinine administration.
5. The employment of the test is strongly indicated pending more definite diagnosis of pyrexial cases. The presence of an unexpected positive reaction may suggest malaria: its absence may be equally significant in the contrary direction.
6. The reaction is never positive in uncomplicated sandfly fever.

I wish to thank the Officers Commanding, Indian Military Hospital, Rawalpindi and Bannu, for affording me all facilities for investigation of cases and Lieutenant-Colonel A. C. Hammond-Searle, M.C., R.A.M.C., for advice and help.

A Mirror of Hospital Practice

A CASE OF EMPYEMA NECESSITATIS, CURED BY ASPIRATION ALONE

By MOHAMMED YAQUB KHAN, M.B., B.S., P.C.M.S.
Assistant Surgeon, Civil Hospital, Isakhel (Punjab)

U. N., a Muslim male, aged 50 years, was admitted in the Civil Hospital, Isakhel, on 12th May, 1932, with the following history :

About three months previous to his admission, the patient had an attack of acute illness, with high fever, cough, and pain in the left side of the chest. The acute attack lasted for about two weeks; but he never recovered fully and has had fever and cough with expectoration ever since. He continued to get weaker and complained of breathlessness even on slight exertion.

On physical examination the chest showed the typical signs of effusion in the left side—limited expansion of the chest on the affected side, dull percussion note, very much diminished vocal fremitus and resonance, and nearly inaudible breath sounds. The dullness was well marked up to the level of the fourth thoracic vertebra and a few crepitations were heard on both sides.

There was a red, fluctuating swelling in front of the chest about the seventh and eighth left ribs; it had the appearance of an abscess on the point of bursting. It was diagnosed to be an empyema arising during the course of an attack of pneumonia and the external swelling was the pus from the pleural cavity pointing on the surface (empyema necessitatis). The diagnosis was confirmed by an exploratory puncture.

From the 12th to the 19th of May his temperature ranged from 97°F. in the morning to 100 to 101°F. in the evening.

On the 19th, a spot in the ninth intercostal space in the axillary region was anaesthetized with 1 per cent novocain solution, a trocar and cannula of a Potain's aspirator were inserted and about 20 ounces of pus were drawn out.

The pus was greenish-grey in colour and fairly thick in consistency. Unfortunately there was no equipment to examine the pus bacteriologically.

The patient showed improvement immediately after the aspiration; the fever disappeared the next day; the cough and general condition was also decidedly better. The external swelling, however, showed no sign of becoming smaller.

Another aspiration was done on the 23rd May. This time only about 5 ounces of pus came out; it was brownish-grey in colour and much thinner in consistency, being sero-purulent in character.

After this second aspiration the swelling began to subside so that within about five days it disappeared altogether. The patient had no subjective symptoms, fever, cough or breathlessness; on physical examination, however, the affected side still had a slightly dull percussion note and feebly-heard breath sounds. On 30th May the patient left the hospital without permission.

More than a year afterwards I happened to meet the patient. He told me that he had experienced absolutely no trouble afterwards; and had been perfectly normal ever since. I examined his chest and found it quite normal. I consider that this man was permanently cured of his empyema by aspiration alone.

I am indebted to K. S. Dr. Muniruddin, Civil Surgeon, Mianwali, for his permission to publish these notes.

[*Note.*—Empyema necessitatis is defined as an empyema in which the pus burrows externally, producing a subcutaneous abscess which finally ruptures and results in spontaneous cure without operation. This case does not therefore quite fulfil the requirements of this definition.—Ed., I.M.G.]

A TREATMENT OF ACUTE INTESTINAL OBSTRUCTION

By SARDUL SINGH, M.B., B.S.
State Hospital, Gilgit

ACUTE intestinal obstruction occurs so suddenly and the patient is so ill that transportation to a large hospital is frequently impossible.

Under these circumstances any measures that can help the patient are deserving of consideration and trial.

The following method is perhaps not extensively known :—

According to St. Leger Brockman, as quoted by Maingot in his *Management of Abdominal Operations*, the toxæmia following intestinal obstruction or ileus is due to the absence of bile and pancreatic secretion from the intestines. This condition arises owing to the frequent vomiting that occurs in these cases.

The treatment recommended is rectal injection of human bile two or four ounces in normal saline repeated four hourly until all signs of toxæmia have improved.

Human bile is, practically speaking, not available and the patient's own vomited matter may be collected, strained through muslin, diluted with a little saline and injected into the rectum, or alternatively ox bile may be used.

Recently, a case of acute intestinal obstruction has been under treatment here and, as operation was considered unwise, this method of treatment was used with extremely satisfactory results.

I append a few notes.

In this station, as this is an orthodox Hindu state, ox bile is not available and sheep bile was used instead in addition to the patient's own vomitus.

S. A., aged 25, admitted late on 13th February, 1934, with a history of complete stoppage of bowels of twenty-four hours' duration. The abdomen was much distended, tender and attacks of acute colicky pain were frequent; distended coils of intestine were visible.

Enemata, repeated, produced no improvement.

14th February.—Vomiting started in the morning and also severe hiccough. During the day turpentine stupes, hot water bottles, atropine with strychnine, eserine and pituitrin were all tried but no improvement occurred.

At 9-15 p.m. the general condition of the patient became very bad, and marked toxæmia supervened. Hiccough became very troublesome and vomiting was very frequent. The patient complained of great thirst. The abdomen became much distended and the patient was sweating profusely; pulse 112 per minute. At this time three ounces of vomit strained through layers of muslin diluted with two ounces of tap water was injected slowly into the rectum.

At 10-45 p.m. the pulse had improved, the hiccough ceased and the patient began to sleep.

By 11-10 p.m. the vomiting had ceased and the patient slept soundly.

15th February.—At 6-30 a.m. the general condition of the patient was fairly good, abdomen still much distended although some flatus passed during the night; pulse 104 per minute, satisfactory.

Two ounces of vomit strained through layers of muslin diluted with one ounce of tap water was again injected slowly into the rectum.

9-30 a.m. The appearance of the patient seemed improved but there was still no relief of the obstruction. No vomiting, no hiccough.

6-50 p.m. A few small pieces of faecal matter were passed after an enema.

16th February.—The patient slept a little during the night and was definitely worse next morning. Very delirious and toxæmic; the obstruction was unrelieved.

10-45 a.m. Three drachms of fresh sheep bile diluted with three ounces of normal saline were injected per rectum, and 1 c.cm. adrenaline injected hypodermically.

11-5 a.m. The patient passed a large liquid stool, and the symptoms were much relieved.

Two further stools were passed during the afternoon.

The patient was finally discharged from the hospital in a good condition on the 22nd February, 1934.

During the acute stages of illness nothing was given by mouth. Saline and glucose injections—twenty ounces of saline with five per cent glucose—were given intravenously as required.

The above treatment cannot of course cure a case of true mechanical obstruction but even in these cases it should be of great value in improving temporarily the condition of the patient to allow of his transportation to a hospital and to put him in a better state to stand the anæsthetic and shock of an operation.

I am grateful to Major L. K. Ledger, I.M.S., Agency Surgeon in Gilgit, for permission to publish the notes of this case.

A CASE OF PSEUDOCYESIS FOLLOWED BY TRUE PREGNANCY

By A. P. JANA, M.B.
Contai, Midnapore District

THE patient, aged about eighteen years, in her second pregnancy, was in normal health and of average build. She gave birth to a female child in her first pregnancy in an easy labour.

Menstruation had always been regular previously. There was no suspicion about venereal diseases. Her last menstruation was in June 1932, and the members of the family naturally thought her to be pregnant at the time on the strength of the amenorrhœa. There was gradual enlargement of the abdomen consistent with the time of pregnancy. Fœtal movements were said to have been felt by the mother and female members of the family. Though the first child had stopped sucking, the breasts became enlarged and secreted milk in due course. The primary and secondary areolæ all appeared in succession in due time. Pain of an intermittent nature, in the lower abdomen, was also felt after the seventh month. On the 280th day approximately (in March 1933) the pain, of the nature of labour pain with all its signs and symptoms, started. Intense, short-lasting, intermittent pains continued for the whole day and night. There was no bleeding more than the 'blood show'. A drop of homœopathic medicine (belladonna 30) was given and the pain stopped. On the third day from the onset of the supposed labour pain, the bleeding started without any pain. Bleeding became intense and alarming on the fourth day necessitating treatment. Juice of 'durba' (a kind of grass) and sugar one tola per dose was given three times when the bleeding stopped, but the size and contour of the abdomen remained as it was.

From May 1933 onwards she had excruciating pains every eighth or tenth day lasting for three or four hours. The pain would subside on the application of hot fomentation. In the meantime an ecobolic mixture containing ergot and quinine was administered for five days without effecting any improvement. Potassium iodide mixture was given for three or four days. Hot hip baths and foot baths were given but failed to stop the recurrence of the pain. The size of the abdomen remained stationary. A diagnosis was made, and corroborated by others, of a tumour, probably ovarian cyst, requiring surgical treatment.

From May onwards the patient had been feeling fœtal movement as before and, believing her to be pregnant after the last bleeding on March 1933, the relatives postponed her removal to Calcutta for operation until the time of delivery, i.e., December 1933. Some time in May, I was called in to the case but I could not feel any fœtal parts. The abdomen was enlarged to about the size of an eight-months pregnancy and was almost stony hard. No vaginal examination was allowed. I also thought this to be a case of ovarian cyst and advised operation. Again, at the seventh month her abdomen was said to have been palpated by a doctor member of the family but he could neither feel any fœtal part nor hear fœtal heart sounds. In the meantime many abortifacient drugs were used orally and externally on the abdomen by the local Vaidyas. The external applications were mostly blisters. These drugs were used probably with the idea of evacuating the contents of the uterus or abdomen where the tumour was supposed to have been formed. However, in spite of all these attempts at abortion a full-grown female child was born in the first week of December 1933 after a labour pain lasting only a short time. The labour and puerperium were normal in all respects.

I again examined her in her puerperium and found the abdomen normal in all respects.

Discussion.—The points that arise in this case for elucidation are :—

1. Was she pregnant for nineteen months ?
2. The normal size of the child at birth goes against it, but if not, how can the following signs be defined ?
 - (i) Feeling of fœtal movement,
 - (ii) the appearance of primary and secondary areolæ in due time,
 - (iii) secretion in the breasts in due time,
 - (iv) enlargement of the abdomen consistent with the term of pregnancy, and
 - (v) the onset of labour pain about the normal time of delivery.

3. It may be that the first period was a pseudocycsis and she was pregnant for the second period commencing after the bleeding in March 1933. If so, does a case of pseudocycsis present all the signs and symptoms typical of a true pregnancy ? It should be noted that she was not examined at any time under anæsthesia. Possibly the gradually growing fœtus within the uterus found space in the already enlarged pseudocycetic abdomen. The size of the abdomen remained stationary for the whole of the period of pregnancy from March to December 1933.

4. It is peculiar indeed that the pregnant uterus did not abort in spite of so much rash and indiscriminate use of drastic abortifacient medicines. Different authors have cited such

cases that baffle all attempts to procure abortion.

5. The supposed labour pain which she experienced in March 1933 was probably dysmenorrhœal, because the pain of the first day was accompanied by only a little blood (said to be like 'blood show'). This pain subsided with a free flow of blood on the third day. The bleeding remained for about five days, the normal period of menstrual blood flow.

I must thank Dr. Ashutosh Panda of Bathuari, in whose family the case occurred, for kindly allowing me to note the history of the case and to examine her again in her puerperium.

A CASE OF CARDIAC FAILURE WITH COMPLETE HEART BLOCK

By G. L. SHARMA, M.D., B.S.

Senior House Physician, King George's Hospital, Lucknow

P., AGED 26 YEARS, cultivator, was admitted to the medical wards with the following complaints:—

Breathlessness on exertion—three months.
Cough with a little expectoration—fifteen days.
Discomfort in abdomen.
General weakness.

About three months ago the patient noticed gradual bulging of the abdomen and puffiness over the face and feet. During this time he used to feel exhausted and very tired after doing a little work in the fields. One month ago he suddenly became unconscious while chatting with a friend. He was told about this incident by those who were near him because he himself never realized his attack owing to its very short duration (a few seconds). Shortly before admission into the hospital the patient had noticed blood-stained sputum for a few days.

The patient is a young man of good physique; he is slightly anæmic; his abdomen is swollen, and his face puffy; œdema is present over the ankles and dorsum of feet; his lips are cyanosed.

Cardiovascular system.—

Pulse rate—34 per minute, rhythm—regular, tension and volume—normally good.

Inspection—no præcordial bulging or recession; cardiac impulse outside the mid-clavicular line; pulsation visible in the neck, jugular veins prominent and enlarged.

Palpation—apex beat in the fifth interspace one inch outside the mid-clavicular line; no thrill present in the præcordium; apex beat is slapping in character.

Percussion—Upper boundary of the heart under the third rib; left boundary one inch outside the mid-clavicular line; right border one and a half inches from the mid-sternal line.

Auscultation—Rhythm regular, rate same as pulse; both the first and the second cardiac sounds are feeble and distant suggesting bad quality all over the præcordium; systolic bruit, soft in character, best heard over the mitral area and propagated out to the anterior axillary line.

Blood pressure—102 mm. systolic, 35 mm. diastolic.

Respiratory system.—Moist râles, most marked at the pulmonary bases.

Alimentary system.—No pyorrhœa alveolaris present; liver enlarged three fingers below the right costal margin; the upper boundary is in the fifth interspace; spleen enlarged four fingers below the left costal margin.

Urine examination.—Specific gravity—1012; albumin, sugar, acetone, and bile salts—absent.

Blood examination.—Leucocytes—3,600 per e.mm., polymorphonuclears—54 per cent, lymphocytes—41 per cent, eosinophils—5 per cent.

Urea stibamine test (1 in 10)—faintly positive.

Formaldehyde test—negative. Wassermann reaction (after provocative neosalvarsan) completely negative.

Cerebrospinal fluid examination.—Wassermann reaction—negative, completely; Pandy's test—negative, albumin—0.02 per cent.

Electrocardiography.—The electrocardiogram showed complete dissociation between the auricular complex P wave and the ventricular Q.R.S.

Commentary

Most of the cases of heart block fall within four groups from the ætiological point of view:—(a) the rheumatic, (b) the syphilitic, (c) the acute infectious diseases, (d) and the arteriosclerotic group.

(a) Patients, usually young adults who have previously suffered from rheumatic infection of the heart, may show signs of heart block besides other manifestations of damage to the heart. This may be due to a greater degree of damage to the myocardium and the conduction system, because heart block is so intimately connected with myocarditis and myocardial scars, or the Aschoff bodies may be situated in the pathway of the bundle. In such cases heart block may be induced by full doses of digitalis or drugs of this group. I believe that the case in question had rheumatic infection some time before and developed signs of myocardial failure with enlargement in the size of the heart, congestion at the pulmonary bases, enlargement of liver, engorgement of systemic venous system, œdema on the dorsum of the feet and symptoms of effort syndrome dyspnoea, palpitation, fatigue and præcordial pain on exertion.

One month ago, manifested by a minor Stokes-Adams' attack, he developed complete heart block. There are few signs of valvulitis (mitral) in this case.

(b) The second cause, and probably the most important, is syphilis, the lesions being represented by inflammatory collections of characteristic cells or by the subsequent syphilitic scars. In rare cases a gumma may be found in the upper part of the interventricular septum. An infarct of the myocardium in the region of the bundle due to coronary thrombosis will produce the same result or the scarring may be due to gradual obliteration of the branches of the vessels that supply the bundle. In a young man suffering from gonorrhœa, who suddenly developed a very slow pulse rate, a mass of Neisser's diplococci plugging the artery to the septum were demonstrated. In our case syphilis does not play any part.

(c) Acute infectious diseases like influenza, typhoid, pneumonia and diphtheria may produce a lesion in the conduction system giving rise to heart block and the occurrence of partial heart block during the course of an acute infective disease is a sign and may be the only sign of myocardial involvement. The condition is

usually temporary in these cases. There is no history of any acute infective disease in this case and the duration of cardiac failure present is out of proportion to the damage likely to be done during the course of an acute infection, in which the failure is likely to be acute, and may suddenly terminate fatally.

(d) Arteriosclerosis when affecting the branches of the coronary artery may bring about the condition of heart block. The young age, low blood pressure, and absence of any thickening of arteries negative the possibility of this condition existing in the present case.

Treatment

(1) Absolute rest in bed.
(2) Insulin 10 units twice daily subcutaneously after meals followed by administration of 2 *chittaks* of sugar for one month.

(3) Atropin sulphate 1/100 grain—twice daily—was tried but no alteration in the pulse rate took place.

(4) Tincture digitalis 10 minims with 15 grains of potassium iodide—three times daily—was tried for a fortnight without any effect.

The patient left the ward with a slow constant pulse rate of 36 per minute. The symptoms of effort syndrome dyspnoea, palpitation, fatigue and precordial distress had disappeared.

I am very much indebted to Colonel G. T. Burke, M.D., F.R.C.P., I.M.S., Physician to King George's Hospital and Professor of Medicine, University of Lucknow, for permission to publish this case.

ACUTE PSOAS ABSCESS

By V. SRINIVASAN, M.B., F.R.C.S.

CAPTAIN, I.M.S.

(Surgical Specialist, Calcutta)

A COLLECTION of pus in and around the psoas major muscle is generally chronic in nature and secondary to tuberculous disease of the spine. However, sometimes it is of an acute type. Such a case is seldom diagnosed correctly, not because the condition is rare or obscure but because the frequency of its occurrence is not appreciated. Recently Sworn (1933) has described three cases and quoted more from the literature. Baer, Bennett and Nicholas (1923) discuss forty-two cases of psoas abscess due to causes other than tuberculous disease. The following case, recently under my care, illustrates the usual features of this condition:

K., a boy aged 9 years, was referred to me as a case of tuberculous lymphadenitis of the groin. The history was that on 26th January, 1934, he got up at night to pass water and during micturition felt severe pain in the left loin, shooting down the left thigh and to the root of the penis. The pain persisted for a few hours after which it became easier. The same day he developed a fever of 101° which remained continuous for three or four days and then became suppurative in type. Along with this, the boy could not straighten his left leg. When first seen by me on 16th February, the boy was acutely ill, wasted, had a coated and dirty tongue, and a temperature of 102° F. The left thigh was kept flexed to a right angle and attempts to straighten it passively were strongly resisted and very painful.

The abdomen was rigid, the rigidity being more marked on the left side. Careful palpation showed a sausage-shaped swelling in the left iliac fossa, with its long axis parallel to the inguinal ligament. The swelling was hot, tender and bony with a suggestion of softness in the centre. Careful examination failed to reveal evidence of spinal disease. The movements of the hip joint except extension were quite painless and free. Total leucocyte count was 18,000 per cubic millimetre. X-ray showed no bony lesion of the spine, ilium or hip joint. No other septic foci were discoverable. The urine showed no abnormality.

On 17th February, the swelling in the iliac fossa was explored with a needle and syringe and a few drops of thick pus and blood withdrawn which showed staphylococci and pus cells. On 18th February, the abscess was opened through an incision above and parallel to the inguinal ligament. It was extraperitoneal and was tracking down from near the lower pole of the left kidney. Counter drainage was established through a tube in the loin and the wound closed.

Subsequent progress was uneventful and full extension of the hip joint was regained in a month's time.

Discussion

Ætiology.—Acute psoas abscess may be primary or secondary. The secondary form may be due to a perinephritic abscess which tracks downwards along the psoas (this is favoured by the arrangement of Zuckerkandl's fascia) or an empyema which has burst below the 12th rib. It may follow acute osteomyelitis of the ilium or lumbar vertebra. It may be secondary to an appendix abscess which has burst extraperitoneally. Sometimes it follows suppuration of the retroperitoneal lymph glands particularly those along the common and external iliac arteries. The primary form is usually pyæmic in origin. In favour of this view are: the patient is often very ill previously; the onset of the abscess is quite abrupt; there may be other abscesses; the symptoms often subside quite rapidly and the absence of lesions to which the abscess is secondary; further the abscess is confined to the sheath of the psoas.

Diagnosis is quite easy if the possibility of this condition is remembered. The patient has a septic type of fever and complains of pain down the leg on the affected side or referred to the root of the scrotum. The characteristic sign is flexion of the hip which is quite marked and is more than can be accounted for by mere spasm of the psoas. The presence of a sausage-shaped swelling is pathognomonic. There is leucocytosis. Careful examination aided by radiography will eliminate bone disease.

Treatment.—Aspiration should be done first and if the examination of the pus suggests pyococcal origin, drainage should be established. The incision should be over the most prominent part of the swelling; but if there is no local swelling, an incision parallel to and two inches above the outer third of the inguinal ligament is the best. Great care should be exercised not to open the peritoneum. Counter opening posteriorly may be necessary. All loculi should be gently broken down. If the contraction of the psoas does not begin to disappear in a few days.

after operation, weight extension will be necessary. Prognosis is usually very good.

SURGERY OF THE SYMPATHETIC

By V. L. SURYAVANSHI, M.S.

Sassoon Hospital, Poona

THERE are few diseases requiring operations on the sympathetic nervous system and, even in the presence of indications, very few operations are being performed in this country, partly owing to the fact that some of these are rather difficult, and partly to the uncertainty of the results. The following notes will, it is hoped, interest readers :

T. R., a Hindu female, about thirty-five years of age, was admitted into the Sassoon hospital, Poona, on the 29th March, 1932, for an ulcer on the right foot (under the care of another surgeon). She used to smoke much and lived on a mixed diet. Since the age of eleven she had felt alternate coldness and burning in her hands and feet. This was also accompanied by pain. The right foot later on showed signs of gangrene and was amputated at the site of election on the 1st November. The pain and other symptoms were becoming worse day by day and she had to be given morphia. She was kept in the infirmary as an invalid.

I was asked to see her in September 1933: I found her to be extremely emaciated and unable to leave her bed. She had gangrene of the left foot and had already lost four toes; there were deep ulcerations on the dorsum of the foot and black patches of necrosis on the leg up to the knee. The ulcers were very painful and she could not tolerate the weight of a blanket on the foot. The pulse in the dorsalis pedis artery could be felt only at intervals. The radial pulse on the right side could not be felt. The hands were cold. I diagnosed the condition as Raynaud's disease and decided to perform the operation of lumbar sympathectomy on both sides. She consented to this and was accordingly operated on; recovery was uneventful. The ulcers were dressed with zinc and boric ointment containing some perein and the legs covered with plenty of wool and flannel bandages. In about two months time I was surprised to find that all the ulcers had completely healed, the necrosed skin had fallen off and was replaced by new skin and her symptoms in the legs were ameliorated. Her general condition improved considerably by not being troubled with pain and sleepless nights. Encouraged by the result, I proposed to her that she underwent 'cervical sympathectomy' on the right side as the symptoms in the arm on that side were worse. The patient, satisfied with the improvement, readily consented to the operation. Under local anaesthesia, I exposed the cervical sympathetic chain by the anterior route and removed the inferior cervical ganglion and its communication with the first thoracic. I was extremely astonished to note that the pulse in the right radius became perceptible and got this fact confirmed by my colleagues. The symptoms in that arm abated. Although at first unable to bear the weight of clothes on her foot she is now able to move about on crutches resting the left leg on the ground.

If this case had been treated as above in the beginning, I think she would have obtained greater relief.

The surgeon who had amputated her right leg thought it to be a case of thrombo-angiitis obliterans, on this point however I do not agree with him.

A CASE OF HYDATID CYST OF THE LUNG*

By TULSI DASS, M.B., B.S.

and

PIRTHI CHAND, L.M.P.

Civil Hospital, Giddarbaha, Ferozepore District, Punjab

On the 26th April of this year a Hindu boy, fourteen years of age, was brought by his parents for consultation to the civil hospital, Giddarbaha, district Ferozepore, from Bhuchan, a market in the same district. His general ill health was attributed chiefly to short bouts of coughing, a feeling of heaviness in the left chest and a long irregular fever for the previous six months. The boy was examined in routine and it was found that the left side of the chest had restricted movements, gave a dull, solid note on percussion, was airless with complete loss of vesicular murmur and vocal resonance but without any obliteration or bulging of the interspaces, right up to the middle of the scapula behind.

A provisional diagnosis of effusion in the chest was made, and the relatives were informed about the boy's condition and advised to have the chest aspirated before any other line of treatment was adopted. Having obtained their consent we made preparations to aspirate in the ninth interspace at the scapular line. We succeeded with a good deal of difficulty in inserting the trocar and, contrary to expectation, the fluid that came away was unusually clear. The fluid actually began to trickle through the cannula before the trocar was removed.

As soon as the fluid began to collect in the bottle, the boy started coughing, developed dyspnoea and expectorated a clear, viscid, frothy mucus. When about four ounces of fluid had collected in the bottle, the flow suddenly stopped in spite of our efforts to move the cannula in various directions. The cough increased, became incessant and the boy seemed to be in a condition of anaphylactic shock.

It suddenly struck us at this point that it was a case of hydatid cyst of the lung and the question of an immediate radical operation had to be considered. The guardians, on being informed of his grave condition, would not however consent to an operation in spite of our advice.

The child, therefore, was made comfortable in the bed, as nothing could be done except to watch and wait.

The fluid collected was subjected to laboratory tests, both chemical and microscopical. It was of very low specific gravity, non-albuminous and contained traces of sugar. A film from the deposit was prepared and examined under the high power of the microscope. Numerous hooklets were observed which confirmed the case to be one of hydatid cyst of the lung.

The child although in bed was now in agony because of severe cough, dyspnoea, laboured breathing and continually increasing surgical emphysema which had reached from the thorax to the neck and cheeks in about three hours.

The relatives were again made to realize the great necessity for immediate operation to save the child and fortunately gave their consent.

The child was once again put on the table for operation. General anaesthesia was out of the question as the respiratory system was already sufficiently embarrassed. Spinal anaesthesia could not be resorted

* Rearranged by Editor.

to for fear of paralysing the vital centres in the medulla. We decided finally to employ a local anæsthetic.

The skin was completely anæsthetized for a radius of two inches around the original puncture with ethyl chloride and an incision made down to a ninth rib along its axis with all the necessary antiseptic precautions. The periosteum over the rib was denuded to a distance of about one and half inches and a piece of bone one inch long was cut and removed. The pleura was further incised and about eight ounces of fluid gushed out.

When the pleural cavity was almost completely drained and the lung tissue well in view, a second puncture with a long needle and a two-cubic-centimetre syringe was made. A syringe full of fluid was withdrawn from a prominent part of the lung.

This confirmed the origin of the cyst and at the same time encouraged us to make a free incision. The parietal layer of the pleura was stitched to the chest wall all round the wound margin to shut off the cavity and prevent systemic infection. The lung was incised at the place of second puncture, some fluid drawn out and a big cyst about the size of a child's head along with its contents was removed. The cavity was washed out with normal saline, a tube stitched in and the wound closed.

The whole operation took about forty minutes but during all this period local anæsthesia was kept up with generous sprays of ethyl chloride. The child faced the operation very bravely, although he was in great trouble on account of a constant irritating cough throughout. The coughing was beneficial however in expelling the cyst with its brood capsules, etc., from the cavity. The child is still in the hospital and progressing.

Conclusion.—Hydatid disease of the lung though rare still demands special consideration in the diagnosis of respiratory troubles especially in cases with effusion.

2. The disease is an insidious one and often not attended with any great symptoms. The clinician therefore is misled and can easily be thrown off his guard.

3. Before having recourse to tapping it is advisable to make an exploratory puncture, examine the sputum and blood of every patient in the hope of finding something extraordinary (hooklets and eosinophilia, etc.).

4. If a cyst is accidentally tapped, immediate operation is the only expedient.

5. Local anæsthesia if properly administered often obviates the risk of shock and other untoward symptoms.

A CASE OF RESUSCITATION BY PUNCTURE OF THE VENTRICLE

By M. GANGULI, M.B.

Anæsthetist, Medical College Hospitals, Calcutta

P. D., a Hindu male nineteen years of age, was being operated on on the 17th March, 1934, for a right-sided varicocele under pure ether, the induction having been made with chloroform. The operation was started while the patient was completely under surgical anæsthesia and had been given pure ether for about eight to ten minutes. Atropine sulphate, 1/100 grain, was given subcutaneously about half an hour before the induction of anæsthesia which was very smooth without any struggling or shouting.

About three minutes after the operation was started, while the cord was being separated, the patient stopped breathing after taking three or four unusually long deep breaths and the pulse was found to be absent.

The following steps were taken in quick succession. The face was rubbed hard with a towel, the Trendelenburg position was adopted with the legs at right angles to the trunk and the cardiac region was smacked twice with a hot wet towel. The mouth was held open with a gag, the throat sponged and the tongue pulled out and relaxed alternately three times. Simultaneously with the pulling out of the tongue artificial respiration was started and continued without any effect. The heart was auscultated directly without any sounds being audible. The rectal sphincter was dilated and it was found to be so lax as to allow four fingers to go in with ease. As there was no response, the needle of a serum syringe which was at hand was introduced through the fourth left interspace three-fourths of an inch internal to the nipple line and immediately withdrawn. The heart was again auscultated but there was no positive sign. The needle was again introduced a little deeper through the same puncture. A distinct resistance was felt this time as if piercing some muscular structure after passing through the parietes. The needle was held between the index finger and the thumb for about two seconds when suddenly a distinct movement was communicated to it and simultaneously a medical graduate who was feeling the right radial artery said 'yes'. On feeling the pulse the first few beats were found to be feeble, irregular, unequal in volume and tension, and rather slow.

The time that had elapsed between the last expiration with the disappearance of the pulse and the puncture must have been about three minutes.

As the respiration had not returned, artificial respiration had to be continued for about another minute before the first feeble effort at inspiration was noticed. The patient was watched for another six to seven minutes during which time oxygen was given. As it was found that the patient was behaving satisfactorily the anæsthetic—ether—was administered again and the operation completed without any further trouble.

During the period that the patient was in cardio-respiratory paralysis the pupils did not react to light and were not very widely dilated. They were in that degree of dilatation which obtains in deep but safe narcosis with ether. The pupils were fixed in that position the whole time and only started contracting after the pulse and respiration had returned. The patient was so dark that very little could be made out from the colour of the lips or nails.

The patient recovered from the effects of the anæsthetic without any convulsions or prolonged period of unconsciousness. The convalescence was uneventful and he left our care on the fifteenth day from the date of the operation, without any symptoms of changes in the cerebral cortex due to lack of circulation for the few minutes during which the patient was in cardio-respiratory paralysis.

The patient's heart and lungs were normal and he had been operated upon for lymphangiectasis of the left side under chloroform-ether anæsthesia a couple of months ago.

The points of interest are discussed below :—

Primary cardiac failure may occur during the administration of pure ether in a chloroform-ether sequence.

Atropine in grain 1/100 dose does not always prevent vagal inhibition though it may be mentioned that in the present case it is not possible to be certain whether the failure was due to ventricular fibrillation or vagal inhibition. The protective action of atropine before chloroform administration nevertheless seems doubtful.

There was no doubt that the myocardium had ceased contracting as was found with the puncture of the needle, which gave a distinct movement when the heart resumed its contractions.

It must have been the stimulus of the puncture that started the contractions of the heart again.

Though recent researches tend to show that the auricles are more sensitive to puncture than the ventricles, in this case it must have been the ventricle as a longer needle was not at hand at the moment, and the desired result was obtained.

In this country instances of resuscitation by simple puncture of the ventricle has, to my knowledge, not been recorded.

My thanks are due to Professor L. M. Banerjee, M.S., F.R.C.S., surgeon to the medical college hospitals, for allowing me to publish this case and for his kind help in writing this paper.

A CASE OF EXTRAVASATION OF URINE DUE TO A CALCULUS IN A CHILD SIX YEARS OF AGE

By B. SUKHAVANAM, L.M.P.

Honorary Clinical Assistant, Municipal Hospital, Nandyal

N., a male child 6 years of age, was admitted into the Municipal Hospital, Nandyal, on the 23rd April, 1934, at 11 p.m. with retention and extravasation of urine of forty hours' duration.

Condition on admission

Patient toxæmic, quick pulse, dry tongue, abdomen distended and tympanitic and absolute constipation for two days.

Bladder distended up to umbilicus.

Scrotum, penis and perineum swollen and phimosis was also present. No vesical calculus was felt per rectum on three consecutive examinations.

Treatment

A soap-water enema was given without effect.

A dorsal slit was made and the meatus was exposed. A rubber catheter proving ineffective, a small-sized metal catheter was passed very slowly and carefully and an ordinary kidney tray full of urine was drawn off very slowly. Multiple incisions on the scrotum, penis and perineum were then made, and the catheter tied up.

Turpentine stupes to the abdomen were applied. A turpentine enema was given and this time hard scabulous masses were evacuated.

Glucose and water in sips were frequently given by the mouth to tide over the toxic condition.

Progress

Patient was progressing fairly well except for an occasional rise of temperature to 101°F. on three different occasions. Three days later a lump was felt in the right lumbar region and the boy complained of pain there. Turpentine stupes to the abdomen were given and the urine was drawn off every six hours by a rubber catheter after which the swelling and pain subsided.

Twenty-three days later the patient began to leak urine through the peno-scrotal junction. An incision was made in the middle line near the fistulous track and a small urethral calculus $\frac{3}{4}$ inch by $\frac{1}{4}$ inch with one end bigger than the other was removed. After this the patient made an uneventful recovery.

No stone was felt in the bladder per rectum at first probably on account of the smallness of the stone and of its being impacted in the urethra which caused retention and extravasation of urine.

After the drawing of urine the stone might have been dislodged in the subcutaneous tissues and hence it escaped notice. The lump referred to above suggests back pressure on the kidney. Can there have been a calculus in the ureter?

The small size of the stone extracted suggests this to be a ureteral one.

Lastly I wish to thank the assistant surgeon, Dr. S. Ramadas, L.R.C.P., M.R.C.S., for kindly permitting me to use the case notes and valuable suggestions.

Note.—It can scarcely be said that a stone $\frac{1}{4}$ by $\frac{1}{4}$ inch is a small one. It would appear unlikely that a stone of this size could pass down the small ureter of a child. The lump referred to above might have been due to general back pressure from the bladder or possibly to the presence of some other small stone in the ureter. From the fact that the swelling subsided after some urine had been drawn off, the first possibility appears to be the more likely.—Editor, I.M.G.

RUPTURE OF THE HEART

(WITH SLIGHT EXTERNAL MARKS OF VIOLENCE)

By S. R. INGLE

Medical Officer, Mirajgaon (District Ahmednagar)

THE rarity of such an injury and its medico-legal importance have prompted the publication of the following case:—

History of the accident.—A driver of a motor-lorry with about a dozen passengers, while driving over a causeway about eight feet high, lost control of the car, with the result that it fell into the water (knee-deep) below, on its side. One of the passengers aged about twenty-five years died instantaneously while others escaped with minor injuries. The car was practically undamaged.

An autopsy held by me on the deceased to ascertain the cause of the death revealed the following appearances:—

(1) Two ante-mortem contusions, 2 inches by 1 inch and 3 inches by 1 inch each, over the outer side of the right arm.

(2) Contusion over the front of the chest $3\frac{1}{2}$ inches by 3 inches.

(3) All the internal organs were pale in appearance, but healthy.

(4) Oozing of blood from the nostrils and mouth.

(5) Left pleural cavity contained about one pound of watery blood-stained fluid. There were a few ecchymosed patches from half an inch to three-fourths of an inch in diameter over the anterior surface of the left lung.

(6) The posterior aspect of the pericardium was deeply injected; but there was no tear. On opening the pericardium about ten ounces of fluid and clotted blood were found inside. There were two tears admitting the tip of the index finger over the posterior aspect of the right chamber with a few adherent blood clots. No fracture of ribs or vertebræ was detected.

Comments.—Rupture of the heart may occur independently of external marks of violence, or from a slight external violence if it is diseased. Again, external violence may cause rupture of an even healthy heart either with slight marks of external violence or without external marks of injury being visible. The case reported above falls under the former category. Few such cases have been reported; but no explanation has been offered as to the mechanism by which this accident is brought about.

Indian Medical Gazette

AUGUST

MEDICAL RESEARCH

THE popular conception of the medical research worker is a man who spends his life, either looking at small objects through a microscope, or with an intent expression on his face holding up a test-tube to the light, or gazing fixedly at some bubbling fluid in a flask; and above all he makes great discoveries at least once a week. The better educated amongst the laity will, of course, repudiate any suggestion that they share this conception, but, though they may envisage wider fields of activity, they still look upon his life as one continuous romantic exploration of untrodden paths. Even the average medical man usually has a very vague idea of what really constitutes medical research; he has an underlying feeling that it must be done in a laboratory, chemical or bacteriological, or, if he is more advanced in his ideas, he will probably concede pharmacological or biochemical; further, he seems to think that anything done in such laboratories, *ipso facto*, constitutes medical research work.

That this conception of medical research prevails in India is quite obvious from the large number of private 'clinical research' laboratories that have been established in every large town in the country; in these are carried out individual routine examinations of blood, urine, and faeces, which are all very necessary work and useful to the practitioner and his patient, but they remain as individual examinations, they are not correlated with other similar examinations, nor even with the clinical condition of the patient whom the laboratory worker has probably never seen; useful and necessary as such work is to the individual, it adds nothing tangible to the sum of our knowledge of the cause, nature, or treatment of any disease, and is therefore no more research work than is the general practitioner's daily visiting round.

We can go higher in the scale and still find the existence of misconception regarding the nature of medical research work. Recently, a member of a body that deals with the allocation of funds for medical research in India expressed the opinion that, during the present financial stringency, basic research should be given up and only 'urgent medical problems' should be tackled; such a suggestion could only be born of complete lack of experience. Anyone who has attempted to solve any medical problem in this country knows that his greatest difficulties are due to the paucity of basic knowledge, whether this be connected with the identification of insects, or with normal standards for

biochemical examinations. More work has been done on the mosquito in this country than in almost any other in the world, and yet, as every malariologist soon finds out, there are still huge lacunae in our basic knowledge of the bionomics of this insect waiting to be filled. Again, when a biochemical investigation is undertaken it immediately becomes obvious that European and American standards are inapplicable in India and that if the danger of arriving at erroneous conclusions is to be obviated, it is necessary before tackling the 'urgent medical problem' to spend many months investigating the normal standards of the population.

'That is all very well', will probably be the reply, 'but what about the great research workers of the past? Did Jenner, Pasteur, Koch, Manson, and Ross require all this background—this basic knowledge?'

The answer to this criticism was made by one of these pioneers over fifty years ago. Robert Koch, referring to his own discovery of the tubercle bacillus, said that the gold was at that time near the surface but that future generations would have to dig deeply for it. The fact that the gold was near the surface does not in any way detract from the value of the discoveries of these pioneers, for to them lies the credit of looking where others had not thought to look, for recognizing what they saw as gold, and for indicating to posterity where almost limitless quantities of the precious metal were to be found if only they would dig for it. Little gold now remains near the surface—the day of the brilliant though untrained investigator, who works not only alone but in the face of the opposition and criticism of his contemporaries and discovers the causative organism or the transmitting agent of some disease, is passing, if it has not already passed; in future great medical discoveries will be made not by individual and sporadic essays at a problem but by organized and systematic investigations made by teams of trained workers. This does not mean that there is no room for individual workers, far from it; in India it will only be possible in a few of the larger institutions to get a team of workers actually together under the same roof, but work can still be organized and systematic, even if the workers are not in the same town, or in the same province; provided the clinical research worker in the field and the laboratory worker keep a common purpose in view and supplement each other's work, the distance of a few hundred miles that may separate the actual workers need make no difference to the co-operation of the team.

We are in agreement that this is not the time and India is not the place to undertake purely academic research. By this we mean investigations that add to the sum total of the scientific knowledge of the world but that have

no apparent bearing on any medical problem of the day. Admittedly many such investigations in the past have proved invaluable, as one can never foresee where they will link up with some actual medical problem, but there are still so many other investigations waiting to be undertaken which are known to have an immediate bearing on some medical problem that it is not the time to indulge in the luxury of academic research. It will undoubtedly be difficult to differentiate between basic and purely academic research, and many border-line instances can be cited; we will cite one. Some species of the genus *Culicoides* are blood-sucking insects and therefore potential carriers of disease; further, they are parasitic on mosquitoes. They are a huge genus of which there are many species in India; many of these are still unidentified. Recently, when they came under suspicion as possible transmitters of kala-azar, it was found almost impossible to do any experimental work with these insects in the absence of any basic knowledge regarding their differentiation and habits. Taking the other point of view, we should argue that the blood-sucking *Culicoides* being almost entirely cattle-blood feeders are therefore unlikely to transmit human disease, and consequently any entomological investigations on insects of this genus might be considered basic from a veterinary point of view, but academic from a medical. What is academic to-day may however be basic to-morrow, so that this line of distinction is not a sharp one, and it will be best at the present time, when other problems abound and money is short, to keep well away from this line.

Though the circumstances in India and in Great Britain are in every way different it is instructive to consider the type of research work that is being done in the latter country. This can be seen from the reports issued by the Medical Research Council. We will take two examples from amongst the reports that have

been reviewed recently in these columns: 'The chemistry of flesh foods and their losses in cooking' and 'A study in growth and development; observations in successive years on the same children'. Though they have no immediate bearing on any specific medical problem, the importance of these two enquiries cannot be denied; the information obtained will not be useful to one research worker, but to thousands of research workers, physicians and others, and will be referred to repeatedly for many years to come. They are examples of basic but certainly not academic research. We are not suggesting that they would be suitable subjects for research in this country. At the present time far too little is known about the chemical composition of the standard diets of various groups of people in different parts of India for an investigation of the nature of the first of these two examples to be of any practical value, and with regard to the second we have so much to learn about the normal physical standards of the children of the various castes and races that it will be many years before the expenditure of time and energy on such an elaborate enquiry on any single group of children would be justifiable.

In India there are still large gaps in our basic knowledge much closer to the specific medical problems we are attempting to solve, but as time goes on these will be filled, and the tendency will be for the medical research worker in this country, following the lead of his prototype in western countries, to make wider and wider circles around his objective.

To return to Koch's simile, as we have said above, the time is rapidly passing even in India when the gold will be found in any appreciable quantity near the surface; it is therefore time to discourage amateur scratching about in the top layers of the soil and to organize scientific mining, if the gold, which we know exists in far greater quantities than it does in European countries, is to be discovered.

Medical News

THE BRISTOL MEDICO-CHIRURGICAL JOURNAL

THIS journal, which occupies a high position amongst British provincial medical quarterlies, has now completed its fiftieth year. The editors have marked the occasion in a very practical way by issuing an index covering this half century of publication.

The journal has had numerous contributions from men with a world-wide reputation as well as from many who have subsequently become famous. The names of Hey Groves, Rendle, Short and Watson-Williams are essentially associated with the Bristol school, but their fame—as well as their books—has spread to the furthest limits of the British Empire.

Amongst names familiar to our readers we see Leonard Rogers, F. P. Mackie, and, inevitably, V. B. Green-Armytage.

There have been few years during the life of the journal when a Watson-Williams has not been associated with it, it is therefore appropriate that Mr. E. Watson-Williams should be mainly responsible for this useful and well-arranged index.

THE O'CONNOR MEDICAL ASSOCIATION

At a meeting of the Panitola Medical Association, held at Tinsukia on 8th June, the following resolutions were proposed by Dr. A. C. Dey of the Rajgorali Tea Estate, and carried unanimously.

1. That the Panitola Medical Association records its profound grief at the irreparable loss it has sustained through the death of Dr. F. W. O'Connor, M.A., M.B., B.Ch., D.M. & H. (Canb.), the President and Founder of the Association.

2. That this Association feelingly observes and records its deep sense of gratitude and obligation to its late lamented President, of his whole-hearted devotion to the cause of the Association and for his extremely courteous and sociable manners.

3. That as a mark of respect and also with a view to perpetuating the memory of the Founder of the Association the name 'Panitola Medical Association' be changed and renamed 'The O'Connor Medical Association, Panitola'.

4. That this Association records its deep sympathy for Mrs. O'Connor and her children in their bereavement.

5. That a copy of this resolution be sent to Mrs. O'Connor through the deputation consisting of the following members:—Dr. B. N. Bornah, Dr. N. B. Kar, Dr. K. M. Gauguly, Dr. G. C. Sil, and Dr. S. N. Mitra.

MEDICAL COUNCIL FOR INDIA

We have from time to time referred to the formation of a Medical Council for India, but, as the subject became acutely controversial, we have recently, in pursuance of our policy of avoiding controversies of a medico-political nature, abstained from reference to the subject. Now however this council is a *fait accompli*, it has held two meetings, and its inspectors of examinations have been selected. The three inspectors are Sir Kedar Nath Das, Dr. Tirodkar and Dr. Farquhar Macrae.

As there has been much misunderstanding about the history of the foundation of this council, we are giving below, from the *Statesman* of 2nd July, an extract which appears to us to be an accurate and unprejudiced account of the sequence of events.

Until 1922, for about 40 years, the Medical degrees granted by the Universities of British India were recognized by the General Medical Council, largely no doubt because the Medical Faculties were staffed by members of the Indian Medical Service, with whose qualifications and knowledge of the standards which obtained in Britain they had reason to be satisfied.

At this time there was some outcry in England about the lack of any fall in maternal mortality and the question of proper education in midwifery was very much in the public eye. This led to an inquiry into the training in this subject in India, and Sir Norman Walker, at that time Chairman of the Examination Committee of the General Medical Council, came to India to investigate the matter.

The conditions in Madras and Bombay were found to be such as to ensure suitable training in this subject but at Lahore, and Lucknow and, though to a less extent, in Calcutta, owing to the purdah system, they were found to be unsatisfactory. As a result of his advice, arrangements were made for students from these three Universities* to go elsewhere to obtain their training in midwifery.

INSPECTION SYSTEM

The conditions at Madras were so satisfactory that unconditional 'recognition' was granted to graduates from that University; but with regard to the other five recognition was only given for one year, and that only on condition that they should agree to be 'inspected' by some one on whose reports the General Medical Council could rely.

For the purpose of this visiting, inspecting and reporting, Col. Needham, I.M.S., was selected, and in

order that he should be fitted for his work arrangements were made that he should visit and investigate the conditions of medical education in America and in Britain. It was also arranged that he should attend at final examinations in Britain so as to familiarize himself with the standard required there before the Graduates or Licentiates were eligible for admission to the Medical Register kept by the General Medical Council. (It should be made clear here that in England the minimum standard both of education and examination for Licentiates and Graduates was exactly the same).

For five years the Universities of Lucknow, Allahabad and the Punjab and Bombay were 'recognized' by the General Medical Council, as a result of Col. Needham reporting that, while the standard was not equal to that at Home, yet such progress was being made that 'recognition' for a further period of one year, subject to further inspection and report, should be given.

In the case of the University of Calcutta the same course was adopted, except for two years in the middle of the term when they refused to be inspected, and their graduates for these years automatically ceased to be eligible for admission to the Medical Register kept by the General Medical Council. At the end of these two years the University asked for inspection and their graduates were again restored to the Register.

YEAR-TO-YEAR 'RECOGNITION'

In 1927 at the request of the Secretary of State, the General Medical Council sent Sir Norman Walker again to India to report to them on Medical Education there. He went with Col. Needham and saw the conditions in the various Universities and found that in all except Madras there had been progress since his previous visit, and advised in this fashion to the India Office. The condition at Madras (which owing to illness he had not been able to visit during his previous visit) was not considered to be sufficiently good to justify 'recognition' without inspection, and Sir Norman advised the General Medical Council to continue the 'recognition' of all six Universities only from year to year subject to satisfactory reports from the Inspector. This was continued until the beginning of 1930, Col. Needham being seconded, and visiting and reporting on the education and examinations.

In his report to the Secretary of State, Sir Norman had advised the formation of a Medical Council in India similar to that in Britain which would undertake the overseeing of medical education and examinations in the Universities of British India, so that there would be no necessity for the General Medical Council even appearing to interfere with the autonomy of these Universities. As a matter of fact, on two occasions, some years before, Bills had been introduced by unofficial members of the Legislative Assembly; but largely because of Provincial jealousies (Medical Education being under the Montagu-Chelmsford Scheme a subject for decision by the Provinces) these never came to anything.

For two years after Sir Norman's visit the inspection and year-to-year 'recognition' was continued, but in the Autumn of 1929, notwithstanding repeated warnings as to the consequences which would follow, the Standing Finance Committee refused the grant necessary to enable the 'inspection' to be carried out.

RECOGNITION REFUSED

Under the Acts (1859 modified in 1886) which constituted the General Medical Council in Britain they are held bound to satisfy themselves that the minimum standard of education and examination is maintained before they can put the name of any licentiate or graduate on their Register. As evidence, that such a minimum standard was being maintained in the Universities of British India, was thus, by the action of the Finance Committee, taken away they had no alternative but to refuse recognition to graduates from these Universities after February 1930.

* This plan, we understand, was not put into effect in the case of the Calcutta University, but there was some reorganization of the existing arrangements for practical teaching of midwifery.—Editor, I.M.G.

The Government of India, knowing as they did that this decision automatically prevented graduates from Indian Universities not only from being eligible for certain posts in the Government service, but also from being able to practise in England and such colonies as the Malay States, Natal and Ceylon, where many Indians are employed, tried various ways of getting out of the impasse pending the formation of a Medical Council in India.

The principal plan adopted was to appoint distinguished members of the Indian Medical Service with experience of medical education and examinations to visit and report on the examinations at the Universities.

These reports the General Medical Council refused to accept as satisfactory evidence such as would justify them in according 'recognition' for several reasons.

(a) They held that individual reports on individual examinations did not ensure that the standard required by the various inspectors could be so uniform as that given by one inspector visiting and reporting on all of the Universities, and that such uniformity of standard was essential.

(b) They felt that as the Inspectors were themselves teaching and examining in the Universities it would be rather invidious for them to report adversely on the teaching and examination in other Universities, and that they were bound to be unconsciously influenced in their opinions by this fact.

(c) Though this did not bulk so largely in their minds, their decision was also influenced by the fact that none of the inspectors who had been appointed had recent experience of the standard required at the examinations in Britain.

EXPERT FROM ENGLAND

Meantime, efforts were made to get an Act passed to constitute a Medical Council for India, but largely because of inter-provincial jealousies, and a misconception as to the status of Licentiates of the various Medical and Surgical Corporations in Britain (all of which were granting diplomas in Medicine long before Medical Education became a function of the Universities) these were unsuccessful until the Autumn of 1933 when the Indian Medical Council Act was passed.

The Government of India thereupon asked the High Commissioner for India in London to make an effort to get a medical man from Britain with experience in reporting on both medical education and examinations to come out in the capacity of Secretary to the Council.

It so happened that Dr. Farquhar Macrae who had retired from practice had for four years been engaged in reporting to the General Medical Council both on examinations and education, and after investigation of his qualifications the High Commissioner recommended to the Indian Government that he should be offered the position. This was done and he accepted and arrived in India in February.

Flatulent Dyspepsia : Its Causes and Treatment

By JOHN HENDERSON, M.D., Ch.B., F.R.F.P.S.G.
(Abstracted from the *Practitioner*, Vol. CXXXII, No. 4, April, 1934, p. 425)

FLATULENT DYSPEPSIA is largely a 'lay' term with a wide reference to all forms of gastric disorder in which flatulence is a prominent feature, and in which there is not any discoverable organic lesion. Even medically it is commonly used with similar significance, as it is a diagnosis which meets with ready acceptance by the patient and the patient's relatives. Flatulence, or the presence of an excess of gas in the gastro-intestinal tract, may occur simultaneously in the stomach and intestine, though in the majority of cases it is confined to the stomach. Obviously it may result from: (1) An excessive production of gas of some kind from chemical changes, usually by fermentation or by putrefaction; (2) an excess of air swallowed—ærophagy in some form; (3) deficient elimination or absorption.

Ærophagy.—In ordinary circumstances in health a certain amount of air is swallowed: (1) With food, more with fluids than solids, and more when feeding is hurried and mastication deficient; (2) with saliva, and hence more when for some reason this is excessive. In certain diseases also associated with pain, particularly when this pain is paroxysmal as in cardiac disorders, angina pectoris, and various types of colic, especially hepatic, the cessation of pain is often associated with copious eructations. The origin of the flatulence here is doubtful, but is most likely air swallowing.

The term ærophagy here is used to describe a condition which may arise from an acquired habit, unconsciously, particularly in those with some form of digestive difficulty, or more classically at the present day it refers to the several types which occur independently of dyspepsia and as part of a pure neurosis. In the former type the patient has a feeling

of discomfort or distension in the stomach, which is felt to be due to 'wind', and which he attempts to ease by eructation. As there may be little or no excess of gas the attempt is unsuccessful and results in the swallowing of air. Repeated attempts, however, result in such an accumulation of air that eructation is ultimately successful and apparent relief ensues for a time. This may become a habit. In the latter and more severe type there may be severe attacks of noisy eructations following one another in rapid succession, perhaps going on for hours or days, and in some such cases mental excitement produces a paroxysm. Large quantities of air are swallowed with saliva until the stomach is distended, when spasmodic movements of the diaphragm are set up which pump the air backwards and forwards between the stomach and œsophagus, till finally it is expelled with a noisy report. The whole process may be clearly observed in some cases, but in others the air swallowing may not be perceptible. The gas thus eructated is, of course, odourless and tasteless. This condition is more common in hysterical women and neurasthenics, but has also been observed in children, and several instances have been noted in one household. These cases would appear to be rather on the increase, as I have seen several within recent weeks.

Deficient elimination of gas will occur whenever there is diminished absorption owing to catarrhal conditions, or to portal obstruction in hepatic cirrhosis, or cardiac failure with consequent backward pressure, or when there is an atonic dilatation. Swallowed air and the gases of fermentation are insufficiently absorbed with the result that flatulence may become a troublesome feature.

With the increase of accuracy in diagnosis in gastric disorders due to modern methods of examination the term dyspepsia has acquired a much more limited significance, and many cases formerly grouped as acid dyspepsia, or atonic dyspepsia, are now recognized as early stages of gastric ulcer or catarrh, as mild cases

of acute gastritis, or as symptomatic of general affections such as anemia or renal disease. Apart then from definite organic lesions in the stomach which give rise to dyspeptic symptoms, two groups of cases are separable: (1) Functional dyspepsia, *i.e.*, without obvious pathological changes; (2) nervous dyspepsia, associated with definite nervous temperament or with definite neuroses, such as neurasthenia or hysteria. The distinction between these is, of course, somewhat arbitrary, as both are based on disturbances of function, either motor, sensory, or secretory, or a combination of these.

So far as flatulence is concerned, it is almost entirely found (at least in a well marked degree) in cases in which the disorder is an error of defect. Hypochlorhydria, or sub-acidity, is met with in those who follow sedentary mental occupations, especially towards middle age, in women towards the climacteric period, or associated with neurasthenia or hysteria. Accepting this as the special type of flatulent dyspepsia for the purpose of this paper, the most constant symptom is a sensation of fullness and oppression in the epigastrium and under the left costal margin, which may amount to actual pain. This comes on soon after the taking of food, and persists often for most of the day, with flatulence, headache, drowsiness, and constipation. Vomiting is not a feature, but when it does occur it affords a welcome relief. The tongue is pale, flabby, broad, and indented by the teeth. The distension of the stomach by gas may cause upward pressure on the diaphragm, and this in turn may give rise to cardiac embarrassment with palpitation and fluttering in mild cases, attacks of pseudo-angina in others, and even may induce an attack of true angina or asthma in those liable to such paroxysms. The condition may be partially relieved by gaseous eructations. Full inquiry should be made, as in all cases of disturbed digestion, of the time taken over meals, the nature and the quantity of food taken, and the regularity of feeding. Deficient teeth, deficient mastication, and constipation are almost always the prominent features in the history and etiology.

The above condition is often associated with defective motility of the stomach, and may then result in atonic dilatation (*i.e.*, non-obstructive) due to atony of the muscular coat. This tends to be progressive unless the cause is removed. A history of poor general health, chronic dyspeptic symptoms, and obstinate constipation is often obtained. Poor physique, and bad or deficient teeth are almost constant accompaniments. In this form flatulence is a prominent feature, usually with fermentation as the condition becomes more advanced, and a test meal shows the lack of free hydrochloric acid, though the total acidity may be normal or increased owing to the increase of organic acids. An x-ray examination after an opaque meal shows the shape and outline of the stomach, the position of its lower border, and the lack of motility with prolonged retention. Complete absence of free hydrochloric acid in the gastric juice (achlorhydria) is rare in functional or nervous types of dyspepsia, though it is an almost constant feature in cases of chronic gastritis, carcinoma of the stomach, and diabetes mellitus, and is a characteristic precursor or accompaniment of pernicious anemia. The most extreme type, achylia gastrica, in which there is entire absence of gastric juice, both acid and ferments, is rare as part of a pure neurosis. In any case, it is as a rule associated with hypermotility, so that there is little time for gas formation. This condition can only be diagnosed by complete gastric analysis.

The diagnosis of *aerophagy* is not, as a rule, difficult when the physician has an opportunity of observing the patient during a spasm or paroxysm of eructation. The patient collects some saliva in the mouth, slightly flexes the head on the chest, closes the mouth and swallows. Thus the air is forced into the oesophagus, producing a sound which is believed to be an act of eructation whereas in reality it is the opposite. On opening the mouth air is belched forth noisily, and then swallowing and eructation follow closely on one

another. When in doubt the diagnosis can be confirmed by x-rays, under which by suitable arrangements the whole process may be observed in operation.

Treatment

In all cases of flatulent dyspepsia it is safe to say at the outset that success in treatment can seldom be expected if the gastric symptoms alone are considered. Attention should be directed in the first instance to the cause or causes in operation, and these should, if possible, be removed or corrected, and any constitutional condition suitably dealt with. Worry and mental exhaustion are best countered by change of air and scene when this is possible, and in cases in which the neurasthenic or neurotic factor is strong a course of Weir-Mitchell treatment, with isolation, absolute rest, and massage, may be beneficial.

The importance of dental attention cannot be too strongly emphasized, as proper mastication of food is the foundation of all treatment. Bad teeth should be removed, defective teeth suitably treated, and a sufficiency of teeth insisted upon, and generally the proper toilet of the mouth should be stressed. Constipation, which is almost universal in such cases, should be corrected, not by occasional purges, but by regular stimulation of the bowel. In this connection abdominal massage suited to each individual patient is a valuable aid, perhaps supplemented by abdominal exercises. Regular exercise should be advised, avoiding over-fatigue. A short rest both before and after meals is beneficial, though not always possible. Faults of hasty eating, overeating, or overdrinking should be corrected, and the times of meals suitably spaced. It is advantageous to prescribe in detail the diet suitable for each case, as thus both the quality and the quantity can be regulated. As a general rule, all highly-seasoned or indigestible foods should be forbidden, and unless alcohol in some form is considered necessary it is better omitted. Even tea should be weak and used sparingly. The use of tobacco should be restricted, and in some cases (especially where acid is in excess) forbidden.

These are general rules which can be adapted for application to all cases, but with regard to medicinal treatment it is of the utmost importance to avoid indiscriminate drugging, as such patients are only too apt to fly from one remedy to another, and to add a 'drug dyspepsia' to their original ailment. We should discourage at every opportunity the habit which is very prevalent at the present day of what may be termed 'drawing-room prescribing', on the ground that what is suited to the needs of one may be entirely unsuited or even harmful to others. Medicinal treatment to be on proper lines must be directed both to the general and the local needs. Tonics or sedatives may be necessary as the case demands, and the constipation which is an almost constant feature should be regulated by a cascara preparation, either the evacuant given thrice daily in suitable doses or cascara given in a mixture form thus:—

R. Extracti cascarae sagradae liquidi ..	℥iss
Liquoris potassii ..	℥iii
Tincturae nucis vomicae ..	℥iii
Aquam chloroformi ad ..	℥vi
℥ii i.d., a.c.	

I have found magnolax a very useful remedy in all forms of gastric and duodenal disorder, given twice or thrice daily in dosage sufficient to produce a daily evacuation. Further medicinal treatment should be on lines calculated towards correcting deficiencies or neutralizing excesses in the gastric juice in the various types of disorder to which reference has been made. The best results therefore can be expected in those cases only in which a careful gastric analysis has been carried out to provide the necessary data.

When *hypochlorhydria* is present special dietetic instructions should include limitation or exclusion of meats and farinaceous foods, and especially of bulky vegetables, such as potatoes and cabbage, and the exclusion of pastry and other indigestible articles. Fats should

be avoided, though butter may be allowed in moderate quantity. Light, strained soups may be permitted. Meals otherwise should be dry, fluids only to be taken after the meal. Tea, if taken, should be weak. It may be thought advisable in this form to allow a little whisky or brandy. An alkaline bitter mixture given before meals is often valuable in neutralizing organic acidity, and may improve both appetite and digestion by stimulating gastric secretion. Such a mixture may take this form:—

R Sodii bicarbonatis	gr. xv
Tincturae nucis vomicae	mv
Infusi gentianae compositi	ʒii
Aquam chloroformi ad	ʒi

Hydrochloric acid, with or without pepsin, is essential in such cases:—

R Acidi hydrochlorici diluti	mxx
Glycerini pepsini	ʒi
Syrupi aurantii	mxx
Aquam ad	ʒiv

To be taken 15 or 20 minutes after meals.

For the relief of flatulence, should it be necessary, sipping hot water, plain or with added carminative as peppermint or cinnamon, may be beneficial, or a few drops of the essential oils may be given on sugar. When the deficiency of acid is greater, as in achlorhydria or achylia, naturally much greater doses of hydrochloric acid are called for, up to ʒii or even more without or with pepsin, with a flavouring of orange juice or syrup, and given well diluted to be sipped during meals. Experimentally it has been found that the individual need for acid in such cases is a variable quantity, so that the requirement for each case may only be arrived at by trial.

Atonic dilatation.—Here the regulations as to diet are similar to the foregoing, but the meals should be in similar quantity as well as dry; the fluids are better taken between meals. Alkaline bitter mixture before meals as before, with acid following, should be employed, but it may be considered advisable to supplement these by a pill calculated to increase the muscular tone of the stomach:—

R Extracti physostigminae	aa. gr. ʒ.
Extracti nucis vomicae	aa. gr. ʒ.
Excipient quantum sufficit		
One pill night and morning.		

In this form a daily stomach lavage may be necessary at the outset, and abdominal massage and exercises should be advised. Short-circuiting operations should be reserved only for cases in which the above line of treatment fails to relieve the condition, or for those in which there is marked difficulty in emptying the stomach, as shown by x-rays and evidence of fermentation. Such extreme measures are rarely necessary.

Hyperchlorhydria.—In those cases of hyperchlorhydria which may be associated with flatulence, the diet should consist of light meats and proteins, fish and eggs, but soups are better excluded, as well as all greasy materials except butter in moderation. An alkaline mixture or powder after meals is indicated, and it is advisable to time the dose so as to anticipate the main increase in acidity. This can, of course, only be accurately done with the aid of a fractional test meal, but, as a rule, the most suitable time is a half to one hour after meals:—

R Sodii bicarbonatis	} aa. gr. xx
Bismuthi oxycarbonatis	
Magnesii carbonatis lev.	
To be taken in water or milk.		

Or this combination may be given in mixture form with sufficient mucilage, and perhaps then supplemented with benefit by the use of a carminative water as vehicle.

In the purely nervous types, tonic or sedative drugs may be required, or special combinations to correct deficiencies or excesses as shown by gastric analysis, but the main line of treatment here is to gain the confidence

of the patient, and, organic disease being excluded, to give him assurance as to recovery.

Ærophagy may call for special treatment. Many cases subside when the true condition is carefully explained to the patient and suitable restrictions are made as to eructations, but in more severe cases more may be required. It may be necessary to isolate the patient and to use disciplinary measures, including the periodic passage of the stomach tube, keeping it in position for several minutes. Actual lavage of the stomach may at times be considered beneficial. It is well to remember that this condition is prone to relapse, and the knowledge that such relapse may call for a repetition of disciplinary measures is often a good corrective for the patient. Belladonna or atropine in careful dosage, with a carminative or sedative vehicle, is at times of service in relieving the actual spasms.

Clinical Manifestations of High and Low Plasma Magnesium

By ARTHUR D. HIRSCHFELDER, M.D.

(Abstracted from the *Journal of the American Medical Association*, 7th April, 1934, Vol. CII, No. 14, p. 1138)

ALTHOUGH a great deal of clinical significance has been attached to variations in blood calcium, variations in blood magnesium have entirely escaped notice. Very little has been known even about what happens when a patient takes an ordinary purgative dose of epsom salt. One observer found that a normal man excreted 28 per cent of the ingested magnesium through the kidneys in twenty-four hours, and another 21 per cent. Using a new and convenient method for the quantitative determination of magnesium in blood plasma and urine, we have found that seven normal men excreted from 40 to 44 per cent (average 42.6 per cent) of the magnesium taken in a single ordinary purgative dose of epsom salt within twenty-four hours after ingestion. However, in spite of the large amount of magnesium absorbed, the concentration of magnesium in the blood plasma (normal, from 1.8 to 2.5 mg. of magnesium per hundred cubic centimetres; average normal, 2.09) is scarcely affected (average increase, 0.24 mg. of magnesium per hundred cubic centimetres; maximum increase, 0.41 mg.). In normal dogs and normal rabbits the percentage of ingested magnesium that is excreted and the concentration of the magnesium in the blood plasma are almost exactly the same as in man, and with corresponding doses by mouth the plasma concentration also remains practically unchanged. In animals the percentage of the ingested magnesium that is excreted in the urine is practically constant, regardless of the dose ingested or of the concentration of magnesium in the blood plasma.

HIGH PLASMA MAGNESIUM (HYPERMAGNESEMIA) AND EPSOM SALT PURGATION

However, when the kidneys are injured, the results are totally different. We have found in animals in which renal injury had been produced experimentally that less magnesium is excreted than normally. The excretion of magnesium is less in animals in which the tubules are more severely injured than the glomeruli (corrosive mercuric chloride nephrosis) than in those in which the glomeruli are injured more than the tubules (cantharides glomerulonephritis). The decrease in excretion of magnesium corresponds quite closely to the decrease in excretion of phenolsulphonphthalein but does not correspond to the alterations in excretion of xylose. We have found also that in nephrectomized animals and in animals with renal, and especially tubular, insufficiency the ingestion of magnesium sulphate causes a tremendous and rapid rise in plasma magnesium, sufficient even to bring them into a state of coma. Coma occurred whenever the plasma calcium reached or exceeded 17 mg. of magnesium per hundred cubic centimetres of plasma. This exactly coincides

with the level at which coma sets in after the subcutaneous injection of magnesium salts.

We have therefore studied the effects of the ingestion of ordinary purgative doses of magnesium sulphate on the plasma magnesium and the general physical condition in a series of patients suffering from renal disease. In all these patients, just as in the nephritic animals, a tremendous rise in plasma magnesium occurred within from four to six hours after an ordinary purgative dose of magnesium sulphate (epsom salt) had been taken by mouth. While one such dose was not sufficient to raise the magnesium concentration in the plasma to the level at which coma sets in (about 17 mg. of magnesium per hundred cubic centimetres of plasma), it often did rise to about two-thirds of that concentration (from 9 to 11 mg.) and a number of the patients did show a decidedly increased drowsiness or even a light coma accompanying the increase in plasma magnesium.

Since a single ordinary dose of epsom salt by mouth can raise the concentration of magnesium in the blood of nephritic patients to two-thirds of the concentration at which coma sets in and since with larger doses it is easy to induce coma in nephritic animals, it seems probable that a few repeated doses of epsom salt would induce coma in the patients. It is therefore most probable that there are every year many hundreds of cases of coma occurring in nephritic patients which are diagnosed uræmic coma but which in reality are magnesium coma caused by the use of epsom salt as a purgative. Since experimental animals could be brought out of this coma instantly and their lives could be prolonged by the intravenous injection of calcium chloride, the intravenous injection of calcium chloride would probably restore such patients to consciousness.

We are not stating, nor do we think, that all or even most cases of uræmic coma are due to magnesium intoxication, but we are merely calling attention to the fact that a condition of coma easily mistaken for uræmic coma can be induced in nephritic patients by epsom salt purgation. Magnesium citrate would unquestionably have the same effect.

Our results in no way contradict those of Blackfan and others who have administered magnesium sulphate intravenously for the control of uræmic convulsions, and for eclamptic convulsions. Since they gave intravenously in carefully controlled doses only sufficient magnesium sulphate to produce subsidence of the convulsions, they stopped the administration as soon as a sufficiently high level of magnesium concentration in the blood had been reached. However, when the drug is administered by mouth and absorbed continuously from the intestine without regard to its concentration in the blood, this level can easily be exceeded.

Since our experiments on animals with renal insufficiency have shown that coma cannot be induced by tremendous doses of sodium sulphate, it would appear that sodium sulphate should be the saline purgative of choice in patients with renal disease.

Our experiments on animals showed also that animals whose plasma magnesium was only slightly raised (to 5 mg. or more) were much more sensitive than normal animals to ordinary doses of morphine. This explains Dr. Osler's old aphorism that 'in severe nephritics and very old persons morphine should be given with caution'. Epsom salt was Dr. Osler's favourite saline purgative and was administered almost as a routine in his wards at Johns Hopkins Hospital.

LOW PLASMA MAGNESIUM (HYPOMAGNESÆMIA)

A form of tetany has been induced in rats that were raised on a diet free from magnesium, it seemed probable that cases showing convulsions or other conditions of increased neuromuscular activity would be encountered clinically in which the plasma magnesium is low.

Two of these were cases of parathyroid tetany. This accords with the experimental results and the clinical observations of others who also found low blood

magnesium in some but not in all cases of parathyroid tetany.

In view of the cases we have seen, it is evident that there is a clinical syndrome associated with low plasma magnesium accompanied by a condition of hyper-irritability of the neuromuscular system, often associated with muscular twitchings or convulsions. These cases are probably more common than has been realized.

At least in the patients whose kidneys are pathologic the twitchings or convulsions can be relieved by the administration of a purgative dose of epsom salt by mouth.

SUMMARY AND CONCLUSIONS

(1) When normal individuals take epsom salt by mouth they excrete about 40 per cent of the ingested magnesium in the urine in twenty-four hours; but the concentration of magnesium in the blood plasma does not rise appreciably.

(2) The concentration of magnesium in the plasma may vary greatly under clinical conditions.

(3) There is a clinical syndrome of high plasma magnesium (hypermagnesiæmia) accompanied by somnolence or coma.

(4) This may be induced in patients with renal insufficiency by the oral administration of one or more purgative doses of epsom salt.

(5) Many cases of coma in nephritic patients, diagnosed uræmic coma, may be simply magnesium coma induced by epsom salt purgation. From such coma patients could probably be awakened by intravenous calcium chloride.

(6) Sodium sulphate is preferable to epsom salt for patients with renal insufficiency.

(7) There is a clinical syndrome of low plasma magnesium (hypomagnesiæmia) accompanied by muscular twitchings or by convulsions.

(8) When this occurs in patients with renal insufficiency, the twitchings or convulsions are relieved by oral administration of epsom salt.

Amœbic Dysentery The Outbreak in Chicago

(From the *British Medical Journal*, 14th April, 1934,
Vol. I, p. 672)

So many conflicting reports of the now well-known outbreak of amœbic infection which commenced in Chicago on 16th August last year have been made that it is a relief to have published by those most directly concerned with it the actual sequence of events. Briefly what happened was this. On 16th August two cases of amœbic dysentery were notified from two hospitals. Inquiry showed that both the patients had fed at a certain hotel where cases of diarrhœa were found to have occurred. On the following day a laboratory was established in the hotel, and 'stools from all the food-handlers were collected and examined, under the supervision of trained technicians who were experienced in the diagnosis of amœbiasis'. The result was that by the end of the month, fifteen clinical cases (we are not told if these were actual cases of dysentery) and eleven carriers were discovered among 364 food-handlers, a percentage of about 7.1. The situation was watched during September, and no new cases arose which could not be attributable to earlier infection.

PUBLIC HEALTH MEETING AT INDIANAPOLIS

On 9th October attention was called to this incident at the annual convention of the American Public Health Association in Indianapolis. It was given publicity in the local press, with the result that on the same day it was brought to light that two members of a family in Indianapolis had been affected with amœbic dysentery after a visit to the hotel in Chicago. Further inquiry in this city disclosed a total of eight such cases. This discovery, and the appearance of some new cases at the hotel, led to the institution of further examination

of the staff and the dispatch of a questionnaire to 16,000 persons who had stayed at the hotel during June, July, and August 1933. This last inquiry, which was followed up by long-distance telephone or telegram urging immediate medical care for those afflicted, resulted by 8th November in the discovery of thirty-five cases of 'diarrhoeal disturbance' among those 16,000 guests who had stayed at the hotel.

'It was then decided that the situation was sufficiently serious to justify the issue of a general warning to the Press.' This was carried out on 9th November, and again on 10th November, while on 14th November a special broadcast was made over the N.B.C. network from coast to coast and in Canada, with an appeal to those suffering from intestinal disorder to see their doctors, and to physicians to be on the look out for 'amœbic dysentery'.

INVESTIGATION OF FOOD AND WATER

The second examination of the food-handlers at the hotel, completed by the middle of November, revealed the fact that, though those detected at the first examination had been removed, others were found to be infected who had not been so at first. It was therefore concluded that the control of food was not checking the infection. Examination of the water supply was then undertaken, and it was found that there were serious defects which might permit of the contamination by sewage of food and drinking-water. Another hotel is now mentioned in which a very serious condition of the water system was discovered, and in which a high incidence of amœbic infection also occurred. Finally, it is stated that in the hotel first considered five surveys of food-handlers and two surveys of non-food-handlers had been completed by the end of January. The result was the discovery of infection in 165 food-handlers and in 141 non-food-handlers out of approximately 1,100 employees. Exact details of these examinations are not given, but it may be presumed that the food-handlers found to be infected at any time were at once removed and replaced by others, but we are not told if the latter were known to be uninfected individuals. Furthermore, we do not know if the well-attested fact was recognized that, owing to the intermittency of the appearance of cysts in the stool, a single examination of a group of people yielded a number of carriers which is only about one-third of those which can be discovered by repeated examination.

The broadcast mentioned above resulted in the report of 721 clinical cases of amœbic dysentery in 206 cities, including Chicago, as apparently originating from the same source. In addition, 1,049 carriers of *E. histolytica* were brought to light in Chicago, presumably in places other than the two hotels, by the investigations. A general laboratory survey of all the principal hotels and larger restaurants was also made, but no parallel to that of the two original foci could be found, though it is reported that in an industrial plant, in Chicago employing 375 workers a connection allowing river water to contaminate the water supply was made in December. This was followed shortly after by an outbreak of diarrhoea. Investigation by the Board of Health revealed seven cases of amœbic dysentery, seventy-one carriers of *E. histolytica*, and three cases of typhoid fever.

REPORT OF THE SPECIAL COMMITTEE

The interest taken in the infection was so great that the President of the Board of Health eventually appointed a special committee to examine the situation, and it met in Chicago from 22nd to 26th January inclusive. It reports that until 1933 amœbic dysentery had not figured largely in the morbidity and mortality reports in Chicago, or indeed in any city in the United States. The outbreak in 1933 embraced about 800 reported cases, most of which became apparent in cities other than Chicago. A large majority of these were traced to two hotels as probable sources of

infection. The report says that the unprecedented nature of the outbreak must be borne in mind, for until this time amœbic dysentery had not been known to occur as an epidemic disease in a civil population. Though this is the case, the examination of the records and laboratory materials, preparations, and cultures led the committee to the view that the cases diagnosed as infected with *E. histolytica* were actually of this nature.

It is noted that the examinations (presumably single ones, and not repeated ones as made at the hotel) carried out have shown that 3.9 per cent of employees in hotels and restaurants in general in Chicago are carriers of *E. histolytica* or suffer from amœbic dysentery—an incidence which is about equal to that among the population of the United States in general. In the hotel first examined the percentage of infection among the employees was at times as high as 18 per cent, that among the food-handlers being approximately the same as that among those with other duties. This fact suggested that structural defects, either permanently or intermittently operative in the two hotels, were associated with an unusual incidence of amœbiasis. Such defects, the committee states, no doubt exist in other hotels, but only special circumstances bring them into play to cause a severe epidemic. Such special circumstances are necessary, for it is known, the report says, that extremely large doses of *E. histolytica* have to be administered to both man and animals to produce infections comparable with those observed in this epidemic, in which the incubation period was short, the lesions were severe, and the exposure often minimal.

DO AMŒBIASIS EPIDEMICS OCCUR?

The above reports raise once again the whole question of the method of spread of *Entamoeba histolytica* and of whether actual epidemics of amœbiasis arise. At the commencement of the war it was thought that amœbiasis was accounting for practically the whole of the invaliding from Gallipoli. This was due not only to lack of experience in the diagnosis of intestinal protozoal infections, which is notoriously difficult, but also to a misconception regarding amœbiasis on the part of those handling the cases. They considered it an acute infectious disease like cholera or bacillary dysentery, whereas actual amœbic dysentery is rather the periodic dysenteric manifestation of a chronic amœbic infection. It seems not improbable that the actual dysentery is caused or stimulated by some intercurrent bacterial infection, or other irritant, acting in a carrier, so that one is led to wonder, in the incident recorded above, whether, assuming that the diagnosis was correct, the occurrence of two cases of amœbic dysentery on one day in persons who had fed (we are not told when) at the same hotel is sufficient justification for the assumption that the amœbic infection had actually been acquired there. Even though inquiry had elicited the fact that there were cases of diarrhoea at the hotel, the immediate establishment of a laboratory there appears to indicate that amœbic dysentery was being looked upon as an acute infection apt to spread rapidly. Such a procedure is perhaps surprising to those who, from a long experience of the disease and its diagnosis, both in the tropics and in more temperate climates, have never observed that amœbiasis spreads rapidly in epidemic form from case to case. One is also led to wonder how in a city like Chicago, where amœbiasis is said to have appeared so rarely in the past, it was possible to find, at such short notice, technicians with the necessary experience to carry out the examinations accurately. The laboratory nevertheless returned a high percentage (7.1) of carriers of *E. histolytica* in this hotel, and later in another hotel and in an industrial plant; finally, 3.9 per cent of carriers were detected among employees of other hotels and restaurants in Chicago. Allowing for the fact that the repeated examinations at the first hotel were bound to yield a higher percentage of carriers than the fewer examinations of employees at other places, it

seems clear that the action taken, whether justified or not by the circumstances, has revealed a widespread carrier condition in the city—so much so, that there is some ground for asking whether some of the individuals who were supposed to have been infected in the two hotels may not already have been carriers before coming to Chicago, while others may have become so at other places in the city, where, in the warm season, they must undoubtedly have taken food and drink outside their hotels. It is notorious that, under the conditions of tourism, diarrhoeic disturbances are far from uncommon.

A SUGGESTION

From all that is known of experimental infection and the dosage of cysts required to produce it, it is difficult to imagine any form of contamination of food or water with fecal matter, even when direct connections exist between the water supply and sewage system, which will allow people complacently to ingest the enormous doses of cysts required to cause amœbic dysentery, and to lead to the development of amœbic infections to the extent they are supposed to have done after very short incubation periods, which in some cases, we are privately informed, were not more than two days.

On the other hand, bacterial infections, or food poisoning, or other intestinal irritants, may light up amœbic infections or even give rise in carriers to dysenteric symptoms. Therefore, though infections were undoubtedly taking place in the hotels examined to an undetermined extent, as well as in other parts of the city and in the United States generally, it would appear from the data available hardly necessary to revise our conception of amœbiasis in the direction of looking upon it as an alarming disease demanding immediate preventive measures such as are necessitated by sudden and unexpected outbreaks of cholera, bacillary dysentery, or food poisoning. A possible explanation of the outbreak is that the immediate action taken, and the publicity given to it, aroused interest in an incident which otherwise would have passed unnoticed, and brought to light a condition of affairs in Chicago which had been in existence for a considerable time.

Pulmonary Tuberculosis Recent Types of Operation

By HOWARD LILIENTHAL, M.D.

(Abstracted from the *Journal of the American Medical Association*, 14th April, 1934, Vol. CII, No. 15, p. 1197)

TUBERCULOSIS is a disease that begins locally and is followed by general dissemination. In this respect it resembles many other infectious diseases as, for example, syphilis, and like syphilis, it destroys tissue, leaving scars or fibrosis when the infection has been overcome. The local destruction by either tuberculosis or syphilis may produce mechanical conditions that are permanent even though the disease itself is no longer active. One example is stricture of a hollow viscus. These residual disturbances may require operations for relief or even to save life.

Since the discovery of reliable methods of killing the spirochete, the need for operations in syphilitic disease is seldom felt. On the contrary, deformities left by tuberculosis of the lungs are still frequently encountered and form the principal group that calls for operative therapy. The cure of tuberculous cavities with their dangers of locally spreading the infection, of septic absorption or of mixed bacterial contamination and of further destruction of pulmonary tissue is the chief object of operative procedure.

The day must come when a direct biologic attack on the bacillus of tuberculosis will result in the control and, perhaps, in the final disappearance of the disease but at present one can hope only for an arrest of progress with cicatrization with or without calcification or ossification, which in ordinary circumstances prevents the continued advance of the malady.

Methods employed in the treatment of this disease may be divided into three main groups:

A. Medical treatment, so called, which might better be described as the non-operative treatment by hygiene.

B. Operative treatment.

Both of these have for their object the resulting 'cure' by rest and by scar formation of the least harmful character.

The third method, which is now under intensive investigation, is:

C. Biologic treatment.

Since this paper will deal solely with operations, most of them comparatively new, I will not discuss the medical treatment, including hygiene, voluntary rest, and the like, nor will I touch on the biologic therapy of the future.

EXTRATHORACIC PROCEDURES

Of the extrathoracic procedures, the most common is that of paralyzing the diaphragm on either one side or both sides by interrupting its nerve supply.

There has been some question concerning the inhibition of the act of expectoration because of the phrenic paralysis. I have not found this to be the case but rather the opposite, since the paralyzed diaphragm in coughing is pushed violently upward by the compressed abdominal viscera.

Paralysis of the diaphragm, by attacking the phrenic nerve, may be brought about by (1) contusion, (2) injection, (3) division, (4) resection and (5) avulsion.

If the temporary effects of the contusion of the phrenic nerve by crushing with forceps wears off too quickly, Douglass states that a second contusion may be performed with little difficulty through the scar of the former incision. He has also affirmed that phrenic neurectomy can be regarded as successful only 'when the x-ray film no longer reveals a cavity and when the sputum has been negative on concentration for at least three successive months'. This definition of the success of plurenicectomy seems rather rigid when one considers that tubercle bacilli in the sputum may come from a lesion, perhaps a very small one, in the opposite lung.

In general, the sole method by which the permanent arrest of the disease can be demonstrated is by roentgenograms. I agree with Fales that if after six months of roentgenologic observation there is no visible activity or change, the disease may be regarded as stationary or arrested.

In considering these valuable procedures on the phrenic nerve, much has been said regarding their harmlessness and perhaps too little concerning untoward effects that are occasionally though rarely observed. Truesdale of Fall River referred to the effects of gastric dysfunction by dislocation of the stomach. This had usually been noted after left-sided operations, but recently disturbances on the right side have also been observed. In one of my own cases in which posterior apicolysis had been preceded for some months by phrenic neurectomy, the patient had serious abdominal symptoms with vomiting which necessitated attempts at gastric lavage. Four surgeons and one gastrologist attempted to pass the stomach tube, on every occasion without success. The tube entered the stomach cavity only once and was instantly expelled. All other attempts were futile, both with the ordinary stomach tube and with the intranasal Levine tube. Later on when the patient was convalescent (without lavage) a roentgen examination of the esophagus and stomach revealed no abnormality of the former but a transverse position of the stomach and, with the rising of the right diaphragm, apparently an angulation of the pyloric region, which probably accounted for the acute dilatation with vomiting, regurgitation and belching.

Phrenic nerve avulsion is the most radical method and on the whole is the most generally applicable. The approach that is oftenest employed is through a transverse incision about an inch or more above the clavicle,

where the nerve, when normally situated, can be easily found as it passes downward and inward across the anterior scalene muscle. The exposure which I employ has the advantage that the resulting scar is almost invisible and that identification of the nerve is easy. The incision is made through the skin on the clavicle—not above it—and it extends from the external attachment of the sternocleidomastoid muscle along the clavicle for an inch or even two, for I find it advisable sometimes to carry the inner portion of the approach a little mesial to the edge of the muscle. With careful blunt dissection and resection, the subclavian triangle is exposed. One retractor above and one mesial are necessary, but no retraction is required below because the clavicle is, of course, immovable. The nerve will be seen on the anterior scalene muscle running downward and inward. It should be bluntly raised and a few drops of the anæsthetic solution injected into it. I usually follow this injection with a few drops of alcohol. The alcohol is injected in order to infiltrate as much as possible the nerve below the point of section in case too short a piece should be removed by avulsion, so that there will be at least an interruption of a considerable part of the nerve. The nerve is then divided in the upper part of the wound, and the lower part is caught in the usual manner and twisted out. The skin is closed with a few metal clips or fine sutures, and if there has not been rough dissection no drain is required. If, however, there has been hæmorrhage or if considerable manipulation has been necessary, I use a temporary drain with a split rubber tube to be removed in forty-eight hours. My dressing is a light pad of gauze over the wound itself and a thick pad in the supraclavicular fossa. This is held in place with a strip of adhesive plaster running from the front of the chest obliquely across the shoulder almost to the spine. If elastic adhesive plaster is at hand, it will assure a springy dressing, comfortable and safe.

In addition to the anomalies that have been described in the literature, there is one that I have twice encountered; namely, the situation of the nerve far beneath the fascia covering the muscle and between the deeper fibres of the scalenus itself.

The size of the phrenic nerve varies much. I have seen it as small as a thick horsehair and in one instance so large that had I not been able to identify it by the patient's subjective sensations I might have thought I was dealing with another nerve, in spite of its characteristic location.

This is not the place to discuss the details of therapeutic effects of the operation; it would take too much time and space. I may state, however, that the low approach to the nerve which I have described makes it less likely that accessory nerve connections will be ignored even though these branches are not seen.

No matter what operation is done there are opportunities for failure or accident, the most serious one being injury to the subclavian vein. The low exposure that I advise has made it possible to see this vessel and form an idea of what is happening to it during the avulsion of the nerve.

I have three times injured the thoracic duct where it enters the subclavian or internal jugular vein, but in none of these cases was there the slightest trouble because of leakage. A small packing firmly compressed by the subsequent dressing was removed in two days with no further leakage. It should be mentioned here that in the cases in which violation of the thoracic duct has been followed by leakage and starvation there has been malignant or inflammatory disease, with dense infiltration of the surrounding tissues, preventing the collapse of the injured duct.

Recently an attempt has been made to produce a depression of the first and other ribs by section of the scalene muscles. I mention this merely because it is a modern operation and comes under the title of this paper. It does not appear to me to be of any real value when compared with the other methods at our disposal, especially the later forms of apicolysis.

After all, it must be remembered that when the first rib has been resected posteriorly, even though only a small part of the bone has been taken away, there is tremendous dropping and rotation of the remainder of the rib, so that it becomes almost parallel with the long axis of the body.

Another extrathoracic method for lessening the capacity of the pleural space is the production of pneumoperitoneum by which both diaphragms are pushed upward. This is particularly applicable in bilateral disease.

It has been noted that in tuberculous women when the terminal months of pregnancy have filled the abdomen and forced the diaphragm upward there is improvement in the pulmonary condition and that after the confinement the return of the phrenic domes to their normal position has been followed by manifestations of recrudescence of tuberculosis.

I have not made use of pneumoperitoneum for this purpose although I have frequently employed it in the roentgen diagnosis of diaphragmatic hernia. I am therefore unable to speak from personal observation.

I have found it prudent not to paralyse the diaphragm before the induction of pneumothorax and have been able to demonstrate clearly by roentgenograms that the paralysed diaphragm is pushed downward by a moderately tense pneumothorax, until it reaches the normal level.

Alexander has devised a method for lessening the excursion of the ribs in respiration by dividing (or otherwise blocking) the intercostal nerves. He does not necessarily reserve this procedure for patients who are so feeble that they cannot withstand thoracoplasty, although he has performed it in cases of this kind. The suggestion is interesting but it does not appeal to me, since it is intended to produce rest alone, with only a minimal lessening of the capacity of the pleura. It probably has its application but the cases must be rare. Then, too, there follows a disagreeable numbing of the cutaneous sensations in the distribution of the divided nerves which is not encountered in thoracoplasty, for no nerves are here blocked or divided. Alexander makes no mention of hemiparalysis of the abdominal muscles, which are supplied by the six lower intercostal nerves. Were these nerves merely cut, the muscular function might return; but with resection or even avulsion this would seem impossible. It is difficult for me to conceive of a patient so ill that when an operation of any kind is considered he could not endure a carefully graded thoracoplasty under local anæsthesia. After all, there must be a well functioning contralateral lung to secure success. Here again it is hardly fair for me to express an opinion, since I have never performed the operation. It is mentioned merely for the sake of completeness and because of the important experimental quality of the work.

OPERATIONS ON THE BONY THORACIC WALL

First, as to the skin incision in paravertebral thoracoplasty. One of the disadvantages, especially in the case of a female patient, has been the extension of the scar high up on the shoulder. Recently Maurer has changed this so that the upper limit of the scar is below the spine of the scapula. By proper retraction upward it is perfectly feasible to resect the upper ribs, including the first. This leaves a space of unmarked skin, permitting the patient to wear a gown with a V-shaped neck.

Probably the most frequent cause of early post-operative death, though the accident may not always have been recognized has been the impairment of respiratory and cardiac function in the contralateral lung by bandages that encircle the chest. No bandage or binder, no matter how loose, should be permitted to envelop both sides of the chest. The surgeon himself should apply the dressing immediately after the operation by holding a narrow gauze covering in place with adhesive plaster, which should not pass farther on the well side than the spine and in front

to the distal edge of the sternum. The lower half of the thoracoplasty may, however, be held firmly by adhesive plaster, passing from the midthoracic spine obliquely downward and forward across the abdomen to the opposite bony pelvic region. Compression of the diseased side can thus be secured without the slightest impediment of the motion of the opposite hemithorax. For this purpose I use a wide strip of the heavy adhesive strongly elastic material known by the trade name of Elastikon. To the ends of this material pieces of ordinary adhesive plaster of equal width should be stitched to prevent the edges from curling up. A support of this kind may be left in place for many days and the dressing can be changed by lifting the plaster away from the gauze beneath.

The various splints and braces that have been recommended for this purpose are to my mind too complicated and uncomfortable.

In posterior thoracoplasty, a few points worth remembering are the following:

Occasionally the compression or collapse may not appear to have been successful even after a few months, the ribs uniting by bony bridges from end to end instead of dropping downward as they should. In these cases other resections should be made. The method is a good one but the second incision is not necessary as a routine. Years ago I operated in several cases by incisions through the original posterior scar, an almost bloodless procedure. The anterior parts of the ribs were thus easily found by dissection and anterior retraction. It has not been difficult for me to take away as much bone as I desire, even to the costal cartilages, without the complication of a second incision, and with complete mechanical success.

Sometimes there is striking improvement and even disappearance of bacilli after an operative result not anatomically perfect. This is doubtless brought about by a stiffening of the thoracic walls with consequent rest. Further thoracoplasty may be considered if symptoms of disease recur.

Another procedure that I find to be a decided improvement on the older methods is the combination of posterior apicolysis with first stage thoracoplasty, the anterior and axillary routes being avoided. I now regularly perform posterior apicolysis at the first session in thoracoplasty. I make the original incision downward and then around the scapula, which is finally mobilized. The operator can carefully strip away the apical parietal pleura, push the lung downward and effect the compression of any ordinary cavity in this region. Those with calcified walls will be referred to later.

Rather than use a wax, paraffin or other rigid filling for this extrapleural cavity, I much prefer a method, which I have several times described, namely, packing with crumpled rubber dam. One end of the rubber dam packing is led out at the lower angle of the wound, the rhomboid muscles are firmly sutured and the skin is closed over all except the drainage opening below. In from three to five days or longer, if the packing is well tolerated, the dam may be removed and replaced by a soft rubber tube of good size (about 30 French). There will be discharge for some time, but gradually healing of the extrapleural cavity by granulation will occur and the walls will be drawn in permanently obliterating the cavity. There is no tendency for the lung to rise to its original place in the thorax. Should thoracoplasty of the lower part of the chest be necessary, this can be done at another time through an incision connecting with the mesial part of the first one.

In any operation for collapse or even compression of the whole or a part of a lung, signs of cardiac distress may appear because of dislocation of the mediastinum with its contained vital parts. Cyanosis, dyspnoea or other alarming symptoms should be the signal for removal of the packings or of the pressure from without. Relief will almost certainly follow.

The rubber dam packing will increase the volume of the extrapleural cavity in four days, from double to treble the size that was present at the end of the operation.

TRANSPLEURAL OPERATIONS NOT ON THE LUNG

The commonest transpleural operation not on the lung is of course the induction of artificial pneumothorax. This procedure is so well known that it is unnecessary to go into details. The value of this therapy has been greatly enhanced by the brilliant invention of the operating thoracoscope by Jacobæus, with its comparatively safe division of adhesions which would otherwise nullify the effects of the pneumothorax. The section of these adhesions by the electric cautery with its obscuring smoke and danger of infection or hæmorrhage when pulmonary tissue happens to form a part of the adhesion has been largely supplanted by operating with a coagulation current, which is smokeless and which will minimize the hazard. Several new instruments of this type have been devised, but the one that has impressed me most is that of Dr. Louis R. Davidson of New York. It requires but a single opening through the chest wall instead of two (one for observation and one for the cautery).

It has been stated that adhesions in the posterior part of the pleural space are difficult to reach, especially those which are wide and flat. I question that it is worth while to try to divide adhesions of this kind, and yet occasions may arise in which it may be justifiable. When this cannot be carried out through a single thoracoscopic opening in the chest I would suggest that, as in Jacobæus's original operation, another opening more advantageously placed can be made for the purpose of dividing the adhesions under the guidance of the eye at the telescope in the original thoracic wall perforation. Eloesser of San Francisco has gone so far as to divide adhesions, using the approach of actual wide thoracotomy and closing the chest after the adhesions have been divided between ligatures. It has always appeared to me that thoracoplastic procedures would perhaps be safer than this method and yet I can understand how even this radical step may eventually prevent permanent loss of function in healthy lung, which might otherwise be sacrificed in destroying the function of the diseased part.

The tendency of modern surgery is to conserve the breathing space of a lung when only part of it is hopelessly diseased.

To return to the discussion of uncomplicated artificial pneumothorax, a special danger may be here mentioned. I refer to dislocation of the mediastinum, to which I have already referred.

A means for combating this annoying complication was recently called to my attention. If deviation appears after the induction of pneumothorax of a comparatively low tension, it should be regarded as a danger signal and measures should be taken to stiffen the mediastinum before proceeding with any further collapse therapy. Berck has gone so far as to make experiments on the mediastinal space itself to produce rigidity, but this seems to be an operation of too great magnitude and peril. Dr. Herben has shown that the injection into the pleural sac of an aseptic irritating substance, such as gomenol and oil or liquid petrolatum alone, later to be withdrawn, has a tendency to produce pleural thickening and the much-to-be-desired rigidity.

Two contrasting cases of my own have impressed this strongly on me. The first patient, operated on years ago by thoracoplasty, immediately after the procedure became cyanotic and in danger of death; loosening the adhesive plaster dressings relieved the condition, but immediate perfect collapse was thereby prevented.

The other patient was a young woman on whom thoracoplasty had been contemplated but in whose chest Dr. Herben recognized dangerous mediastinal mobility after only moderately tense pneumothorax. This was overcome by temporary oleothorax with

gomenol. When the mediastinum became rigid I succeeded in achieving good thoracoplastic obliteration of the diseased lung, with final disappearance of all symptoms and with absence of bacilli from the sputum.

OPERATION OF THE LUNG ITSELF

I now come to the consideration of the more radical intrapleural measures. These are mainly operations on the lung itself and I shall mention first the direct drainage of cavities. There are two principal reasons why this should be performed; first it should be performed when the cavity harbours mixed infection which becomes dangerous to life. The mere presence of tuberculosis as a primary factor should not prevent the treatment of such a cavity as if it were a non-tuberculous or even a putrid lung abscess. The first case in which I had recourse to this operation occurred a number of years ago. The patient had a large cavity in the upper central part of the right lung, and after the first stage of thoracoplasty there was high fever and great distress because, apparently, the compression of the thoracic wall had impeded emptying by way of a bronchus. Nearly three weeks later I realized that unless direct drainage was accomplished my patient would lose her life. Therefore, with considerable misgiving, I performed pneumonotomy and drained the cavity fearing, as was the general belief, that because of the tuberculosis the resulting fistula would become permanent. There was immediate relief and in due time the thoracoplasty was completed. Contrary to my fears the fistula closed and the cavity has had to be opened twice since then, the last time only a few months ago when the entire roof was removed and the wound treated by packing. So long as the cavity is open the patient is comfortable but if it closes there is cough with distressing asthma. At the present time the hollow seems to be obliterating naturally and I have great hope that this troublesome case will eventually terminate happily. At any rate the woman is alive and active nearly ten years after the original operation.

Since then I have opened other similar cavities and feel convinced that, when there is a great quantity of sputum and the surgical compression from without cannot be attained, it is far safer in the presence of a healthy contralateral lung to drain freely through the chest wall rather than to subject the individual to the dangers of cough and probably spill-over infection.

Cavities with calcified or ossified walls but with large secreting surfaces with profuse expectoration, whether bronchiectatic, multiple or single, form a very serious and difficult class. The usual extrapleural operations are inadequate, and drainage through the chest wall may leave permanent disability.

At the 1933 meeting of the American Society for Thoracic Surgery, Dr. Harold Neuhof presented a method for the collapse of those cavities in which it can be demonstrated that there is no free space between the two pleural layers. He incises the layers covering the abscess until he reaches a cleavage plane beneath which there is a collapsible wall. Then with careful manipulation he obliterates the cavity and holds the compression by packings, covering these with mobilized periosteum as well. While I have not attempted this procedure, I believe it may have an important place in thoracic surgery.

As a last resort, especially in the bronchiectatic cases, it seems to me that resection of the rigid walled cavity should be done either at one sitting or in divided stages according to the conditions encountered. Indeed, I feel that eventually resection of the lung will become one of the operations of recognized worth in certain cases of localized pulmonary tuberculosis. Thus far, though I have resected many pulmonary lobes for suppurative disease, I have not had the opportunity to apply the principle in cases of phthisis.

ELECTROSURGERY

Another new and important adjunct in operations on the chest wall is electrosurgery. When properly carried

out the electric incision of the skin insures aseptic conditions unobtainable by the ordinary instruments. The tissues must be divided with a quick sure stroke, so that cell destruction along the walls of the wound may not be so great that healing will be delayed. There is another distinct advantage in the small number of hemostatic ligatures, the blood flow from vessels of small size being checked by coagulation through hemostatic clamps. I have performed a secondary complete paravertebral thoracoplasty with resection of ten ribs without the application of a single ligature. There was primary union throughout. Those who are interested may care to read a recent article which I contributed on this subject.

Electrosurgery in thoracic disease should be confined to the chest wall, for if it is employed within the pleura and especially near the heart there is danger that the muscle of that organ may be made to contract abnormally, with fatal result.

EMBOLISM AND MASSIVE COLLAPSE

Among the dangers always to be considered in any operations on the chest for tuberculosis, two are outstanding. They are massive collapse of the better lung and cerebral air embolism. Bacterial embolism with metastasis to the brain is, of course, always possible, and there is no way in which this can be prevented. The danger of air embolism can be greatly diminished by keeping the patient's head lower than his chest during any operative procedure on the wall or cavities of the thorax. Massive atelectasis in thoracic surgery can be treated, but the accident cannot at present be prevented.

ANÆSTHESIA

With the appearance of tribrom-ethanol as a powerful pre-operative hypnotic, a valuable agent is available which relieves the patient of mental anxiety and excitement and which, when properly given as an adjunct and not as a true anæsthetic, becomes a genuine blessing in many operations on the chest. But there is one important contra-indication, namely, the habitual expulsion of a large amount of sputum; for, in spite of the precaution of pharyngeal suction during operation, the long-continued sleep afterwards is liable to be accompanied by aspiration into the better lung. Therefore I do not use tribrom-ethanol in any case when there is profuse expectoration.

SUMMARY

1. Tuberculosis as a disease is not amenable to surgical treatment. Anatomic conditions of a pathologic and threatening nature resulting from the disease may be treated by surgical procedures.
2. The chief object is the obliteration of tuberculous cavities and the conservation of healthy lung.
3. Operative procedures are divided into: (1) extra-thoracic, (2) operations on the chest wall, (3) trans-pleural operations not on the lung, and (4) operations on the lung itself.

The Enlarged Prostate : Considerations in Advising Surgical Treatment

By J. G. YATES BELL.

(From the *Medical Press and Circular*, 4th April, 1934, Vol. CLXXXVIII, p. 310)

IN advising surgical treatment for the prostatic patient there are four established operations that must be borne in mind, and the selection of the suitable method can be correctly advised only after careful consideration of each individual case. This should entail close co-operation between the general practitioner, who knows much of importance in the patient's way of living and details of general health, and the urologist, who will have particulars of the special function tests and knowledge of the type of gland to be dealt with. In many cases, including patients on the border line of cardio-vascular trouble, as well as those with the

established results of urinary obstruction, the opinion of a physician experienced in the risks and stress relative to these various operations is of great value. A physician, no matter how brilliant, can hardly be expected to say whether a patient would stand a prostatic resection when he has never seen the operation performed, and is ignorant of the shock, hæmorrhage, etc., entailed.

The risks of prostatectomy have led in the past twenty years to the introduction of various instruments intended to remove per urethram portions of the obstructing part of the prostate gland. Owing to the inability to control bleeding and to the 'blind' nature of the operation, results were bad, and justifiably these early transurethral manipulations passed into disfavour. The introduction of the endothermy cutting current as a means of checking hæmorrhage, and the perfection of visual and irrigation systems whereby the cutting and its site can be clearly seen, have brought a change fortunate for the prostatic patient. As with all new operations that are successful, enthusiasm led surgeons to try transurethral resection for every prostate, and by so doing the mortality and complication rate rose rapidly, and the operation was condemned by conservative surgeons. Happily, urologists now agree that there are certain cases likely to benefit most from prostatectomy, and others from transurethral resection, and by careful consideration of each patient individually the right operation may be chosen; it is by a middle course, with caution and experience, that the operation of transurethral prostatic resection has become established as a surgical procedure with most benefit to the patient. There are two methods of transurethral resection—the punch cautery and the endothermy wire-loop resection; this latter is most used in England, the instrument being frequently some type of McCarthy resectotome.

The choice of anæsthetic varies; but for all except some cardiac cases a low spinal anæsthetic, preferably spinocain or percain, is excellent. The writer has used avertin with gas and oxygen in some nervous patients, and where an absolute minimum of anæsthetic is required, it is perfectly satisfactory to inject novocain into the sacral foramina and hiatus; but every now and then this anæsthetic fails to work, and so it is not recommended as a routine. Before any of these it must be emphasized that the mouth must have had attention in the matter of septic teeth, many post-operative pulmonary complications being entirely due to neglect of this.

SELECTION OF OPERATION

Suprapubic prostatectomy remains the operation of choice for a patient who is in good condition generally, and who has enlargement affecting mainly the lateral lobes; all very large prostates are best removed by this method.

Perineal prostatectomy has until recently been suitable for certain fibrous prostates and malignant cases, but has been supplanted by resection, and now it has little indication except for a few very rare cases of cyst, and possibly tuberculosis.

Transurethral prostatic resection.—Fully to appreciate the scope of this operation, one must consider what is actually done. In an average case, tissue is removed varying from one to ten grams in weight from the most obstructing situation; obviously, when the obstruction is a small median lobe or a small fibrous prostate, the tissue removed at 'one sitting' is adequate to relieve the obstruction and the symptoms; but when there are bulky lateral lobes, two or three 'sittings' may be necessary to provide a satisfactory channel; in some very large prostates as many as six sessions at intervals of about ten days may be necessary; and it is obvious that most patients would quite rightly prefer the major operation, involving only one anæsthetic and a shorter stay in hospital, and here prostatectomy should be done unless there is a definite contra-indication.

Transurethral resection is a minor operation in the sense that shock is very slight, and immediate danger in an experienced cystoscopist's hands almost negligible, and the average patient is fit to leave hospital in ten days. Hæmorrhage, reactionary and secondary, is rare, and can be stopped by electro-coagulation, and very infrequently needs packing through an open bladder. The chief complications result from infection, and appear as epididymitis, cystitis, pyelitis and pyelonephritis, and may be very largely avoided by careful pre-operative treatment, especially with adoption of temporary preliminary suprapubic drainage in obviously infected cases and by careful after-treatment, ensuring that no obstruction occurs to urinary flow through the in-dwelling catheter left in the urethra for the first four days after resection.

Uremia needs all the precautions exactly as for prostatectomy: the surgeon must know by his clinical examination and renal function tests that the kidneys are adequate; any patient not satisfying these requirements, and even border-line cases, are best advised to have a preliminary suprapubic drainage. The presence of this drainage is additionally useful at the time of operation, as septic complications are rendered more unlikely, and most patients who have a horror of suprapubic drainage will consent when it is pointed out that it is only for a short time, and that risk to life in their case is likely to occur without this precaution.

Suitable types of gland for this treatment may be grouped into four main headings: Middle lobe cases; small fibrous prostates; carcinoma (inoperable by reason of fixity); 'prostatisme sans prostate'. These four groups all give excellent results, and are the 'ideal' cases for resection. Two further groups may be added—the middle lobe with slight lateral lobe enlargement, and lateral lobe cases where for some reason suprapubic enucleation is deemed inadvisable; this includes men of advanced years with short expectation of life, where, surely, to both the surgeon and the patient, a few years of temporary relief must seem preferable to a guaranteed cure at considerable risk after a severe operation.

In the selection of cases, firstly, the history must be taken into account: a gradual onset of dysuria long continued usually indicates lateral lobe preponderance, hæmaturia—a congestive condition likely to be troublesome at resection. A patient of fifty-five years will more frequently prove to be a middle lobe case than will one of seventy-five.

Having decided that the prostate is the cause of the trouble, the first point to establish is whether preliminary suprapubic drainage is necessary. Whether it be followed by enucleation or resection is of no account, and can be decided after the drainage; moreover, the value of digital and visual examination of the bladder, carried out at the preliminary operation, is often of the greatest help in selecting the method suitable.

Obviously infected or uræmic patients present no difficulty as to the course to adopt. It is the patient with tests (daily urine output, residual urine, urea concentration and blood urea) which are only on the border line of safety who may need careful overhaul before it can be decided to operate without drainage. The general appearance is of help: the fat, florid patient with barrel chest and large abdomen is liable to uræmic 'ileus', as well as chest complications, and, always a poor subject for prostatectomy, he is safer with a suprapubic tube at the operation of resection. If the patient has moderate tests, but is thin and sallow, err on the side of caution.

Occasionally a border-line case with a short history and small residual urine can be brought to a fit state for operation by drainage with an in-dwelling catheter for a week; but great care must be taken to avoid infecting the urinary tract, and, on the whole, suprapubic drainage is preferable because of this danger.

The tongue remains a good guide; there is the dry, brown fur, and the raw-beef tongue with shedding of

epithelium, indicating considerable renal damage. There is also a large flabby dyspeptic tongue which accompanies the symptoms of indigestion of early uræmia, and indicates a need for cystotomy. The blood pressure and the state of the arteries are helpful guides to the load on the heart imposed by prostatic obstruction, and must always be investigated.

Urine obtained at the cystoscopic examination must be examined for bacteria, pus and albumen, all of which are indications for drainage.

The length of the interval between drainage and the resection varies from two weeks to six months, until the renal function is adequate, infection has subsided, and, in the longer delays of cardiac and pulmonary cases, until the heart has responded to the improved renal function, or the weather is more propitious to a bronchitic chest.

Rectal examination, while affording information regarding consistency and mobility, fails in the common border-line case to establish the localization of the enlargement with its appropriate treatment, but in very large prostates and in carcinoma this may suffice, although it is the writer's habit to cystoscope all prostate cases.

Cystoscopy is the most certain way of learning the site and nature of prostatic obstruction in each individual case. It has been the writer's invariable practice to cystoscope all prostate cases in the past owing to the frequency of associated conditions such as vesical carcinoma, diverticulum, stone, etc.; and now with the information required as to the nature of the prostate itself, surely this examination must be regarded as a necessary prelude to treatment. It involves no repetition of instrumentation, as residual urine and other tests can be carried out at the same time, and with modern cysto-urethroscopes full inspection of the posterior urethra is done simultaneously. X-ray pictures of the prostate by instillation of opaque fluids into the bladder and urethra are not yet accurate enough to replace cystoscopy, but may be this examination will be perfected shortly.

Permanent suprapubic drainage for prostatic cases is happily now rarely necessary, being reserved for extremely feeble patients unsuitable for a catheter life for reasons of difficulty or pain at instrumentation, who would not tolerate a 'hair cut and shave' in two stages, and for some malignant prostates where the size of the gland or tortuosity and occlusion of the urethra prevent the passage of a resectotome. The comparative mild nature of the operation, with short convalescence entailing small expense to the patient, will result in cases presenting themselves early for treatment before associated cardio-vascular changes are established. The general practitioner will be able to encourage this, with decrease in the morbidity rate and saving in expense to the patient.

To sum up, suprapubic prostatectomy remains the operation of choice for fit lateral lobe cases, and for

all very large prostates; transurethral resection is to be recommended for all other cases except a few feeble patients who must be content with drainage. The choice of operation in the border-line cases of lateral lobe enlargement is made most satisfactorily only after close co-operation of the patient's doctor, the urologist, and an experienced physician.

A Protective Mask for Use after Operations on the Eye

By H. KIRKPATRICK, M.B.

LIEUTENANT-COLONEL, I.M.S. (Retd.)

(From the *British Medical Journal*, Vol. I, 10th March, 1934, p. 431)

ACCIDENTAL injury of an eye whilst convalescing from an intraocular operation is an unfortunate complication which is sometimes met with. A protective shield should be (1) light and strong, (2) comfortable to wear, and (3) so constructed that it cannot be displaced by any movement of the patient's head on the pillow. Until recently, in my experience, no available device entirely fulfilled these requirements; but Messrs. Clement Clarke, 16, Wigmore Street, have now made for me a mask which appears to be wholly satisfactory.

The material is a composition resembling celluloid, and the mask is shaped to fit closely the orbital margins and superciliary ridges. The material is sufficiently rigid to afford protection and is yet sufficiently elastic to allow the mask to fit nearly every case. If necessary, however, it can be remoulded for an exceptional patient by softening it in hot water.

There is a bulging prominence in the shield over each eye, and the centres of these prominences are removed to allow proper ventilation. The mask can be used over a dressing instead of a bandage and is tied in position by two tapes which pass round the head, one above the ears and the other below. The shield will serve as a comfortable protective shade after the dressings have been removed. A separate shield for each eye can be used if desired, but a mask which covers both eyes is usually to be preferred.

Reviews

- (1) **HUMAN SEX ANATOMY.**—By R. L. Dickinson, M.D., F.A.C.S. 1933. Baillière, Tindall and Cox, London. Pp. xiv plus 145 with 191 figures. Price, 45s.
- (2) **THE SINGLE WOMAN: A MEDICAL STUDY IN SEX EDUCATION.**—By R. L. Dickinson and L. Beam. 1934. Baillière, Tindall and Cox, London. Pp. xxx plus 469. Price, 23s.

THE traveller of thirty years ago when he took his seat in the train was usually offered by the book vendor a selection of Nat Gould's sporting novels, a volume of detective stories, and possibly a book, with a suggestive title, by Victoria Cross. To-day he will probably

be able to buy his book of detective stories, as these have recently enjoyed another phase of popularity, but for the rest he will be offered a selection of books on sex hygiene, married love, and contraception. Whether this is 'a good thing' for the human race is a matter of controversy, but the general opinion is that it is better for us to have these 'facts of life' forced upon us, than deliberately withheld from us by the universal conspiracy of silence that existed a quarter of a century ago. A middle course would naturally have been ideal, but that is not the way of this world.

During this controversy the medical profession as a whole has 'sat on the fence'. It is not very difficult to understand the reason for this. The position of the

medical man has been a difficult one; despite the fact that he may have M.D., M.R.C.P. after his name, and despite the fact that the sex relations of man and woman are not only a necessary prelude to one of the most disturbing of physiological functions which the human organism performs but are in many other ways intimately connected with health and ill-health, his practical knowledge on this fundamentally important subject may consist only of what he has acquired during his own personal experience, and this may have been very limited; it is not to the enhancement of the prestige of the medical profession that it should be otherwise. The practitioner will probably find that his advice is often sought by patients to whom he can tell nothing that they have not already gleaned from the popular sex literature of the day. He has no literature of his own to which he can turn to repair the gap he has discovered in his knowledge and it will not improve his position in the eyes of his patient if he quotes from the books she (or he) has been reading. Further, he has to accept the statements made in these popular or quasi-medical books because he has not the fundamental knowledge of the anatomy and physiology of sexual intercourse on which he can form any judgment. Little wonder then that many medical men have taken up a reactionary attitude. This is not, we feel assured, the attitude of the medical profession as a whole, and everywhere there are signs that the subject is now being tackled in a scientific manner, but the data on which the literature of a branch of science is founded cannot be built up in a few years. However, fortunately we have men amongst us who were born before their time. This remark is particularly applicable to Dr. R. L. Dickinson who is responsible for a very important series of books published under the auspices of the National Committee of Maternal Health, an American organization. He practised for fifty years as a gynaecologist and obstetrician, throughout which period he made the most remarkable collection of sex histories of his patients, and of notes, diagrams, and measurements of their genitalia. His *Human Sex Anatomy* is based on the latter collection, and his series of three books, of which the second, *The Single Woman*, has just been published, on the former. For the *Anatomy*, which is a beautifully produced volume, he has not depended entirely on his own experience, but has drawn from many other sources. A number of the drawings are made from his own patients and cross references are given to the case histories published in the other books; the statistical graphs are also based in some instances on figures from his own experience, but added to these is the experience of many observers in many lands. The diagrams of the anatomical relationship of the genitalia during coitus are deductions from a thorough knowledge of the various anatomical types in both sexes, but are nevertheless, as the author admits, guesses, and will remain so until the science of x-ray photography advances sufficiently to allow us to take actual photographs of the male organ *in situ*.

The author is conscious of the incompleteness of his work and is most insistent that it is to be considered only as a foundation on which sex anatomies of the future can be built. However, most readers of his book will be very surprised that so much information is available.

The bulk of the other book is made up of sex histories; this, the author explains, is inevitable where one is dealing with a comparatively new subject, as it is necessary to give the full data on which conclusions are based. With this attitude we agree; this book would certainly lose ninety per cent of its value without these case histories. The comparison of his first fifty with his last fifty patients provides very interesting material for the student of human social custom. The clothes may be different, but the women within them are very much the same; the single woman of to-day gets pregnant a little more frequently, but more single women of 1895 suffered from venereal disease; his later

patients appeared to be more outspoken and honest, but this, the author thinks, may have been due to his increased experience in gaining their confidence. This brings us to perhaps the most remarkable feature of the book—the evidence of the growth of the confidence that the author inspired; at the first visit his patients were often inclined to be reticent, but at their later visits—and they all seemed to come back to him, some for forty years—they confided their innermost thoughts and gave intimate details of their lives, details that they had probably never discussed with their closest friends. (In justice to the author it should be mentioned that this confidence was not betrayed and that the case histories have been denuded of any details that could possibly lead to the identification of the patients, and in some instances alterations in non-relevant medical details have been made to complete the disguise).

These two books will help to lay the foundations of what we hope will develop into a scientific medical literature on the sexual relationship of man and woman. Both books are eminently unsuitable for the non-medical reader and we sincerely hope that they will not find their way into the railway station bookstall. To label them 'for medical men only' would ensure their wide sale amongst the laity, but there must be some other way of discouraging their sale in other than medical bookshops and we hope that the publishers will do what they can in this matter.

If the last quarter of a century has been remarkable for the quantity of its popular sex books, let us hope that the next will be distinguished by the quality of its medical sex literature.

L. E. N.

MEDICINE: ESSENTIALS FOR PRACTITIONERS AND STUDENTS.—By G. E. Beaumont, M.A., D.M. (Oxon.), F.R.C.P., D.P.H. (Lond.). Second Edition. 1934. J. and A. Churchill, Limited, London. Pp. xviii plus 746. Illustrated. Price, 21s.

The first edition of this book was reviewed in these columns just a little over a year ago. We must congratulate the author on this well-deserved success.

Even in eighteen months things happen and a certain number of alterations and additions have been made. Only a few pages have been added to the book, it is gratifying to note, because one of the outstanding features of the first edition was the nice judgment that the author had displayed in his choice of matter for inclusion. With time and the world's literature at his disposal anyone can write an encyclopædia on a subject; to write a concise account requires a profound knowledge.

The two most important alterations are modifications of the names and doses of drugs to conform with the British Pharmacopœia of 1932, and the adoption of a new classification for the anæmias. His choice of Davidson's classification is a wise one; it is certainly better than the division into micro- and macro-cytic anæmia which has no ætiological basis at all.

The sections dealing with tropical diseases are on the whole very satisfactory and up to date. Plasmochin and atabrin are mentioned in the treatment of malaria. It is however disappointing to see that sodium antimony tartrate is the only treatment given for both kala-azar and oriental sore; in the case of the former disease, tropical workers are unanimous in their opinion regarding the superiority of the pentavalent compounds, the most successful of which have now been in use for ten years. In the leprosy section we note that hydriocarpus has acquired a superfluous 'n'.

This book is an ideal one for the student and we strongly recommend it to teachers of medicine in this country. It should also prove a useful reference book for practitioners.

L. E. N.

CLINICAL STUDIES ON THE PHYSIOLOGY OF THE EYE.—By J. Grandson Byrne, M.A., M.D. 1934. H. K. Lewis and Company, Limited, London. Pp. x plus 144, with 49 illustrations. Price, 10s. 6d.

THIS work has been written for the benefit of the physician to help him in the practical application on the human subject of the author's experimental work upon the eye.

As the writer points out, the ultimate aim of the diagnostician is to get as clear an insight as possible into the nature, extent and significance of derangements in the living patient and to interpret these in terms of disordered physiological mechanisms, all of which presupposes an intimate knowledge of the normal ones.

Hitherto the study of pupillary changes and of pain and hyperalgesia incidental to somatic and visceral disease have been little more than of transitory academic interest to the general practitioner. From his experimental work, the author believes he has succeeded in establishing the mechanistic hypothesis for pain, referred pain and tenderness in general, and in his present work he records and discusses some of his experimental and clinical findings.

The book consists of fourteen chapters dealing with the mechanism of pupil reactions under various circumstances, and of which the ones on the mechanism of anisocoria and the Argyll-Robertson phenomenon are perhaps the most instructive and interesting.

The author wisely points out the importance of a thorough training in the theory and practice of general medicine before one can be a skilled specialist in the art of ophthalmology. The prescribing of glasses may seem to be easy, but should not be undertaken in a light-hearted manner in the treatment of disordered ocular functions. Accommodation for both near and far is carried out by neuro-muscular mechanisms, and it should be remembered in disorders of accommodation that treatment should be directed to the restoration of the defective neuro-muscular functions. The underlying cause of the factors should first of all be dealt with and the clinical findings, as arranged by the author under the three headings, physical, mental, and endocrine-vitamin deficiency, furnish the indications for general treatment. The prescribing of glasses should be of secondary consideration, and they should only be prescribed under compulsion after taking into account the handicap which the wearing of glasses when once started may have on the complete restoration of ocular functions. The author considers that in these modern times far too many individuals of all ages are wearing glasses. Many of these people really only require glasses temporarily for the relief of eye strain, which later become contra-indicated as they tend to retard restoration of function in the affected ocular mechanisms.

The book is a most excellent one, written in clear, simple language, and well illustrated, and the author is to be congratulated for having made such a valuable contribution to the literature of British ophthalmology. We cordially recommend it and it will be found a most valuable, not only to the ophthalmologist but to the general physician, help in the early diagnosis of disease.

E. O'G. K.

ORTHOPÆDICS IN CHILDHOOD.—By W. L. Sneed, M.D. 1932. J. B. Lippincott Company, Philadelphia and London. Pp. xviii plus 318, with 145 illustrations. Obtainable from Messrs. Butterworth and Company (India), Ltd., Calcutta. Price, Rs. 15-12

THIS is a volume of the everyday practice series—a series of books meant to give recent information on the subjects they deal with. In this volume the whole subject of surgical diseases of childhood is dealt with. The manner is generally superficial and is apparently meant to mark out a line of treatment after the diagnosis is made by the general practitioner and to

point out the indication for expert opinion and treatment. The clinical side of the diseases has been briefly touched upon—apparently intentionally—while several methods of operative procedure, which are of doubtful value, find place in it. There are two useful chapters on physio-therapy and surgical appliances which should prove valuable to the practitioner. Short anatomical descriptions of the regions dealt with should prove useful to the busy practitioner for whom the book is intended, but some of these need revision and correction—with revision the book should improve considerably and should be of great help to those for whom it is intended. The printing, the general scheme and the illustrations are excellent.

L. M. B.

MINOR SURGERY OF THE URINARY TRACT.—By H. C. Bumpus, Jr., Ph.B., M.D., M.S. (in Urology), F.A.C.S. 1932. W. B. Saunders Company, Philadelphia and London. Pp. 124, with 57 illustrations. Price, 15s.

THIS compact volume is one of the Mayo Clinic monographs. It describes the treatment of the more common and important diseases of the urinary tract by modern methods—several of the methods of treatment described, such as that of transurethral partial removal of the prostate by special instruments, can hardly be called minor surgery. To the patient such procedures will appeal as there apparently he is not subjected to a cutting operation as it is commonly understood. By the use of a cleverly designed urethrocystoscopic instrument, partial removal of the prostate by cutting into it, or partially destroying it by fulguration, destroying bladder tumours by the latter method and electro-coagulation, and removal of ureteral stones have opened out a field for this branch of surgery which promises a great future for it. The author lays down his instructions very carefully and briefly and his descriptions have the weight of experience and dexterity behind them. The methods are highly specialized and require a considerable amount of training and experience to prove successful at the hands of the practitioner. The book is attractively printed and the illustrations are excellent.

L. M. B.

BENIGN TUMOURS IN THE THIRD VENTRICLE OF THE BRAIN: DIAGNOSIS AND TREATMENT.—By W. E. Dandy, M.D. Balilière, Tindall and Cox, London. Pp. 171, with 120 figures. Price, 22s. 6d.

UNTIL a few years ago the case of cerebral tumour usually remained in the hands of the physician; that is to say, it was thought better to do little and pray for a miracle than to hasten the end by surgical interference. There were of course exceptions, but tumours of the third ventricle were not included amongst these. Times have now changed and the advent of the ventriculogram and the electro-cautery have made procedures possible that were hitherto undreamt of.

That benign tumours of the third ventricle are not exceedingly rare surgical curiosities is shown by the fact that the experience of one surgeon has included twenty-one cases, and that it has been possible to collect forty-seven other cases of this condition from the literature; the latter were all diagnosed in the post-mortem room.

The diagnosis and treatment of these twenty-one cases is described in detail, with the aid of some most excellent diagrams, ventriculograms, photographs and photomicrographs that make every stage in the procedure perfectly clear. Exact localization is first effected by means of ventriculography, that is to say by tapping a lateral ventricle and replacing the fluid by air, and then taking roentgenograms of the head; the tumour can sometimes be seen, but as a rule the diagnosis is made on the visualization of the air-filled ventricles.

The author, who is a professor of surgery at the Johns Hopkins University, is to be congratulated, not only on the marvels of surgery that he has wrought but on the writing of a book that is a model of concise description of intricate procedure, and the publishers on a most beautiful example of book production.

NEURO-ANATOMY: A GUIDE FOR THE STUDY OF THE FORM AND INTERNAL STRUCTURE OF THE BRAIN AND SPINAL CORD.—By J. H. Globus, B.S., M.D. Sixth Edition. 1934. Baillière, Tindall and Cox, London. Pp. xv plus 240, with 89 illustrations. Price, 16s.

NEURO-ANATOMY is very definitely a 'special' subject. The textbooks of anatomy and physiology give one some information on it but not sufficient for specialists, or even for the embryo specialists, in psychology, neurology, or nerve and brain surgery.

The subject lends itself very well to the 'atlas' form of treatment, and the book under review is a sixth edition of a neurological atlas that has already made for itself a considerable reputation in America as well as in other countries. One of the features of this atlas is that the diagrams are not heavily labelled; in fact some of them are not labelled at all, so that the student can identify the various structures for himself; this will help him to visualize and memorize them better than if he were 'spoon-fed'. Needless to say the text provides the clue to the identities of these structures so that there can be no danger of misunderstanding arising, if the text is followed intelligently.

The idea of self-instruction is further developed by the inclusion of 53 plates that are 'blanks' of different portions of the central nervous system. The pages are perforated so that the student can tear out each plate, label the different structures, fill in details, and then replace them in the book.

It is a book that should prove very valuable to students, more especially those preparing for one of the higher examinations.

PRACTICAL X-RAY THERAPY.—By H. Davies, M.A. (Oxon.), M.R.C.S. (Eng.), D.M.R.E. (Camb.). J. and A. Churchill, London. Pp. viii plus 134, with 47 illustrations. Price, 8s. 6d.

THIS little book sets forth in a lucid and interesting manner the elementary facts in connection with x-ray therapy.

The preliminary chapters deal with points in connection with apparatus, measurement of x-ray dosage and care of the patient. These are followed by short chapters on the treatment of various diseases which are amenable to this form of therapy, and finally there is an appendix giving a series of depth-dosage tables.

The author does not pretend to deal exhaustively with his subject, but merely to give an outline of the methods used, the aim and scope of x-ray therapy.

The book is thoroughly up to date and, while it can be recommended to the notice of the student and practitioner, it will also be read with interest by the expert.

J. A. S.

THE DERMATOGESSES OR OCCUPATIONAL AFFECTIONS OF THE SKIN.—By Robert Prosser White, M.D., M.B., C.M. (Ed.), M.R.C.S. (Lond.). Fourth Edition. 1934. H. K. Lewis and Company, Limited, London. Pp. xvi plus 716, with 72 illustrations on 66 plates. Price, 35s.

It is sad to have to record that the author died only a few days after going through the final proofs of the fourth edition of this standard work.

This book, which deals with a very difficult and vexed subject, is increasingly in demand with the development of modern industry. It is a mine of information, a veritable encyclopædia on the subject,

and will we feel sure greatly benefit dermatologists, insurance companies and the various industries. The present edition includes a considerable amount of new material, keeping it abreast with the modern developments in industry. There are very few industries which the author has left untouched. The masterly way in which he has dealt with the various physical and chemical agents used in different industries, the chances of getting affected by these agents, and the way these act on the human skin, demonstrate the author's untiring energy, his wide experience and his vast knowledge on the subject. The exhaustive references on every page and an index comprising more than a third of the book will be extremely useful to workers in this field. This has been rendered possible through the efforts of Miss Anne Newbold who is intimately acquainted with the current dermatological literature.

In a treatise like this there are bound to be some points where it is possible to differ from the author's opinion, e.g., we do not agree that industrial irritants cannot give rise to permanent hypersensitiveness—an 'allergic condition'—in a healthy individual. A normal person in our opinion may become permanently hypersensitive to a particular industrial irritant, or 'allergen', to which he was not sensitive previously, and he may continue to remain so for a considerable period of time after the irritant has been removed, sometimes throughout his life; and further he will not only react to that particular irritant, but also to other allied substances.

A simpler style and less use of dermatological terminology would have been better appreciated, but the excellent photographs and admirable coloured plates have amply compensated these minor defects.

L. M. G.

THE COMMON DISEASES OF THE SKIN: A HANDBOOK FOR STUDENTS AND MEDICAL PRACTITIONERS.—By R. Cranston Low, M.D., F.R.C.P. Second Edition. 1934. Oliver and Boyd, Edinburgh. Pp. xiv plus 317, with 150 illustrations—eight of which are in colour. Price, 12s. 6d.

THE introductory sections on the anatomy, physiology and pathology of the skin, on the diagnosis of skin diseases, and on the general principles of their treatment are all very clear and concise, and should prove useful to the student. The different skin conditions with their picturesque but not very useful names are then discussed one by one; these are arranged in groups, some with reasonable classifications, such as, Diseases of Animal Parasites, and Fungus Infections, others with unreasonable ones, such as Scaly Eruptions and Dermatitis and Allied Conditions. These, however, are according to the usual tradition in books on skin diseases and we direct no special criticism at the author on this account. Only the common diseases are dealt with and every attempt has been made to avoid confusing the student by even referring to the rarer skin conditions, a very satisfactory feature for a book of this scope.

The illustrations, many of which are in colour, are of a high quality and should prove useful diagnostic aids. The book is of very suitable size for the student to carry and is altogether eminently suited to his requirements. We can also recommend it to the practitioner.

LYOPHILIC COLLOIDS: THEIR THEORY AND PRACTICE.—By M. H. Fischer and M. O. Hooker. 1933. Baillière, Tindall and Cox, London. Pp. viii plus 246, with 84 illustrations. Price, 22s. 6d.

THE senior author of this book is already a household name among students of colloid chemistry. His attempts however at the application of this branch of the subject to such medical problems as oedema and acidosis are less well known outside of the U. S. A. The book is divided into three parts. Part I deals with the general nature of lyophilic colloids. The

essential difference between lyophilic and lyophobic colloids is clearly explained. The latter, the simpler and better known, may be looked upon as solid particles (disperse phase) in a fine state of subdivision suspended in a fluid medium (continuous phase), e.g., colloidal silver or gold in water. The former consists of particles of a strong solution of, for example, soap in water (disperse phase) suspended in a weak solution of the soap in water (continuous phase). The distinctive feature of this type is that under certain conditions such as lowering of the temperature or withdrawal of water the phases may be reversed and a gel formed. Once this occurs the continuous phase is now the original disperse phase and the new disperse phase consists of droplets of a weak solution of soap in water. At the extreme gel formation these droplets may be completely absorbed by the solid continuous phase. Part II discusses the more or less commercial chemical applications such as the livering of paints and the composition of cosmetics, etc. Part III discusses the biological applications. The authors in part I have shown that the imbibition of water by such lyophilic colloids is conditioned by the presence of acids, alkalis and neutral salts. It is suggested, for instance, that in a condition of acidosis the proteins of the cell combine with the acids, imbibe more water and thereby bring about a condition of oedema. It is further pointed out that as the proteins combine with the acids there may be scarcely any change in the pH of the tissues. The suggestion is interesting in view of the fact that there is still a body of opinion that considers that there is some extra-renal factor in oedema secondary to nephritis, apart from salt retention and cardiac failure. The enthusiastic medical with physico-chemical leanings would do well to remember however that the total water balance of the body is controlled to a certain extent by other factors such as pituitrin and the new extract from the cortex suprarenalis which appears to influence the mobilization of sodium from the tissues to the blood. It is to be regretted that the author has not taken up the physical chemistry of the blood proteins, where the conditions would be less complicated than *in vivo*. The book however should prove suggestive to the serologist. It is clearly written, contains no mathematical formula, and should be comprehensible to anyone with quite an elementary knowledge of chemistry.

H. E. C. W.

A NEW APPROACH TO DIETETIC THERAPY.—By E. Földes, M.D. 1933. Richard G. Badger, Boston. Pp. xii plus 434. Price, \$5.00

This book is particularly well named, as nearly two-thirds of it is devoted to the 'approach', that is to say, to the development of the argument on which the author's theory of dietetic treatment is based. His argument is shortly this: all the functions of the body are governed by simple physico-chemical laws, they are all interdependent on one another, and they can all be influenced, directly or indirectly, by adjustment of the mineral and water retention and elimination. This adjustment can be effected almost entirely by suitable dietary. The diseases in which mineral and water retention plays an important part are discussed, the author's anti-retentional diet is described and explained, and finally a number of cases are quoted in detail in support of the theory.

To discuss effectively the merits and demerits of Dr. Földes' theories it would be necessary to write a book of length equal to the one under review, as this consists of page after page of close argument, each conclusion leading to the next. It cannot be denied that most of the physiological and pathological functions of the body are dependent on physico-chemical laws, but it seems extremely doubtful if they can be explained on the simple physico-chemical laws of osmosis, diffusion and membrane equilibrium as we know them to-day, and in many cases the author's arguments are involved and unconvincing.

It is always a good thing to approach a subject from a fresh angle and Dr. Földes has certainly done this. The dietitian and the biochemist will find the book stimulating. We can also recommend it to the practitioner who always likes to take a view different from that of the majority.

LABORATORY MEDICINE: A GUIDE FOR STUDENTS AND PRACTITIONERS.—By D. Nicholson, M.D., M.R.C.P. (Lond.). Second Edition. Thoroughly revised. 1934. Henry Kimpton, London. Pp. xv plus 566. Illustrated with 124 engravings and 3 coloured plates. Price, 30s.

It is less than four years ago that we had the pleasure of reviewing the first edition of this book. We gave it as our opinion that it would prove useful to the medical profession and it is gratifying to see this opinion vindicated by an early demand for a second edition. We made two minor criticisms, and in the second edition both the defects that called forth these criticisms have been rectified.

A number of additions have been made and a few sections have been brought up to date, especially those on hypogranulocytosis, aplastic anæmias, the classification of anæmias, blood grouping and transfusion, blood calcium and phosphorus, water metabolism, the serum diagnosis of syphilis, immunity tests and immunization in diphtheria and scarlet fever, convalescent serum in poliomyelitis, measles, mumps and whooping cough.

These additions have enhanced the value of this book without adding seriously to the bulk and we can whole-heartedly endorse our previous opinion that it is a book which will be of very great value to the student and practitioner.

L. E. N.

BLOOD DISEASES IN GENERAL PRACTICE.—By A. Pinney, M.D., M.R.C.P. 1934. (Pocket Monographs on Practical Medicine.) John Bale, Sons and Danielsson, Ltd., London. Pp. 92. Price, 2s. 6d.

This pocket monograph series of books on practical medicine has proved a great success, and we must congratulate the publishers on their enterprise. However, it cannot have entailed any great mental strain on their part to think of the name 'Pinney' when the question of a book on blood diseases arose; they are fortunate in having been able to negotiate the next step successfully.

It is quite impossible to dismiss the subject of blood diseases in twenty-five thousand words and the author has necessarily had to skate rapidly over the surface. The information he has given is up to date and will be found valuable by the practitioner. The question of ætiology is not gone into to any great extent. Suggestions for treatment are made, but they are seldom explicit; some readers will be disappointed by this. No attempt at classification of the anæmias has been made; it was probably thought that this would be out of place in a book written mainly for the practising doctor, but we cannot help feeling that the only way that a proper grasp of the ætiology, and therefore indirectly of the treatment, of the anæmias can be obtained is by classifying them. This is by no means the best example of the books of this series, but nevertheless practitioners will find it very useful indeed.

L. E. N.

A TEXTBOOK OF PHYSIOLOGY FOR MEDICAL STUDENTS AND PHYSICIANS.—By W. H. Howell, Ph.D., M.D., Sc.D., LL.D. Twelfth Edition. 1933. W. B. Saunders Company, Philadelphia and London. Pp. 1132, with 308 illustrations. Price, 32s. 6d.

HOWELL'S is one of the best known of the American textbooks on physiology. It was first published about thirty years ago, and it has gone through twelve editions and an equal number of reprintings during

this period. The subject is such a vast one that it is difficult to keep a textbook within reasonable dimensions; the temptation to add to the chapters rather than to revise and rewrite them must be considerable. During the period of three years since the last edition advances have not been made in every branch of the subject so that it has only been necessary to revise certain sections, e.g., those on the vitamins, on the hormones, and on the chemistry of muscle contraction, but these sections have been recast and not simply patched. In a subject like this it is very difficult to pick out significant advances in our knowledge for inclusion, knowing as one does that even these now significant advances have not carried us to finality, but are simply steps which will in their turn be forgotten. The author seems to have achieved this very successfully, and to have written a well-balanced book.

The book is of a useful size, the print is clear and not too small, and there are a number of well-chosen diagrams and other illustrations. It is altogether a very satisfactory book for the student.

THE NEW-BORN BABY. A MANUAL FOR THE USE OF MIDWIVES AND MATERNITY NURSES.—

By E. Pritchard, M.A., M.D. (Oxon.), F.R.C.P. (Lond.). 1934. Henry Kimpton, London. Pp. xl plus 272, with 9 illustrations. Price, 4s. 6d.

INFANT-WELFARE work in India suffers much from the lack of liaison between the teaching given to health visitors and to midwives on the care of the new-born baby. Insufficient attention is paid to the preparation of the midwife for this aspect of her duties during the lying-in period, and the little book *The New-Born Baby* from the authoritative pen of Dr. Eric Pritchard is a valuable guide to the scope and nature of the knowledge which the pupil midwife and the medical student alike should acquire during their term of service in the maternity wards.

The book is easy to read and since it is full of personal preferences, with reasons annexed, it is never dull. The chapters on the value of correct education of the respiratory, circulatory and digestive systems and on the training of the heat-regulating mechanism are specially useful and some interesting suggestions are made on the relationships between vitamin deficiencies and the occurrence of 'pink disease' and hæmorrhages in the new-born.

The book is written to fill a gap which has been viewed by the author from both sides, that is, in his double capacity of consultant to a midwifery training hospital and to a welfare clinic, and if widely used, as it deserves to be, it will do much to help the midwife and health visitor to give the correct advice to the lying-in and nursing mother, respectively: the advice now given is seldom uniform and often conflicting. Its use will also hasten the day when the full usefulness of the maternity and child-welfare services will be experienced.

J. M. O.

MIDWIFERY FOR NURSES.—By R. Andrews, M.D., B.S. (Lond.), F.R.C.P. (Lond.), F.C.O.G., and Victor Lack, M.B., B.S. (Lond.), M.R.C.P., F.R.C.S. (Edn.), M.C.O.G. Seventh Edition. 1934. Edward Arnold and Company, London. Pp. viii plus 268. Illustrated. Price, 6s.

THIS book contains the essentials of midwifery for nurses expressed in a particularly clear and concise manner without irrelevant details and with a minimum of scientific terms. It should be of great value as a short textbook for midwives.

The emphasis throughout is on the normal and practical side of the subject. The chapters on puerperal sepsis and eclampsia are rather poor in detail from the point of view of practice in India, and the chapter on contracted pelvis is written entirely from the point of view of practice amongst Europeans. But with these

modifications in mind, the book might well form a basis for teaching purposes in India, for the fundamental principles are insisted upon and particularly clearly and simply expressed.

M. I. N.

MOTHERHOOD *: A GUIDE FOR MOTHERS. Fourth Edition. 1934. Published by Messrs. Cow and Gate Limited, Gullford, England. Pp. 246. Illustrated. Price, 1s.

MESSRS. COW AND GATE have issued a fourth edition of their small book *Motherhood*. It is attractively produced and interestingly written and a thoroughly reliable guide to mothers in the care of their own health and that of their babies. The methods of production and the advantages of 'Cow and Gate' milk are naturally given prominence in the chapters on artificial feeding and an appendix gives an account of the uses of various other 'Cow and Gate' products, but the book in addition contains a fund of sound advice on the general management of babies and the treatment of minor ailments.

A MEDICAL SURVEY OF ADEN, 1933.—By Lieut.-Colonel E. S. Phipson, D.S.O., M.D. (Lond.), M.R.C.P. (Lond.), D.P.H., D.T.M. & H., I.M.S. 1934. Cowasjee Dinshaw and Brothers' Press, Aden. Pp. 90, with 9 plates

IN the minds of those of us whose homes are in Europe and whose work is in India, Aden occupies a significant place. When we leave our own countries for the 'glamorous' east, we may think that Port Said, with its Selfridge-like store on the front and its entertainments so obviously arranged for the tourist, is a bit of a fraud, but Aden, with its heat, its dust, its smells and its camels, is, we feel sure, the real thing. And likewise when we retire after many years of toil, Aden again looms very large; it is where we give rupees and receive change in annas for the last time, and if we are theatrically disposed it is where we throw our topes overboard as the ship sails out of the harbour. To the writer, who long since made his first voyage and will, he hopes, not make his final one for some years, Aden still has a significance, as it is where the port health officer, the civil administrative medical officer, and the medical officer in charge of the European civil hospital, in the person of one extremely cheerful individual, always comes (or come) on board. One speculates for the rest of the voyage on how, in this very trying climate with such exacting duties, he manages to maintain this cheerfulness. Perhaps it is the multifariousness of his duties which prevent him from brooding over the heat. One of his recreations appears to be authorship and Colonel Phipson has written a most readable and interesting account of the medical administration of Aden, with particular reference to the last ten years, during which time he has served there continuously.

We will not discuss this book in detail here, as we have made an abstract from it which will be found in a subsequent number of the *Indian Medical Gazette*.

We recommend our readers to obtain a copy of this book, which we hope is on sale in Aden, when next they arrive at that port. It will add considerably to their possibly-flagging interest in this isolated spot on the edge of the Arabian desert.

[*We have been informed by Messrs. Cow and Gate that the book can be obtained for Re. 1 (post free) to any destination in India from their Agents in India who are Messrs. Carr and Company, Limited, Ballard Estate, Bombay, from their Agents in Burma who are Messrs. E. Solomon and Sons, 460, Dalhousie Street, Rangoon, and from their Ceylon Agents who are Messrs. Miller and Company Limited, Colombo.—Editor, I. M. G.]

Abstracts from Reports

LEAGUE OF NATIONS HEALTH ORGANIZATION, EASTERN BUREAU. ANNUAL REPORT FOR 1933 AND SUMMARY OF PROCEEDINGS OF THE EIGHTH SESSION OF THE ADVISORY COUNCIL HELD AT SINGAPORE, 5TH AND 9TH FEBRUARY, 1934

DIRECTOR'S REPORT ON THE WORK OF THE EASTERN BUREAU FOR THE YEAR 1933

Advisory Council

THE Advisory Council met at the offices of the Bureau, Singapore, on 29th March, and continued its deliberations until Saturday, the 1st April. A short summary of the proceedings, together with the resolutions, was printed with the report for 1932. The Council, on the last day of the session, appointed Dr. Hermant, Inspector-General of Medical and Health Services, Indo-China, as Chairman for the ensuing year and Dr. Wu Lien-teh, Director of the National Quarantine Service of China, Vice-Chairman. The meeting of the Council was attended by delegates from each country represented upon it, with the exception of British India. The Council was pleased to have the assistance, in addition, of delegates from Hong Kong, Philippine Islands and Straits Settlements.

In December, Lieutenant-Colonel Russell assumed office as Public Health Commissioner with the Government of India in succession to Major-General Graham. The latter was the first Chairman of the Advisory Council and retained this position for the first four years of the Council's existence. His absence from future Council meetings will be much regretted by the other members and by the officials of the Bureau, who have received unflinching support from him throughout his connection with its work. It is understood that Colonel Russell will in future represent British India on the Council.

In view of the fact that less than twelve months would have elapsed if the meeting of the Council for 1934 were held at the ordinary time, early in February, it has been decided not to convene a full meeting of the Council in the early part of 1934. It is hoped, however, that the Chairman and Vice-Chairman will be able to consult with the Director in regard to the programme for 1934 and that an opportunity may present itself during the meeting of the Far Eastern Association of Tropical Medicine, later in the year, for Members of the Council to hold at least an informal discussion regarding the working of the Bureau. It will be remembered that, when the constitution of the Advisory Council was under consideration, a suggestion was approved that at intervals a meeting of representatives of all health authorities in the Eastern zone should be held, in addition to meetings of the Advisory Council. Although this question has been previously raised at meetings of the Advisory Council it has so far not been carried into effect. It is, however, under consideration as to whether it may be possible to organize such a meeting during 1935. If this could be done, the opportunity would present itself for a discussion on rural hygiene in the Far East, in regard to which a considerable amount of information has already been forwarded by various countries to the Bureau.

Fourteenth Assembly

The report of the Health Organization, which was submitted during the Fourteenth Assembly at Geneva, contains a reference to the extension of the National Quarantine Service of China, by reason of which the Eastern Bureau was able to obtain more rapid information regarding the epidemiological situation of the

ports under Chinese control. It also referred to the decision of the Advisory Council in favour of creating at Singapore, under the auspices of the Health Organization and in collaboration with the Government of Straits Settlements, an international course of malariology, the theoretical and laboratory work of which would be carried out at the Medical College at Singapore.

Epidemiological intelligence

This service continues to be the main purpose of the Bureau's existence. Since 1925, when the Bureau first commenced to function, efforts have been directed towards the improvement of this service, and these efforts have met with such success that the only real shortcomings at the present time are a lack of cabled information in regard to the situation in Vladivostok and incomplete knowledge of the exact situation in certain inland provinces of China and in British Indian States.

Correspondence has taken place with the authorities in French India with regard to the possibilities of expediting weekly returns, which at present are received somewhat late. Arrangements have been come to by which cabled information, and also information sent by post, will be despatched at such time as will enable the Bureau to receive it at the same time as it reaches the Minister for the Colonies in Paris.

Disease incidence—Plague in ports

Compared with the previous five years the incidence of plague in Eastern ports has been relatively slight. This applies more particularly to ports in the Near East, such as Alexandria, Port Said, Suez and to Tamatave. It also applies to Rangoon and, to a lesser extent, to Colombo.

Rodent plague

The degree to which attention was paid to examination of rodents for plague infection varied in different ports. The returns showed that 4,000 or more rodents were examined each week in Bombay, and it was rarely that all rodents were found to be free from infection. The extent of the rodent infection varied definitely with the season, a noticeable increase in the number found in Bombay being seen during the latter half of February and throughout March and April. From the end of April onwards the number found infected remained much smaller. Plague-infected rodents have been detected in Bassein, where the greatest number was found in April and May, but where odd infected rats were discovered throughout other portions of the year. In Rangoon, however, where plague-infected rodents have been found during the year, the most noticeable feature has been the absence of infection amongst those examined from the middle of February until the end of June, although the number examined remained steady during that period. Colombo has found at intervals infection amongst the rodents, but here, as in Rangoon, none was detected during the months of March, April, May and June.

General

The returns from ports show that plague infection is confined to a few only, but that these are endemically infected, with seasonal exacerbations in certain cases. The danger of transfer from these ports varies however. Bombay has a large export trade in raw cotton which has been shown to be a suitable medium for transfer of plague infection, while the main export from Rangoon and Bassein consists of rice. This again is incriminated as a medium suitable for plague transfer. Ceylon, on the other hand, exports tea, rubber, coconuts, etc., products which are not regarded as being in the category of rat-attracting cargo. Bangkok being the centre for the export of rice from Siam, and Saigon for Indo-China, are both potentially dangerous, as is also Phnom-penh. There is, however, a marked difference in the volume of merchandise exported from these

ports. For example, Bassein, though situated in the delta region of the Irrawaddy, and being a collecting centre for rice, is only a minor port compared with Rangoon, through which over 80 per cent of the trade of Burma passes. Pnom-penh is accessible to ocean-going vessels, and, although of much less commercial importance than Saigon, it has a large trade with the latter port and may be a source of plague infection of even more importance. It is a noticeable fact that the principal port in British India from which raw cotton is imported, as well as the principal ports of the chief rice-exporting countries of the East, namely, Burma, Siam and Indo-China, are the plague centres of the East.

Plague in countries—British India

The mortality curve for 1933 differs from that constructed from the mean mortality figures for the preceding five-year period. The latter curve shows an increase in prevalence through January and February, to reach an apex in March, which is maintained until April, after which it falls quickly and the minimum level occurs during June. This is followed by a gradual but definite rise throughout July, August, September and October, and from then on to the end of the year. In 1933, however, the mortality remained at an almost constant level throughout January, February and March, and at a much lower level than the mean of the preceding five years. The tendency to fall throughout April and May was present and the lowest level was reached in June. From this time onwards, however, the mortality figures have risen more sharply than in the previous five years and the mortality has been much higher.

The provinces in which plague occurs are mainly three, Bombay, United Provinces and Punjab. The alteration in the mortality curve is explained by a comparison of the seasonal prevalence for the year in these, and, to a lesser extent, in certain other provinces with that of the mean for the preceding five years.

The maximum seasonal prevalence in United Provinces occurs in March, that of Punjab in April and of Bombay in October, while Central Provinces and Bihar and Orissa also have their highest mortality in February and March. In 1933, however, the mortality in the United Provinces was much below the average, reaching a maximum figure of 150 deaths only in the week of heaviest mortality as compared with the mean maximum of 1,850 deaths in one week for the preceding five years. The plague situation at this period of the year in this province was thus the principal factor in determining the shape of the curve for British India as a whole for the corresponding period.

Indian States.—The returns from the Indian States are incomplete, but the States of Hyderabad and Mysore and the Indian States in Bombay Presidency have shown a considerable mortality. In the group of Indian States and agencies, which includes the Indian States in Bombay Presidency, there was a heavy mortality in January, February and March, followed by a minimum mortality in April and May. This was followed by a marked rise to maximum figures at the end of August. Again, towards the end of October, a very high mortality was recorded which was due probably to the influence of the Bombay States, which have recorded a higher mortality in 1933 than in any of the preceding five years.

Cholera in ports—British India

Consideration of cholera in Eastern ports in 1933 resolves itself mainly into a chronicle of events in Calcutta, which, as usual, has been infected throughout the year. The disease has followed the usual course fairly closely and consequently has shown a marked tendency to increase in prevalence in the latter half of March, which tendency is continued sharply throughout the month of April in the last week of which the peak was reached. During May and June a marked fall in the number of cases occurred, and,

from the middle of June onwards, the disease has continued, but in endemic form. Compared with the curve showing the mean for the previous five years, 1933 has shown a higher peak which was reached about two weeks earlier than that for the quinquennial mean. This increased incidence has been quite considerable being approximately 25 per cent above the average for the previous five years.

Among other ports of British India, *Chittagong* has shown a much heavier incidence than in 1932, but this year's record, however, compares very favourably with 1931. The greater proportion of the cases in 1933 occurred in April and May, although sporadic cases were reported at intervals throughout the year.

Madras, which, during the five years preceding the one under review, was heavily infected in 1928 and in 1931, was entirely free from the disease from March 1932 until the last week of October 1933. After this, and until the end of November, sporadic cases were reported, but at the beginning of December the disease appeared in epidemic form, but quickly abated, the epidemic prevalence disappearing by the middle of December.

The other ports of British India from which cases were reported include *Bombay*, *Moulmein* and *Rangoon*, in each of which sporadic cases only were recorded. The same condition of affairs prevailed at *Vizagapatam*, where the cases were practically confined to the weeks ending 29th July to 12th August.

Cholera in countries—British India

Cholera has been very light in British India as a whole during 1933. Compared with the mortality for the preceding five years the disease this year has caused deaths which are only approximately one-tenth the mean figure of the preceding quinquennial period. Russell has drawn attention to the tendency of cholera in India to follow a six-year cycle, but points out that adherence to this cycle is not necessarily constant, nor does this tendency explain the problems associated with the epidemiology of the disease.

In many of the provinces—e.g., Bihar and Orissa, United Provinces, Central Provinces,—the year 1930 showed the highest mortality for the quinquennial period 1928—1932. The year 1930 was also the year of maximum mortality in Bihar and Orissa, United Provinces and Central Provinces for the six-year period 1925—1930, whereas Bengal and Madras Presidency reached their peak in 1928, and Bombay and Punjab in 1927. It is probable that 1933 was at the bottom of the cholera cycle but the number of deaths has fallen so very rapidly since 1930 as to suggest that several favourable factors were at work.

The position, compared with 1932, is that cholera mortality showed over the whole year a definite rise in Central Provinces and Bombay Presidency and a definite decrease in Bengal and Madras Presidencies as well as a slight decrease in Assam and in Bihar and Orissa.

The graph shows that there was the usual tendency towards an increase of mortality in March, but the mortality, instead of continuing to rise sharply in April, remained steady for the first three weeks and then decreased to a minimum in June. This was followed by a steady rise throughout August, September, and the early part of October, before the fall commenced later in that month. The explanation of this variation in the graph from that of the quinquennial mean is seen when those for individual provinces are studied.

Burma

The situation in Burma in regard to cholera in 1933 has been extremely favourable when compared with the mean mortality of the preceding quinquennial period. The picture for that period is of steady mortality throughout the year with a maximum in April. During the last quarter of 1932, however, the mortality was practically non-existent, and this happy state of affairs was continued throughout January and

February of 1933. Throughout April, May and June there was some increase, with maximum figures in July which were much below the average. From August onwards only sporadic cases have occurred.

Smallpox in ports

The early part of 1932 was particularly notable for the epidemic prevalence of smallpox throughout Eastern ports.

Between Alexandria in the Near East and Hong Kong in the Far East many ports recorded a greatly increased prevalence of the disease as compared with the records of the preceding five years. In *Alexandria* the epidemic which commenced in December 1932 increased steadily in January, to reach a peak in the early part of February 1933. The epidemic prevalence fell sharply throughout the remainder of February and through March, and was completely finished in April.

General

A noticeable feature of the returns is the almost complete absence of cases from certain ports of British India, e.g., Chittagong, Moulnicin and Tuticorin. The records of the previous five years show that cases are rarely recorded in *Chittagong*, but *Moulnicin* had in 1928, 1929 and 1930 small epidemics, while *Tuticorin* was visited similarly in 1932.

Smallpox in countries—British India

The year 1933 has been an unfavourable smallpox year in British India, and this fact was seen very early in the year when the high incidence which had developed in the last quarter of 1932 was continued. The peak was reached in April, being a little later than had been the average for the preceding five years. The normal sharp decrease in numbers took place in May and June, with the onset of the south-west monsoon, and this has continued through the succeeding months until October, when an increase commenced.

The mortality in most of the provinces has been higher in 1933 than 1932, and particularly has this been the case in Delhi, Bengal, Bombay and Bihar and Orissa.

Research programme—Plague

Dr. Hirst's contributions to the study of plague epidemiology have been further added to during the year by the publication of the results of 'A Rat-Flea Survey of Ceylon' which contains also 'A Brief Discussion of Recent Work on Rat-Flea Species Distribution in relation to the Spread of Bubonic Plague in the East Indies'. The author expresses the view that the conclusion reached by King and Pandit that 'the flea species factor is of the first importance in the spread of plague' in South India applies equally well to Ceylon.

China.—The rat-flea survey at Shanghai has been continued throughout the year. Of the two prevailing species of rats, *R. rattus* and *Rattus norvegicus*, the former was many times more numerous than the latter throughout the period. The highest flea index was recorded in the month of May, but relatively high figures were also recorded in October, April and December. *Leptopsylla musculi* was the prevailing species, but the presence of *Ceratophyllus anisus* was also determined regularly, with a maximum index in April and May. *X. cheopis* was absent during March, April and June and only a few of the species were found in January, February and May. The index, however, which was 0.01 in May and 0.00 in June was 0.1 in July, 0.75 in August, 0.3 in September and 0.59 in October. The rise in August was more noticeable in that *X. cheopis* was practically the only flea species present during the month. During July and August the mean temperature was 83.7°F. with a mean relative humidity of 82.3 in July and 79 in August. The rainfall was just over two inches in July, but in August was 5.4 inches.

Cholera

Asheshov, in his report for 1932-33 on the Bacteriophage Enquiry, states that he has 'chosen the problems to be studied in such a way that the results obtained might directly help the practical application of bacteriophage'. Some of these problems deal with the results of cultivation on vegetable and synthetic media, the influence of hyperaerobic conditions on virulence, the preparation of pure cholera phage antigens free from vibrio substance, the degree of absorption of cholera phage, the influence of carbohydrates and the development of cholera phage, and the continuation of the search for cholera phage races which are at the same time virulent against the common intestinal bacteria.

Bacteriophage

The biological nature of bacteriophages has been the subject of discussion by Burnet and others. The former concludes: (1) that bacteriophages are independent micro-organisms, viruses which are obligate parasites or symbionts of bacteria, and (2) that there are many different types of bacteriophage which may differ widely in particle size, as well as in almost every activity by which a phage can be characterized.

Andrews and Elford, using filtration methods, have calculated the physical measurements of bacteriophages and find the diameter of the smallest one yet examined identical with that found by the same methods for virus of foot and mouth disease. The size of any one bacteriophage has been found to be remarkably constant and uniform, independently of the nature of the bacterial organism which it attacks, and it is unchanged by purification (Report of Medical Research Council, 1931-32).

Shanghai.—Investigations carried out during the year in Shanghai indicated that practically all samples of 'non-waterworks' water examined, i.e., water from rivers, creeks, ponds and wells, contained non-agglutinating water vibrios. Experimental work is being carried out to determine what happens when true cholera vibrios, water vibrios and mixtures of both are added to water of various kinds. Water vibrios are being grouped according to the scheme established by Finkelstein, and interest is naturally centred on the degree of relationship, if any, which exists between the different groups of vibrios.

Bacteriophage.—Evidence of cholera phage was found in two river and four creek samples examined.

Carriers.—No carriers were found among over 500 specimens of stools examined from hospital inpatients.

Meteorology.—A great deal of meteorological data has been obtained, and from an analysis of this it is possible to show that, in the last seven years, high absolute humidity favours cholera epidemics, but is not always followed by them. Charts from a number of ports showed that cholera only became epidemic when the absolute humidity was above 0.4 in. (cf. Rogers). Deficient winter and/or spring rainfall is apt to be followed by an outbreak of cholera, whereas heavy rainfall appears to have the opposite effect. As the spring of 1933 had a high rainfall, the conditions seemed favourable for a light cholera year, which was actually the case.

Cyclical tendency.—A study of cholera epidemics in Shanghai has also suggested an indefinite four-yearly epidemic cycle.

Calcutta.—Linton's further work in Calcutta tends to establish a closer relationship between water vibrios and true cholera vibrios. Previously it had been thought that water vibrios were distinguishable by having an arabinose-containing carbohydrate, while pathogenic forms had a galactose-containing substance. This is not now found to be a distinction in that two strains from clinical cases of cholera have been found to be arabinose-containing.

Pasricha, de Monte and Gupta have produced experimental evidence that, in regions like Calcutta where cholera is endemic, there exist bacteriophages under the influence of which in the laboratory certain strains

of atypical non-agglutinating vibrios can acquire the property of agglutination with cholera specific serum.

They conclude that vibriophages play an important part in the epidemiology of cholera and that they are one of the important factors in bringing about a regeneration of degenerated cholera vibrios.

REPORT ON AN INVESTIGATION INTO THE CAUSES OF MATERNAL MORTALITY IN THE CITY OF MADRAS. BY A. L. MUDALIYAR, M.D., F.C.O.G. GOVT. PRESS, MADRAS. PRICE, 12 Annas

The need for inquiry into the factors influencing maternal mortality has been generally appreciated in western countries and in most investigations similar to that reported by Dr. Mudaliyar have already been completed. It may safely be said that western countries have for the moment little more to learn from statistical surveys and that their concern now is to put into operation recommendations based on established data. In India accurate statistical knowledge of the immediate and remote causes of abnormal pregnancy and difficult labour or the results therefrom simply does not exist and the present report is welcome not only for its intrinsic value as the first complete survey of the problem as it exists in one large city in India, but as an indication that the time is not far distant when province as well as city will set itself to a consideration of how improvement in the circumstances of childbirth can be effected.

The inquiry lasted over a twelve months' period; 436 maternal deaths were investigated and recorded on the form represented in appendix I. Dr. Mudaliyar does not claim absolute accuracy either for the figures, the diagnosis of the cause of death, or for the assessment of the point at which failure in the care of the patient first occurred. Lack of medical certification, the time interval between the death and the investigation, the ignorance, prejudice and superstition of the relatives, together with the unreliability of their statements, preclude such a claim, but despite these acknowledged handicaps the report contains a large amount of valuable information and permits conclusions of a reasonable degree of reliability to be drawn.

The maternal mortality rate per 1,000 births is given as 16.6 which the author considers represents rather less than the actual state of affairs. That pregnancy and parturition are often overlooked as primary or as secondary causes of death is evident from the difference in the figures supplied by the M. O. H., namely 29.3, and those investigated by the author, namely 43.6, within the same period. The principal causes of death are given as sepsis 29.6 per cent; hæmorrhages, 12.7 per cent; anæmia of pregnancy, 11.5 per cent; and toxæmias of pregnancy, 9.9 per cent.

Diseases and accidents of pregnancy and puerperium account for 23.4 per cent of deaths, the outstanding single cause being the dysenteries, which accounted for 31 per cent of these.

The primary avoidable factor, the first point at which the management of the pregnancy went wrong is considered, as in the Ministry of Health Reports, under four headings—lack or inadequacy of antenatal care, error in judgment, lack of reasonable facilities, and negligence of the patient and her friends. The percentage of deaths attributed to this factor is 53.44, the outstanding factors being the complementary ones of lack of antenatal care and negligence of the patient or her friends. Out of 436 women, 313 were never examined antenatally, 62 were seen only in the last week of pregnancy and in many other cases the care was wholly inadequate. One hundred and one deaths are classed as due to failure of antenatal care and 62 as due to negligence of the patient. The difference in English and Indian figures under this heading are striking.

Age, 'parity', the spacing of pregnancies, social circumstances in their bearing on maternal mortality are

reviewed in part II of the report. The graph facing page 20 is very instructive and justifies the stress laid by the author on the need for 'a deeper understanding of the necessities of the multipara', a greater regard for 'the spacing of pregnancies' and the value of contraceptive measures.

The rôle of the maternity institution is considered in detail and the need for efficiency in administration, staffing, planning, and equipment as well as sufficiency of accommodation receives a much-needed emphasis. Thirty per cent of the total confinements take place in institutions but as the number of beds available for maternity cases is unfortunately not given and it is impossible to gauge whether the degree of overcrowding, with its attendant dangers, is as serious in Madras as in other cities.

The midwife is recognized as the all-important factor in promoting better midwifery and much space is devoted to the important subject of the health and character, educational qualifications, training and employment of one on whom fall heavy responsibilities for the life or death and the subsequent health of the mother. Dr. Mudaliyar does not apparently contemplate the training of the indigenous dai even as a stopgap. It seems that he will allow her to continue her dangerous trade without let or hindrance until she can be ousted by the trained midwife. His plan presupposes a sufficient supply of good material to be trained and sufficient training schools of a satisfactory high standard to train it—an ideal not likely to be reached for years to come in many parts of India.

The conclusions drawn by the author are that the chief drawbacks to organized attack on the maternal mortality problem are lack of co-operation between the various agencies, namely, general public, doctors, midwives, municipal maternity and child-welfare schemes and institutions and the lack of a proper personnel and trained staff to run the services. He quotes Sir George Newman's remark that no administrative scheme can change errors in judgment, technique and management and points out the danger of rushing through projects for better maternity without proper safeguards in the direction of staffing.

In connection with the plea for a uniform standard of statistics, the warning given in an earlier chapter on the futility of relegating the compilation of vital statistics to clerks and to those who have neither the interest nor the intelligence to appreciate their real worth might very well be repeated. Health officers, judging from the reports, only too readily offend in this matter.

The report is the work of an authority; it deserves careful study and one hopes it will provide the much-needed stimulus to set on foot a widespread movement for the improvement of the midwifery services in India.

ANNUAL REPORT ON THE WORKING OF HOSPITALS AND DISPENSARIES UNDER THE GOVERNMENT OF BENGAL FOR THE YEAR 1932. BY COLONEL A. H. PROCTOR, D.S.O., V.H.S., M.D., I.M.S., SURGEON-GENERAL WITH THE GOVERNMENT OF BENGAL (OFFG.)

This report, apart from the general data of hospitals, dispensaries, incidence of disease, mortality, etc., should be of interest to those concerned with medical education and the whole future of scientific medicine in India.

CALCUTTA HOSPITALS AND DISPENSARIES

Number of institutions.—Forty-four hospitals and dispensaries including the Howrah General Hospital were working in Calcutta at the beginning of the year under report. No new dispensaries were opened nor were any of the existing ones closed during the year.

Patients treated.—Altogether 860,540 patients were treated in the Calcutta institutions, 57,177 were inpatients and 803,363 outpatients as compared with a total of 801,150, viz, 55,063 indoor and 746,087 outdoor

patients, in the previous year; thus there was an increase of 59,390 patients, which is mainly due to an increasing appreciation of scientific medicine and the general popularity of the Calcutta institutions.

Nursing.—On account of the financial difficulties of the Calcutta Hospital Nurses' Institution the recruitment of probationers was stopped from January till August 1932. Although it was re-opened, the nursing staff at the Medical College Hospitals remained insufficient throughout the year. Moreover the number of extra beds increased considerably, especially in the diphtheria and female wards of the Medical College hospitals, thus greatly increasing the work of the already overworked nurses.

It is pointed out that the stoppage of recruitment of probationers is now beginning to be felt in the lack of senior nurses.

DISEASES

Cholera.—The outbreak of cholera in the year 1932 was of a comparatively mild character. The total number of cases treated for this disease was 2,448 against 2,427 in 1931. The mortality among the indoor patients was 536 against 461 in the previous year.

Dysentery.—There were 14,588 patients treated for dysentery during the year under report against 15,020 in 1931, i.e., a decrease of 432 patients. The number of deaths recorded in the indoor department was 236 against 293 in the previous year.

Kala-azar.—Four thousand seven hundred and sixty-four patients were treated against 6,322 in 1931, showing a decrease of 1,558. There were 90 deaths against 115 in the previous year.

Malaria.—The total number of patients treated was 65,467 against 59,227 in the preceding year, showing an increase of 6,240; the number of deaths being 130 as compared with 101 in 1931.

Leprosy.—One thousand four hundred and thirty patients were treated for leprosy in the general hospitals against 1,278 in 1931—an increase of 152 cases. Only 12 cases were treated in the indoor wards with no record of death.

Influenza.—There was a noticeable increase of influenza cases during the year under report. A total number of 28,169 patients were treated in the Calcutta hospitals in 1932 against 25,733 during the previous year—an increase of 2,436 patients.

Smallpox.—This disease prevailed in a rather milder form during the year under report. The number of cases recorded for this disease in the Calcutta hospitals and dispensaries was 391 against 501 in 1931—a decrease of 110. In the indoor wards there were 273 cases with 92 deaths against 424 with 140 deaths in the preceding year. The death rate was 33.70 against 33.02 in 1931.

Tuberculosis of the lung.—The total number of patients suffering from this disease was greater than that of the previous year, viz, 10,035 as against 8,525 in 1931. The largest number of patients was treated in the Medical College hospitals, viz, 4,261 against 2,848 in the previous year. Next comes the Campbell hospital with a record of 1,088 cases against 1,278 in 1931. In the indoor wards of the Calcutta hospitals there were 1,131 cases with 421 deaths against 1,367 cases with 611 deaths in the preceding year.

Beri-beri.—The total number of patients treated for this disease during the year under report was 3,247 as compared with 1,854 cases in 1931, showing an increase of 1,393 cases. Among the indoor patients there were 29 deaths against 3 in 1931.

Diseases of the eye.—The total number of patients treated for the diseases of the eye was 78,372 against 71,897 in the preceding year—an increase of 6,475. The eye department of the Medical College hospitals treated the largest number of these patients, viz, 32,866 against 28,578 in 1931. The increase is an indication of the popularity which the eye departments of the Calcutta hospitals, especially of the Medical College hospitals, are gaining year by year.

Diphtheria.—A separate arrangement for the treatment of diphtheria cases exists in the Medical College hospitals. The total number of cases treated in the Medical College hospitals was 174, of which 165 were inpatients and 9 outpatients. The mortality among the inpatients was 89 or 53.93 per cent.

Veneral diseases.—The total number of patients treated for all sorts of venereal diseases in the indoor and outdoor departments of the Calcutta hospitals was 31,190 (22,646 males and 11,544 females) as compared with a total of 28,123 (20,824 males and 7,299 females) in the preceding year. Of these 9,272 males and 4,281 females suffered from gonococcal infection, 8,424 males and 4,643 females from syphilis, and 4,950 males and 2,620 females from other diseases of venereal origin.

Surgical operations.—During the year under review, 59,181 operations were performed on 49,958 patients in all classes of Calcutta hospitals as compared with 58,847 operations on 50,012 patients in the preceding year. The number of fatal cases was 679 against 487 in 1931.

MOFUSSIL HOSPITALS AND DISPENSARIES

Number.—The year opened with 1,178 allopathic, 67 homœopathic, 19 ayurvedic and 9 unani dispensaries in the districts outside Calcutta. The number of allopathic institutions newly opened during the year was 31 and the number closed 9. Of the newly-opened institutions 26 were local fund, 4 private non-aided and 1 railway dispensaries. Of the number closed, there were 1 state public, 1 local fund, 6 private non-aided and 1 railway institutions. The newly-opened institutions following systems of medicine, other than allopathic, comprised of 2 homœopathic and 2 ayurvedic dispensaries. Of the number closed 5 were homœopathic, 6 ayurvedic and 4 unani. The year thus closed with 1,200 dispensaries giving treatment in allopathic system of medicine and 84 dispensaries following systems of medicine other than allopathic, viz, 61 homœopathic, 15 ayurvedic and 5 unani.

Patients treated.—The total number of patients, indoor and outdoor, treated in all classes of dispensaries, including the temporary and subsidized, etc., outside the town of Calcutta, stood at 9,083,248 as compared with 9,190,434 in 1931, i.e., a decrease of 107,186 patients.

DISEASES

Cholera.—The outbreak of cholera in 1932 was of a comparatively mild character. The total number of cases treated for this disease was 5,521 against 10,510 in the preceding year, i.e., a decrease of 4,989 cases. The mortality among inpatients was 201 as compared with 325 in the previous year showing a decrease of 124.

Dysentery.—A decrease is noticed in the number of cases treated for this disease. There were 195,494 patients in 1932 against 208,870 in 1931—a decrease of 13,376. Only 380 deaths were recorded against a total of 534 in the previous year.

Kala-azar.—The total number of patients treated during the year in the mofussil hospitals and dispensaries for this disease was 55,763 against 60,083 in the previous year, showing a decrease of 4,320. The number of deaths from this disease was 255 against 228 in 1931.

Malaria.—This is the most common disease and accounts for the largest number of patients treated. There was a considerable increase in the number of cases during the year over that in the foregoing year, viz, 2,726,313 in 1932 as against 2,697,076 in 1931, i.e., an increase of 29,237 cases.

A decrease is however noticed in the mortality figure, viz, 285 in 1932 against 340 in the preceding year.

Influenza.—The number of influenza cases showed a noticeable decrease during the year under report. The number of cases came down from 176,753 in 1931 to 132,236 in 1932—a decrease of 44,517 cases.

Smallpox.—The disease appeared in a non-epidemic form during the year under review. Altogether 464

cases were treated in the mofussil hospitals and dispensaries in 1932 as compared with 725 in the previous year—a decrease of 261 cases. The total number of deaths recorded was 29 against 31 in the preceding year.

Tuberculosis of the lung.—The total number of patients treated for this disease in the mofussil hospitals and dispensaries was 11,914 against 11,886 in 1931. The deaths among inpatients were 311 against 297 in the previous year.

Beri-beri.—A sudden rise is noticed in the number of cases treated for this disease in the mofussil areas. The number during the year under report was 5,436 as compared with 1,349 in 1931—an increase of 4,087 patients. The total number of deaths recorded was 18 against 11 in 1931.

Veneral disease.—The number of patients treated for this class of disease as compared with that of the previous year is given below:—

	1931		1932	
	Male	Female	Male	Female
Gonococcal infection.	29,897	6,565	27,875	6,597
Syphilis ..	18,031	5,646	17,165	5,689
Other diseases of venereal origin.	7,618	2,903	8,803	3,576
TOTAL ..	55,546	15,114	53,843	15,862

The number of deaths occurring among inpatients treated for these diseases was 30 against 48 in the previous year.

Leprosy.—Persons treated for leprosy in the mofussil hospitals and dispensaries numbered 4,163 in 1932 as compared with 3,225 in the preceding year, showing an increase of 938 patients.

Surgical operations.—The total number of surgical operations performed during the year in all classes of mofussil hospitals and dispensaries was 146,352 as compared with 143,548 in 1931.

Nursing.—During the year no noticeable improvement was made upon the nursing arrangements existing in the mofussil hospitals and dispensaries. In most of the mofussil Sudder hospitals the nursing work was inadequate and unsatisfactory and was done by the compounders, dressers, ward coolies or by friends and relatives of patients.

General remarks.—The financial difficulties referred to in the last report have not become less. It has not been possible to effect much retrenchment. This is not because of lack of appreciation of the financial position, but owing to the very poor financial provision for medical treatment, before the slump. With a few exceptions hospitals in the past were maintained at the lowest possible level of efficiency. As money became available the tendency was to extend activities rather than to improve the efficiency. The result has been that when faced with a call for retrenchment it meant restricting activities. Public opinion would not allow this course to be adopted. On the other hand any advance in quantity or quality of medical relief has been held up. The present condition of Western medicine and its slow progress present a depressing picture to those who look ahead. It can be said that in Calcutta some progress has been made in the last 20 years, but I do not consider even in this city of two million inhabitants that there is a single hospital which approaches a good provincial teaching hospital in England of twenty years ago.

A nursing committee was appointed during the year under review. It finds that in our largest hospitals

and those responsible for the training of medical men, that nursing is either inadequate or non-existent. Similarly in Calcutta no infectious diseases hospital exists. The necessity for such a hospital increases yearly. In 1912, 844 cases of cholera were admitted with a death rate of 35.6. In the last year 2,448 cases were admitted with a death rate of 22 per cent. Smallpox only provided 79 cases in 1912 as against 391 in 1932. Diphtheria has trebled its admissions in the same period. Cerebro-spinal meningitis has apparently come to stay. Measles, enteric fever, dysentery, influenza and pneumonia are all taking their toll. Not all these can be treated in an infectious hospital but provision should at least be adequate for cholera, smallpox, diphtheria and cerebro-spinal meningitis. Turning to the hospitals outside Calcutta the only advance in quality in the last 20 years is that x-rays have been made available in a number of stations. Even this advance is more apparent than real as expert radiologists are lacking. It is the man behind the machine that makes it valuable.

The surgeon-general points out that in spite of the increase of beds in the mofussil in classes I, III and IV in 1932 as compared to 1912 the increase in patients has failed to keep pace with it. In other words 'confidence in Western medicine is diminishing rather than increasing'. It is further pointed out that what Bengal requires is not more hospitals but better hospital staffs. He suggests that

'A start should be made with those hospitals associated with medical schools. It is not to be expected that doctors trained in these indifferent hospitals can contribute anything to increased public confidence in scientific medicine.

The policy of district medical schools would be sound enough if we could provide really efficient teaching staffs and up-to-date, well-equipped and well-staffed modern hospitals. We provide neither. There would be no demand for ayurvedic, unani and homoeopathic dispensaries if our district hospitals were as good as English provincial hospitals. India is to-day in a state of transition, and whatever may happen in other directions I can see little hope of progress in medicine if India loses touch with the West. Before the War the I.M.S., with its constant infusion of new blood and the frequent visits of its officers to Europe, maintained that touch. To-day the I.M.S. officers are largely reduced in number, many of them rarely visit Europe and then only as junior officers, not as officers of ripe experience.

For this reason particularly I hope that the provision for study leave will not be reduced, either for the Indian Medical Service or Bengal Medical Service'.

ANNUAL REPORT FOR THE YEAR 1933 FROM THE PHARMACOLOGICAL LABORATORIES OF THE PHARMACEUTICAL SOCIETY OF GREAT BRITAIN

This report contains a résumé of the research work carried out by the staff and has several suggestions of therapeutic value for those practising in India.

Experiments on the protective action of calcium on the resistance to poisoning by carbon tetrachloride show that the mortality of the mice given large doses of the drug is markedly reduced if calcium lactate is fed one hour previously.

The laboratory has further shown that yeast, if it contains ergosterol, can become a good source of vitamin D when irradiated. The object of those investigations was to produce a cheap and good supply of this vitamin for the poorer classes of women in India.

THE KASHMIR C. M. S. MISSION HOSPITAL 1934; FIFTY YEARS: A REVIEW

ALTHOUGH the title of this report only claims it to be a review of the fifty years 1882 to 1931 it really covers

a much longer period for it describes the first establishment of the C. M. S. Mission at Srinagar by Mr. R. Clark in 1864 and how shortly afterwards his wife began the first medical work of the mission by opening an out-patient department for women.

In 1865 Dr. Elmslie arrived and at first was mainly engaged in itinerant medical work. It is not clear when the actual hospital commenced but the present buildings were erected in 1886. In 1882 Dr. Arthur Neve took over charge and with the exception of four years has since retained this post until his death in 1919. Dr. Ernest Neve, who is at present in charge of the hospital, first arrived in 1886 and followed his brother as superintendent, so the hospital has now been in charge of one or other of the Neves for over fifty years. This is a remarkable achievement and the record of work disclosed in this report is one of which they might well be proud. In addition to carrying on their medical work the Neves have contributed over seventy papers to various medical journals, and several of these articles have appeared in the columns of this journal. Under the heading of 'Fifty Years Ago' we quoted from one of these in our August number of last year. Dr. Arthur Neve also wrote two books, and Dr. Ernest Neve has written three books descriptive of the country

and the latter has also contributed a manual on Kashmiri grammar and conversation.

In years to come we venture to predict that the work of the two Neves in Kashmir will rank as one of the epics of medical missionary work in the British Empire.

THE PRESIDENTIAL ADDRESS OF THE GOLDEN JUBILEE OF THE BOMBAY MEDICAL UNION. BY JEHANGIR J. CURSETJI, M.D.

THE president in his address gave an interesting account of the growth of the society founded by himself along with two others fifty years ago. Great tribute must be paid to the enthusiasm of its founders and to the loyalty of those who kept it going in the lean years it has sometimes had to pass through since its birth.

A résumé of the work done by the union in promoting, in the broadest sense, the efficiency and prestige of the profession in India is given. The reply to the memorandum of the British Medical Association is discussed; this includes some relevant issues on medical education, the efficiency of personnel, economy of administration, and medical research in India.

STUDY OF VITAMIN-A DEFICIENCY IN CEYLON

To the Editor, THE INDIAN MEDICAL GAZETTE:

SIR,—We have read with great interest the 'Study of Vitamin-A Deficiency in Ceylon' by Dr. L. Nicholls, published in the May number of the *Indian Medical Gazette*. May we, however, suggest that the syndrome he describes is a wider deficiency than merely that of vitamin A. The sore mouth and 'neuritis' symptoms have been described as pellagrous by Stannus (see, for example, his review of the subject in *Trans. Roy. Soc. Trop. Med. and Hyg.*, Vol. XXIII, p. 627). Our own observations upon a disease found in Malayan prisons in which the chief symptoms are sore mouth and eczema of the scrotum lead us to believe that this syndrome is due to vitamin-B deficiency. Our conclusions are largely based upon therapeutic tests.

We have not found phrynodermia common but there is no doubt that deficiency diseases vary from country to country. Dr. Nicholls himself says of the incidence of phrynodermia and sore mouth, 'the conditions do not follow one another in uniform curves'. This point suggests that two separate deficiencies may be present. Therapeutic tests would be of great interest in the conditions that Dr. Nicholls has described.

Yours, etc.,
J. V. LANDOR.
R. A. PALLISTER.

GENERAL HOSPITAL,
SINGAPORE,
16th June, 1934.

STUDY OF VITAMIN-A DEFICIENCY IN CEYLON

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Drs. Landor and Pallister appear to consider that in my paper (1934) in your May issue I went astray in attributing 'sore mouth' and certain 'nerve' symptoms to vitamin-A deficiency; they refer to a review by Dr. H. S. Stannus (1930) and to their experiences in Malayan prisons. They suggest that 'sore mouth' and 'neuritis' are due more probably to vitamin-B deficiency. As they refer to the review of Dr. Stannus I conclude they mean principally B.

Since writing the paper I have cut sections of the spinal cords of children who have died after showing symptoms of what I termed 'neuritis'. These sections show early myelin degeneration in patches in the posterior and lateral columns, and also the anterior horn cells appear to have undergone changes. (The method of preventing post-mortem changes has been to inject 30 c.c.m. of 10 per cent formalin in normal saline into the spinal canal soon after death; this preserves the cord pending permission for the post-mortem examination.)

An apparently similar condition occurs in pellagra and pernicious anaemia. But several observers (Hart, Miller and McCollum, 1916; Hughes, Lienhardt and Aubel, 1929; and E. Mellanby, 1926) have described these changes in cords of animals which have been fed on diets deficient only in vitamin A. It is not astonishing that a degeneration of nervous tissue has more than one cause.

I became familiar with pellagra when stationed for four years in the West Indies; and during many years in Ceylon I have searched hospitals, a vagrant home, many prisons, and a large mental asylum for cases of pellagra, but I have never found a case.

'Sore mouth' is prevalent in the vernacular schools, and 'neuritis' and 'sore mouth' are prevalent in the prisons and the asylum, and, if they were due to deficiency in B, it is reasonable to expect that cases of pellagra would occur.

In the review above referred to Dr. Stannus commences by referring to the work of E. J. Wright (1928), who attributes soreness of the angles of the mouth, and skin changes of the scrotum to vitamin-A deficiency.

The signs and symptoms of vitamin-A deficiency are common in Ceylon and a careful consideration of the diets of the children in vernacular schools, prisoners in jails and patients in the asylum showed that they were deficient in vitamin A, but a deficiency in vitamin B was not apparent.

It was for these reasons that I attributed 'sore mouth' and 'neuritis' to vitamin-A deficiency.

It is probable that the signs and symptoms of vitamin deficiencies, which result from a generally poor diet, are not due to single factors. But when reporting preliminary investigations it is necessary for clarity to emphasize the most salient deficiency of the diets in question.

The elucidation of dietary deficiencies in man is an involved subject and must be a very slow process, because there are many possible interactions between the numerous constituents of various diets.

Even to-day many observers are not satisfied that a deficiency of B₁ is a complete explanation of beri-beri; nor that a deficiency of B₂ and a diet containing proteins deficient in certain amino-acids is a complete explanation of pellagra.

The present state of our knowledge indicates that pathological changes may arise from:—

- (1) The absence of a vitamin in the diet.
- (2) The existence of certain substances in the diet which have a toxic effect when vitamins are deficient.
- (3) Insufficient proteins of high biological value coupled with some vitamin deficiency.

I have carried out recently some dietary and therapeutic experiments; the results will be published later, but one point is clear that when vitamins combined with proteins of high biological value (such as 2 eggs daily) are added to the diets, 'sore mouth' clears up usually within a week to ten days, and prynoderma clears up, but requires more time, probably because the pathological changes are more profound. Yet when apparently ample vitamins are given in leaves, cod-liver oil, dāl, green gram, and fruits, these signs clear up but take a very much longer time.

- (4) Vitamins require a certain balance between the mineral constituents of a diet.

For instance Theiler has shown that when horses and cattle are fed on a diet low in calcium and high in phosphates, the horses develop osteoporosis and the cattle thrive; whereas when the diet is high in calcium and low in phosphates the horses thrive, but the cattle

develop 'bone changes'. Two other factors may be added:—

- (5) The vitamins are present in the diet, but a disordered alimentary canal cannot absorb them.

This has been suggested as the cause of alcoholic neuritis.

The signs, symptoms and pathology of sprue resemble those arising from vitamin deficiencies, and it is possible that an intestinal indigestion which prevents the absorption of fats, also prevents the absorption of fat-soluble or other vitamins.

- (6) A disordered metabolism may affect the normal assimilation of necessary constituents in the diet.

Perhaps pernicious anaemia falls under this heading.

Service Notes

APPOINTMENTS AND TRANSFERS

THE King has approved the following appointment:—

Major-General D. P. Gail is appointed Honorary Physician to the King, 15th November, 1933, *vice* Major-General Sir John W. D. Megaw, K.C.I.D., retired.

Lieutenant-Colonel G. Covell, an officer of the Medical Research Department, is placed on foreign service under the Association of the Pasteur Institute of India, Kasauli, for appointment as Officiating Director of that Institute, with effect from the date on which he assumes charge of his duties.

Lieutenant-Colonel M. Das, M.C., Superintendent, Bengal Jail Department, is confirmed in that appointment, with effect from the 20th September, 1932.

His Excellency the Governor, with the concurrence of the Honourable Minister for Local Self-Government, is pleased to appoint Lieutenant-Colonel A. H. Harty, Civil Surgeon, Poona, to hold charge of the post of Superintendent, Central Mental Hospital, Yeravda, in addition to his own duties, during the period of the extension of leave for 2 months granted to Major E. C. A. Smith by the High Commissioner for India. The appointment should take effect from the date from which Lieutenant-Colonel Harty takes over from Captain Taylor.

The services of Major G. C. Maitra, an Officer of the Medical Research Department, are placed temporarily at the disposal of the Government of Burma, for appointment as Officiating Director, Pasteur Institute, Rangoon, with effect from the date on which he relinquishes charge of his present duties as Officiating Director, Pasteur Institute of India, Kasauli.

Major R. M. Kharegat, an Agency Surgeon, is posted as Chief Medical Officer in Central India and Residency Surgeon, Indore, with effect from the afternoon of the 31st May, 1934.

The services of Major S. R. Prall and Major J. S. Galvin are placed permanently at the disposal of the

Government of Bombay, with effect from the 26th June, 1932.

Major A. C. Chatterji is appointed to officiate as Health Officer, Simla, with effect from the 20th May, 1934, *vice* Major S. N. Makand granted leave.

Major J. J. Rooney is appointed substantively to be an Agency Surgeon under the Government of India in the Foreign and Political Department, with effect from the 9th April, 1934.

Major S. Nag, Civil Surgeon, Murshidabad, is appointed as Civil Surgeon, Mymensingh.

The services of the undermentioned officers are placed permanently at the disposal of the Government of the United Provinces, with effect from the date mentioned against each:—

1. Major W. Aitchinson, 1st February, 1932.
2. Major A. J. C. Culhane, 27th January, 1932.
3. Captain C. V. Falvey, 26th January, 1932.

The services of the undermentioned officers are placed temporarily at the disposal of the Local Government specified below, with effect from the date mentioned against the name of each officer:—

Government of Bombay

Major T. A. Doran, 11th June, 1934.

Government of Bengal

Captain E. G. Montgomery, 8th June, 1934.

Captain G. B. W. Fisher, 11th June, 1934.

Government of United Provinces

Captain D. P. Lambert, 13th June, 1934.

Government of Assam

Captain P. H. Cummius, 1st June, 1934.

The services of Major V. S. R. Pandit are placed temporarily at the disposal of the Government of Burma for employment in the Burma Jail Department, with

effect from the date that he assumes charge of his appointment.

The services of Brevet-Major M. S. Gupta are placed at the disposal of the Government of Madras for employment in the Madras Jail Department, with effect from the date on which he assumes charge of this appointment.

The services of Captain K. S. Fitch are placed temporarily at the disposal of the Government of Bengal, with effect from the 26th May, 1934.

Captain K. S. Fitch is posted as Civil Surgeon, Midnapore, *vice* Captain R. Linton, transferred.

Captain R. Linton, Civil Surgeon, Midnapore, is appointed as Civil Surgeon, Barisal.

Captain E. G. Montgomery is posted as Civil Surgeon, Murshidabad, *vice* Major S. Nag, transferred.

Captain G. B. W. Fisher is placed on general duty at the Medical College Hospitals, Calcutta, with effect from the 11th June, 1934.

The undermentioned officers are confirmed in the rank of Captain:—

B. D. Khurana.

E. H. Lossing.

R. J. Jarvie.

M. Sendak.

G. W. Miller.

To be Captain (on probation)

Ilahi Bakhshi, dated 3rd May, 1933, with seniority 5th April, 1932.

(Previous notifications so far as they related to this officer are cancelled).

Lieutenant W. J. Stewart, Medical Officer, Kitchener College Hospital, Nowgong, is appointed to officiate as Agency Surgeon, Bundelkhand, in addition to his own duties, with effect from the forenoon of the 25th May, 1934.

PROMOTIONS

The following promotions are made, subject to His Majesty's approval:—

Lieutenant-Colonel to be Colonel

A. A. McNeight. Dated 1st April, 1934, with seniority 1st August, 1928.

The promotion of Major A. H. Craig to the rank of Major is antedated to 23rd September, 1931.

Captain to be Major

C. V. D. Rose. Dated 25th October, 1931.

Captains on (probation) to be Majors (on probation)

P. V. Karamchandani. Dated 26th February, 1934.

R. K. Misra. Dated 2nd April, 1934.

Lieutenants to be Captains

W. A. N. Marrow. Dated 2nd February, 1934.

H. B. Macevoy. Dated 3rd February, 1934.

M. M. Mansfield. Dated 3rd February, 1934.

J. Guthrie. Dated 3rd February, 1934.

W. J. Stewart. Dated 3rd February, 1934.

R. I. Reid. Dated 8th February, 1934.

J. D. Grant. Dated 20th April, 1934.

W. H. G. Reed. Dated 1st May, 1934.

T. E. Palmer. Dated 1st May, 1934.

D. G. McCauly. Dated 1st May, 1934.

F. C. Jackson. Dated 1st May, 1934.

J. W. Bowden. Dated 1st May, 1934.

J. D. Murdoch. Dated 1st May, 1934.

A. T. Andreasen. Dated 1st May, 1934.

J. M. Slater. Dated 1st May, 1934.

D. R. Tweddie. Dated 1st May, 1934.

C. F. Garfit. Dated 1st May, 1934.

D. K. L. Lindsay. Dated 1st May, 1934.

W. S. Morgan. Dated 1st May, 1934.

M. S. Purvis. Dated 1st May, 1934.

M. E. Kirwan. Dated 1st May, 1934.

R. D. MacRae. Dated 1st May, 1934.

C. J. H. Brink. Dated 1st May, 1934.

W. Maekie. Dated 1st May, 1934.

J. W. Richmond. Dated 1st May, 1934.

G. S. N. Hughes. Dated 1st May, 1934.

A. D. Barber. Dated 1st May, 1934.

Lieutenants (on probation) to be Captains (on probation)

M. Ata-Ullah. Dated 20th April, 1934.

G. B. Thomas. Dated 1st May, 1934.

J. White. Dated 1st May, 1934.

H. A. Ledger. Dated 1st May, 1934.

T. F. O'Donnell. Dated 1st May, 1934.

W. W. Laughland. Dated 1st May, 1934.

S. Ahmad. Dated 1st May, 1934.

C. C. Kapila. Dated 1st May, 1934.

F. W. Allinson. Dated 1st May, 1934.

F. R. Cawthorn. Dated 1st May, 1934.

F. V. Stonham. Dated 1st May, 1934.

J. M. Mathew. Dated 1st May, 1934.

W. B. Stiver. Dated 1st May, 1934.

L. Feinhols. Dated 1st May, 1934.

J. G. Stonham. Dated 1st May, 1934.

G. F. Harris. Dated 1st May, 1934.

F. W. Whiteman. Dated 1st May, 1934.

F. C. Leach. Dated 1st May, 1934.

W. M. E. Anderson. Dated 1st May, 1934.

R. D. Scriven. Dated 1st May, 1934.

V. M. Albuquerque. Dated 5th June, 1934.

LEAVE

Lieutenant-Colonel W. L. Harnett, C.I.E., is granted leave from the 6th June to the 6th December, 1934.

Lieutenant-Colonel R. N. Chopra, C.I.E., Professor of Pharmacology, School of Tropical Medicine, Calcutta, is allowed leave for 1 month, with effect from the 16th July, 1934.

Lieutenant-Colonel M. A. Nicholson, an Agency Surgeon, is granted leave for 3 months and 20 days, with effect from the afternoon of the 31st May, 1934.

Major H. H. Elliott, M.B.E., M.C., an Agency Surgeon, is granted 2 months' leave, with effect from the afternoon of the 12th May, 1934.

Major S. N. Makund, Health Officer, Simla, is granted leave for 26 days, with effect from the 20th May, 1934.

RETIREMENTS

The King has approved of the following retirement:—

Colonel G. C. L. Kerans, D.S.O., retires, 1st April, 1934.

Captain J. S. B. Forde, relinquished his probationary appointment, 28th February, 1934.

The following retirement is permitted, subject to His Majesty's approval:—

Lieutenant-Colonel A. W. Overbeck-Wright. Dated 30th May, 1934.

Notes

THE MANIPULATOR: A NEW DEVICE FOR ISOLATING BACTERIA UNDER THE MICROSCOPE

In the *Zentralblatt für Bakteriologie*, Part 1 (Originals), 1933, Vol. CXXIX, a new plate manipulator has been devised which enables single bacteria to be taken at any time with rapidity and certainty, from colonies or mixtures of bacteria, and used for propagating pure cultures (single-cell cultures). The new process differs radically from all the conventional types of micro-manipulators in that the bacteria are not isolated with glass capillaries (micro-pipettes) from a drop of liquid containing the bacteria, but isolation is performed with an extra-fine metal needle on the surface of the ordinary agar plates, and any transparent culture medium can be used. The needle is made of a special metal, and despite its extreme fineness (diameter at the point is approximately 0.0005 mm.), it can be sterilized

by heat like an ordinary platinum loop. With the needle, it is surprisingly easy to isolate a single bacteria under the microscope and to displace it several centimetres on the surface of the culture medium. When it makes contact with the agar, the needle forces a small drop of liquid out of it and the bacterium floats after the needle, so to speak, during the motion of the latter. In this way, single bacteria can be transported to Indian ink marks previously made on the surface, and this makes it an easy matter to locate again the colonies that have sprung from them, and to inoculate them. Several of such single-cell cultures can be made on one plate. In addition, one or more bacteria can be transferred to a new plate and the needle used, in this way, for the cultivation of microscopic colonies of bacteria. The magnifications ordinarily used range between $\times 500$ and $\times 800$ (high power dry systems).

Objectives constructed specially for the purpose and having a specially large working distance make the process very convenient to work with, and no special skill is required. Even the proteus, so redoubtable as an impurity, can be isolated from soil. As the process only takes a few minutes, the new method can be used by bacteriologists for the pure culture of bacteria from mixtures, thus considerably curtailing the time necessary for making the cultures. One important advantage of the plate manipulator is that it is always ready for use. The apparatus and the microscope are mounted on a common base-plate; but, when the microscope is not being used for manipulations, the metal bracket carrying the micro-needle can be swung clear on a vertical axis, thus allowing the microscope to be used for other purposes as well. When the instrument is required for use, a single manipulation brings the needle into the correct position underneath the objective. Any bacteriological microscope having a mechanical stage can be used. The new manipulator is manufactured by C. Reichert, Optical Works, Vienna.

DAKOL AGAR

THIS valuable agar preparation is packed in convenient sixteen-ounce bottles with white enamel screw caps, the mouth of the bottle being wide enough to allow of the insertion of a dessert spoon. It has a specially palatable flavour, and, as it is manufactured by a firm with a well-established reputation, those using it can rely upon the high quality of the product. It is supplied either plain or with phenolphthalein ($1\frac{1}{2}$ grains in each fluid ounce) and is available also in an eight-ounce size.

The price is very reasonable.

VINVITÆ

VINVITÆ contains, in a readily assimilable form, the glycerophosphates of iron and calcium, together with other mineral salts essential to the metabolism of the human body. The tonic is also reinforced with lecithin, guaiacol, malt, the active principles of cod-liver oil and a very small amount of strychnine hydrochloride. It is specially suitable for persons with weak digestions and is not constipating in action. Clinical experience has proved the value of this tonic over a period of many years for those who are suffering from the after-effects of fever, who are recovering from illness or who desire to improve their general condition.

G. H. ZEAL, LIMITED

Owing to the rapid expansion of their business, it has become necessary for the well-known firm of thermometer manufacturers to find increased space to accommodate their staff and equipment.

They are therefore building a modern north-light ground-floor factory, which they claim will be the largest and best equipped factory for the production of thermometers in Great Britain, if not in the world.

They hope to be fully established in their new works

early this year, when they will be in a position to increase their output very considerably and maintain an even higher standard of quality and better service for delivery than they have done in the past.

The new address of this firm will be G. H. Zeal, Limited, Thermometer Manufacturers, Morden Road, Merton, London, S.W. 19, England.

CHANGE OF ADDRESS

D. J. KYMER AND COMPANY, the old-established advertising agency who have for some years specialized in advertising medical products in the British Empire, and who have within the last decade opened branch offices in Calcutta and Bombay, have found it necessary on account of expansion of business to move from their previous office at 1/3, Whitefriars Street to larger offices in Australia House, Strand, London, W.C. 2.

BURROUGHS WELLCOME AND COMPANY AND DARTFORD

LAST year, His Majesty King George V of England presented the town of Dartford with a charter, incorporating it as a Municipal Borough. As the event was an important one from a local point of view, Messrs. Burroughs Wellcome and Co., whose large drug factory forms a very important feature of this (now) municipal borough, marked the occasion by issuing a very interesting souvenir.

This souvenir, which is a most attractive production, gives a short review of the important historical events that have occurred at Dartford and a short description of the town as it is to-day. There are a number of photographs, including one of this firm's chemical works, flood lighted on the occasion of the Faraday centenary celebrations.

INFANTS' FOODS IN INDIA

THE excessive duty of 25 per cent on Infants' Foods imported into India continues to constitute a heavy and unnecessary tax on parenthood and the infant life of the nation. In a country such as this where these foods are a vital necessity such a tax seems very unfair, and protests have already been laid before the Government.

Repacking of these foods in India in order to escape the full incidence of the duty has already been discussed and indeed adopted in one case by a well-known brand of Colonial food.

Messrs. Cow and Gate have, however, decided that such a step would not be in the interests of their customers and they do not intend to ship their particular food to India in bulk and repack it under tropical conditions. The following statement expresses their attitude:—'Our food will continue to be made in England, and packed and shipped immediately after manufacture in sealed and dated tins, as heretofore. We can conceive of no other method of putting Cow and Gate in the hands of the mother in India and at the same time of giving the absolute guarantee of condition and security which we have always given. While we are intensely anxious to see a reduction in, or the elimination of, the present heavy and anti-social duty we prefer to bear its full brunt rather than to risk lowering our standard of hygiene and safety in the slightest degree. Although our food cannot therefore be reduced in price, we believe we shall continue to have the support and custom of our many friends and clients throughout India who appreciate to the full the vital importance of supreme hygiene in connection with a product of this nature'.

HALLUX VALGUS AND HALLUX RIGIDUS SPLINTS

(POST-OPERATIVE)

THE hallux valgus splint is a modification of Jones's, whose splint has always been found difficult to keep in

position on the toe. It is made of aluminium and has the advantage of fitting closely to the inner border of the forepart of the foot, so that displacement does not take place.

The splint consists of a body and toe-piece. The toe-piece fits to the inner side of the big toe and inclines slightly to the medial side. The body grasps the medial side of the forepart of the foot; its lower border which comes in contact with the sole of the foot is straight; its upper border is cut away to fit the dorsum. It contains a window at the side to prevent pressure on the wound.

After the wound is dressed the toe is fastened to the toe-piece with adhesive strapping. A second piece of strapping surrounds the forepart of the foot and the body of the splint. No further dressing or bandage are required.

It is customary to apply a hallux valgus splint after operating for hallux rigidus. As the aim of the operation is to procure dorsi-flexion of the big toe which has been lacking, a special splint has been designed to hold the toe in this position. The structures beneath the joint have long been contracted as a result of disuse, and by placing the toe in the dorsi-flexed position we keep these structures on the stretch and prevent any further tendency to contraction.

This splint is also made of aluminium and consists of a toe-piece almost at right angles to the body, to

this the toe is strapped with adhesive plaster after the operation. The body of the splint fits to the forepart of the sole and its inner edge is raised to grasp the inner border of the foot, adhesive strapping secures it in position.

There are right and left splints which are made in two sizes, one to fit the male foot and the smaller to fit the female.

It is to be found that, since placing the toe in the dorsi-flexed position after operation, the patient experiences much less pain when movements are started, that the results on the whole are better and that recovery is more rapid.

These splints have been in use for the past five years and have been found entirely satisfactory.

They are made by Messrs. Down Brothers, Limited, London, for Mr. R. Wood Power, F.R.C.S., of Hereford, England.

MALNUTRITION

THAT in most provinces in India the ordinary diet of the people is far from perfect and notoriously wanting in elements essential for the maintenance of the human body, even in ordinary good health, is well known to all. The investigations carried out by the students' welfare committee of Calcutta some years ago revealed the astonishing fact that, out of every ten students, six were suffering from some defect or other, two were entire wrecks, and only two were physically fit. The chief defect was found to be malnutrition. This malnutrition can be remedied only by including in our daily food articles which will tend to give it that balance and scientific proportion necessary to make our diet as sufficient for the needs of the human system as possible. Here the element of cost should also be taken into consideration. It is useless prescribing an article of food of high nutritious value, if its price is such as to place it beyond the reach of many.

The combination of cheapness and the elements necessary to make a perfect food is found in oats. Quaker Oats, a deservedly popular variety of this cereal, has on an analytical examination been found to contain proteins, carbohydrates, fat, calcium, phosphorus, iron and vitamins B and E in just those proportions needed to make it a valuable food for children, nursing mothers, invalids and even adolescents. Its cheapness is an additional advantage, while the ease with which it can be digested makes it acceptable even to those whose digestive organs have lost much of their vitality.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

SKELETAL TRACTION BY MEANS OF KIRSCHNER'S WIRE IN THE TREATMENT OF LOWER LIMB FRACTURES

By W. L. HARNETT, C.I.E., M.D., F.R.C.S. (Eng.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Surgery, Medical College, Calcutta, and
Surgeon to the College Hospitals

THE evolution of fracture treatment may be divided into three periods:—

The primitive, from the dawn of history to the end of last century

In all countries and in all ages fractures were treated by tying a piece of wood or metal to the fractured limb, with the idea of holding the fragments in position, after the surgeon had 'set' it by traction and manipulation to bring the broken ends into apposition. As this manœuvre was usually attempted without anaesthesia it frequently failed and, even if it was successful at the time, the retraction of the muscles reproduced the deformity in a few days, so that shortening often accompanied by angular deformity was the usual result. The value of traction in lower limb fractures was beginning to be recognized towards the end of this period, but as it was applied without suspension its efficiency was impaired; the only exception was Hodgen's splint for fractures of the upper end of the femur, a piece of apparatus based on sound principles which is still occasionally used. The introduction of plaster-of-Paris splints was a great advance, as, if the fragments were properly reduced under anaesthesia and the splint was skilfully made without too much padding, it could be relied on to hold the fragments in position long enough to permit of callus formation advancing far enough to fix the fragments. This is still the best method for superficially-placed bones such as the tibia and fibula, when the shortening can be readily reduced, but repeated checking of the position by x-rays after the plaster has been applied is essential, as there is a tendency to recurrence of the deformity when the limb wastes and the plaster loosens. Prolonged fixation in plaster is apt to lead to troublesome adhesions in neighbouring joints and hence much attention has recently been paid to the use of ambulatory methods, which permit of early use of the limb whilst still encased in plaster. Böhler employs an unpadded plaster splint, the accurate fitting of which allows of early weight-bearing without risk of angulation or lateral deviation of the fragments, but it must be admitted that the fitting of a non-padded plaster cast requires great skill and involves more risk to the skin in a tropical country.

The second or operative period initiated by Arbuthnot Lane

Dissatisfied with the results of fracture treatment as then practised, he advocated the treatment by open operation of all fractures which could not be easily reduced, the levering of fractured ends into position and fixing them by steel plates screwed on to the bones. Lane was a great surgeon and in his skilful hands many excellent results were obtained, far in advance of those usual in that day; all his followers, however, had not his technique and the supervention of sepsis was a grave disaster that usually left the patient much worse off than if the fracture had been treated on orthodox lines, and this after a long and grave illness. As time went on it became apparent that the absolute immobility of the fractured ends led to delay in callus formation, that minor grades of sepsis often led to a rarefying osteitis around the screws which necessitated the removal of the plate at a later date and that, even if asepsis was perfect, fibrosis and adhesions amongst the muscles and tendons followed the wide opening up of the parts, so that the functional result was less perfect than the exact anatomical reposition would lead one to expect. The method was never applicable to compound fractures, as the introduction of a foreign body into a potentially or actually septic wound violated all recognized principles of surgery.

Certain recent fractures are still treated by open operation, where there is some intervening soft tissue which absolutely prevents reduction in any other manner, but plates are rarely used nowadays, the wound is closed and skeletal traction is applied exactly as in a closed fracture. Fractures of the patella and the olecranon will always remain suitable cases for operative treatment. Old mal-united fractures for many years furnished an ideal field for this method, and the writer has had a long series of successful results, but latterly better results have been attained with less sacrifice of bone length by the application of skeletal traction after removal of callus and freshening the bone ends.

The third period, opening soon after the beginning of the Great War

It was quickly recognized that any form of fixed splint interfered with the dressing of the severe compound fractures then met with, that traction was essential to correct shortening, and that the traction to be efficient must be combined with suspension, for choice in a skeleton splint of iron which would permit of ready access to the wound. With the development of the treatment of compound fractures by excision of the wound we are not here concerned. The Thomas' splint which had long been used in the Liverpool school for the treatment of fractures of the femur at last came into

its own, thanks to the influence of Sir Robert Jones and the band of workers he gathered round him, and throughout the war it was used with great success in all the British theatres of war. Traction was ordinarily applied by strapping extension, but in the case of fractures of the tibia and fibula the surface of skin available for applying the strapping was insufficient, so that devices, such as Sinclair's skate, gauze affixed by glue or a stirrup passed beneath the tendo Achillis above the os calcis, were utilized. In the case of low fractures of the femur Pearson's modification of Besley's ice-tongs caliper enabled traction to be applied directly to the bone. This latter appliance was a great advance which enabled shortening to be completely corrected in cases where extensive wounds rendered it impossible to obtain sufficient undamaged skin for the application of strapping extensions, but it had several grave drawbacks. Pressure atrophy of the bone was liable to occur, the calipers unless carefully watched might 'creep' and set up infection in the structures of the knee joint and occasionally the supervention of sepsis led to a low form of osteomyelitis of the femur or even arthritis of the knee joint, with delayed convalescence and troublesome stiffness of the joint. In spite of all these drawbacks however the method was much used during the war, both for the femur and applied to the malleoli for fractures of the tibia and the results were so much superior to those obtained by other methods in dealing with the terrible injuries then met with that its drawbacks were condoned. After the war these drawbacks began to appear more important, especially when they occurred in cases of simple fracture and gradually this method of extension lost its popularity. Steinman's pin, a straight steel pin sharpened at one end, which was driven through the bone was an improvement, but its introduction was laborious for the surgeon and the hole left in the bone was large, so that sepsis sometimes followed. This method, always very popular on the Continent, never had much vogue in England.

The position remained stationary until the introduction by Kirschner of Tübingen of the 'piano-wire' method of extension which, almost universally adopted in Germany and in Vienna for the past few years, has only recently begun to be generally used in England.

This is an ideally simple method of obtaining skeletal traction with the minimum of trauma. A wire of rustless steel of one millimetre or two millimetres in diameter according to the weight to be applied (2 mm. is generally preferable) sharpened at one end is driven through the bone. This may be accomplished either by a hand or electrically driven drill, but in any case the slender wire needs to be supported or it would buckle up under the pressure necessary to force it through the bone. There are various devices to accomplish this, but the cheapest and most

efficient apparatus is that illustrated in figure 1, designed by Soutar. It is an ordinary Colt's bone drill worked by hand, with an extension piece of three metal cylinders which telescope into each other. The wire shown in the figure is clamped into the drill chuck and the extension is drawn out as far as necessary to enclose

Fig. 1.—Drill with telescopic extension and Kirschner wire.

the wire, leaving about one inch protruding. This is pressed against the part to be drilled and the crown wheel is revolved. As the drill penetrates the tubes telescope into each other until the wire has passed through the bone and appeared on the other side, the drilling is continued until the tubes are completely telescoped into each other. The chuck is then unscrewed and the apparatus disconnected, leaving the wire in the bone. The next step is to put the wire under tension sufficient to stand the pull without buckling. Figure 2 illustrates the stirrup of elastic steel

Fig. 2.—Stirrup, tension apparatus and spanner.

used for this purpose. The wire is clamped into the far side of the stirrup, leaving the near-side clamp loose, the screw tension appliance illustrated is then fitted and tightly clamped to the wire. The screw is turned until the wire is under sufficient tension to stand a pull of 15 to 20 pounds, the near-side clamp of the stirrup is

then tightened by the spanner, the clamp on the tension apparatus is released, and it is disconnected, when the stirrup springs apart and holds the wire under tension sufficient to enable it to carry the needed weight. For the femur the best place for the wire is the tubercle of the tibia about half an inch from the surface where the bone is very dense. The limb is put up in a bent Thomas' splint with knee flexed, slung

Fig. 3—Fractured femur with Kirschner wire extension, Thomas' splint and Balkan frame

to a Balkan beam, and 15 to 18 pounds weight, according to the build of the patient, is attached to the stirrup. Extension is maintained for about five weeks, by which time the fracture should be united. The wire is then found to be quite loose and may be cut off and removed without causing pain. A strapping extension is applied for another two or three weeks if there is any doubt as to the firmness of the union, after which a walking caliper splint may be fitted. In many cases union is so perfect that after a further rest of two or three weeks with massage and exercises the patient is able to get up and walk out of the hospital (see figures 3 and 4).

Fig. 4—Near view of figure 3

For a tibia-fibula fracture the wire is passed through the os calcis, the point for drilling the

bone being two finger-breadths below and behind the medial malleolus. The limb is placed in a Braun's splint (figure 5) and the arrangement of

Fig. 5—Braun's splint.

the apparatus is shown in figure 6. Ten to twelve pounds weight is ample—less often suffices—the general principle always being to use only the minimum weight which will suffice to correct shortening without drawing the ends apart. In all cases a sling must be applied to the foot to prevent foot-drop. For tibia and fibula fractures extension may be maintained for much longer; bad compound fractures may need extension for two or three months. In the case of the femur the effect of long-continued traction on the knee joint has to be considered and five weeks is about the limit if the knee joint is not to be rendered unstable by stretching of its ligaments.

Fig. 6—Arrangements for extension of a tibia-fibula fracture.

Extension may be applied to the humerus by passing the wire through the olecranon and to the radius and ulna by passing it through the lower ends of the bones, but of these methods the writer has no personal experience.

On the Continent the wire is always passed under local anæsthesia, but we find general anæsthesia by evipan sodium very convenient;

it gives 15 to 20 minutes' unconsciousness, quite sufficient to get the limb arranged in the splints. The imperfect relaxation obtained is of no moment, as the extension soon stretches the muscles.

For the past eighteen months all fractures in the upper and lower thirds of the femur have been treated in this way, on account of the tendency to displacement of fragments in these situations. In the middle third excellent results are obtainable by Hamilton Russell's method, as described by the writer (1928), but, if the shortening is considerable or the patient is powerfully built, better results are obtained by the Kirschner wire; this gives less trouble to the nursing staff and we now regard it as the best treatment for these cases too. Fractures above the great trochanter are best treated in Whitman's plaster splint.

Simple fractures of the tibia and fibula may be put up in plaster and treated thus, provided the x-ray shows that the fragments are in satisfactory apposition, but if not the plaster is cut off and a Kirschner wire is put through the os calcis and the limb is placed on a Braun's splint, the method which is used as a routine in all cases of compound fracture after the usual excision of the wound.

In mal-united fractures of the femur or leg bones the method gives results far surpassing those obtainable by plating. If the fracture is not more than two months old it is refractured under full anaesthesia and then treated by extension exactly as a simple fracture, if of longer standing with radio-opaque callus, an open operation is performed, the callus chiselled away, the bone ends freshened to open up the medulla, the wound closed and the extension applied. The resulting shortening is far less than if the ends had to be sawn off to permit of plating; weights of 20 to 30 pounds are easily borne by the wire and the shortening is reduced within a few days, after which the weight is gradually lightened. Needless to say the shock of this proceeding is far less than in a plating operation, and there is little risk of sepsis. When union is well advanced a plaster with a walking iron attachment or a caliper splint complete the treatment. The end-results are most gratifying.

A selection of brief case histories, with some radiograms, will illustrate the points referred to:

Case 1.—S. S. B., Hindu female, aged 58 years. Admitted 8th November, 1932. Old fracture of upper third of right femur four months ago. Shortening 1½ inches. X-ray showed sub-trochanteric fracture with adduction of lower fragment and acute angulation. Refractured on the 20th November and extension 15 pounds applied by Kirschner wire through tubercle of tibia; put up in extreme abduction. Wire removed on the 17th December; discharged on the 5th January, 1933, in plaster-of-Paris splint; subsequently fitted with caliper walking splint.

Final shortening ¾ inch; some adduction recurred owing to breaking up of plaster, but walking well in the splint and satisfactory clinical result.

Case 2.—N., Hindu male, aged 15 years. Admitted on the 6th January, 1933. Recent oblique fracture of lower third of left femur. Shortening one and a half inches (figure 7a). Kirschner wire through tubercle of tibia. Wire removed on the 7th February; extension by strapping for two weeks more. X-ray on the 25th February (figure 7b); discharged 3rd April.

Fig. 7—Case 2. (a) Before extension, and (b) six weeks later.

No shortening and patient able to walk. No caliper necessary.

Case 3.—B. R., Hindu male, aged 30 years. Admitted on the 3rd February, 1933; comminuted fracture of tibia and fibula, half inch shortening. Kirschner wire through os calcis; extension 8 pounds and Braun's splint. Wire removed on the 14th March, and posterior splint applied. Fracture in good position.

Discharged on the 21st April, with good union and no deformity.

Case 4.—B. S., Hindu male, aged 20 years. Admitted on the 24th March, 1933; comminuted fracture lower third of tibia and fibula, compound. Kirschner wire through os calcis; 10 pounds traction, Braun's splint and Carrel-Dakin irrigation to wound. Suppuration in wound needed counter openings on the 15th April and 21st April. Wire removed on the 5th June and plaster-of-Paris splint applied.

Discharged still in plaster on the 21st July with union in perfect position.

Case 5.—A. S., Mahomedan male, aged 25 years. Admitted on the 7th April, 1933. Direct violence fracture of left femur at junction of upper and middle third (figure 8a); showed tendency to adduction of lower fragment, half inch shortening. Kirschner wire through tubercle of tibia, 15 pounds traction and Thomas' splint. Wire removed on the forty-seventh day (the reason for this long retention is not recorded in the notes, probably union was progressing slowly,

but the knee joint was not suffering from the prolonged traction) X-ray on the 28th June (figure 8b) shows perfect position and abundant callus. No caliper necessary.

Case 6.—R. K., Hindu male, aged 30 years. Admitted on the 14th July, 1933. Compound comminuted fracture of left tibia and fibula. Kirschner wire through os calcis; 10 pounds traction, Braun's splint. Wire removed on the 7th September and plaster-of-Paris splint applied.

Discharged on the 13th November in plaster. Wound healed, firm union in good position.

Case 7.—A. M., Hindu male, aged 35 years. Admitted on the 4th August, 1933. Bad compound comminuted fracture of tibia and fibula. Shortening two inches

shortening and angulation. Kirschner wire through tubercle of tibia; 18 pounds weight and Thomas' splint; wire removed on the 19th October.

Discharged on 12th November in a walking caliper. Good union with no shortening.

Case 10.—B., Hindu male, aged 38 years. Admitted on the 8th August, 1933. Old fracture of the left femur of two to three months standing. X-ray showed overlapping and angulation with a lot of callus. Shortening two inches open; open operation on the 18th August, ends trimmed; callus removed; Kirschner wire through tubercle of tibia; 18 pounds weight and Thomas' splint. Wire removed on the fortieth day. X-ray on the 7th October showed a good alignment and abundant callus (figure 9).

Fig 8—Case 5. (a) Before extension, (b) on discharge 2½ months later.

Kirschner wire through os calcis; 8 pounds weight and Braun's splint. Wire removed on the 22nd September, plaster-of-Paris splint with walking piece applied.

Discharged 13th October with good union and no shortening, still wearing plaster.

Case 8.—M. I., Mahommedan male, aged 8 years. Fracture of right femur two months ago. Shortening one and a half inches, bad angulation. Open operation on the 19th August, using Henry's incision; ends trimmed; Kirschner wire through tubercle of tibia; 9 pounds weight and Thomas' splint. Good union; discharged with no shortening three months later. No walking caliper necessary.

Case 9.—B. K. R. C., aged 24 years. Admitted on the 11th September, 1933. X-ray showed comminuted fracture middle third of the right femur. One inch

Discharged on the 6th November walking with a stick; no shortening and no caliper necessary.

Case 11.—M., Hindu male, aged 10 years. Admitted on the 31st July, 1933. Compound fracture of right tibia and fibula. Wound excised and put up in plaster by Winnet Orr's method. Wound healed but x-ray showed position not good and one inch shortening. Refractured on the 21st September; Kirschner wire through os calcis; 12 pounds weight. Wire removed on the 23rd October and plaster-of-Paris splint.

Discharged 12th November with half an inch of shortening remaining, but good functional result.

Case 12.—K. N. S., Hindu male, aged 19 years. Admitted on the 16th October, 1933. Comminuted fracture upper third of the left femur. Alignment good

but one and a half inches of shortening. Kirschner wire through tubercle of tibia; 15 pounds weight and Thomas' splint. Wire removed on the 18th November.

Discharged on the 6th December in walking caliper splint with good union and no shortening.

Case 13.—B., Hindu male, aged 40 years. Admitted on the 22nd January, 1934. Severe compound comminuted fracture. Wound excised and put up in plaster-of-Paris splint according to the Winnet Orr's method. Severe sepsis supervened and plaster was removed on the 8th February, when the leg was found to be in such a septic condition that the question of amputation was considered. It was decided to put a Kirschner wire through the os calcis with a weight of 10 pounds and to treat by mercurochrome irrigations on a Braun's

was so far advanced four months later that the wire was removed and plaster-of-Paris splint applied. In neither of these cases did the presence of the wire for four months produce any ill effects. The excellent position of the bones will be noted in the skiagram. I think it may fairly be claimed that such results are impossible

(a) (b)
Fig 9.—Case 10 (a) Before operation, and (b) 2½ months later.

splint. The sepsis slowly yielded to this treatment and the condition of the bones on 10th October is shown in figure 10. At the end of May healing of the wound was so far advanced and the bones uniting in such excellent position that the wire was removed after a stay of three and a half months, and a plaster-of-Paris splint was applied. It is unlikely that this limb could have been saved by any other treatment.

Case 14.—A. A. S., Mahomedan male, aged 26 years. Admitted on the 12th February, 1934. Very severe gunshot wound with compound fracture of the right tibia and fibula, the ends of the bones protruding from the wound. Usual excision of wound; Kirschner wire through os calcis; 10 pounds weight; Braun's splint and irrigations of mercurochrome 1 in 1,000. The x-ray (figure 11) shows the condition one month later, the bone is severely comminuted and there are innumerable pieces of metal in the soft parts. In spite of this union

Fig 10.—Case 13 Antero-posterior view.

of attainment in such bad cases by any other method of extension. The apparatus is not expensive and the technique is soon acquired. The patients are very comfortable and the work of the nursing staff is much facilitated.

For specifications of the splints the reader is referred to two excellent articles by

11. R. Rishworth, which appeared this year in the January and March numbers of this journal.

TREATMENT OF COMPOUND FRACTURES OF BONES OF THE LEG BY SKELETAL TRACTION

By P. CHATTERJEE, M.B., F.R.C.S. (Edin.),
Honorary Additional Surgeon, Medical College
Hospitals, Calcutta

THE majority of cases of fractures of both bones of the leg can be successfully treated with splints and plaster applied after proper reduction and without continuous traction. In oblique or spiral fractures, however, there is a tendency for the displacement to recur as soon as the manipulative extension is discontinued, and also in some cases of compound fractures coaptation of the fragments after reduction cannot be maintained unless adequate traction is continued during after-treatment. In compound fractures with a more-or-less trivial external wound and a moderate amount of damage to the underlying soft structures, open reduction after a thorough surgical toilet of the wound and immediate plastering gives very good results; but when the patients come under observation after the infection has settled in the tissues, or where there is extensive mutilation of the soft parts, the amount of toilet necessary for immediate plastering becomes impossible. In them it is imperative to keep the wounds open for purposes of free drainage of the infection and management of the wound. Winnett Orr's method can be used successfully in certain types of infected fractures, but there still remains a group of cases where any attempt to practice this method will cause the infection to continue and spread along the tissues, considerably jeopardizing the life and the safety of the limb of the patient. In these cases where immediate plastering is impossible one has to depend on continuous traction and proper splinting for their management.

I have found Thomas' bed knee splint bent at the knee to the desired angle admirable in maintaining fixation and giving support. As the presence of infected wounds on the surface

Fig 1—A case of compound fracture of the talus being treated by skeletal traction with Steinman's pin in position.

of the limb prevents the use of the time-honoured sticking plaster extension, I have used skeletal traction by Steinman's pins driven through the calcaneus (os calcis) with uniformly good results. I have treated six cases of compound fractures of the tibia and fibula, and one case of compound comminuted fracture of the talus (astragalus) by skeletal traction. In all these cases infection was fairly severe and sequestra had to be removed before the wounds finally healed. In the compound comminuted fracture of the talus, after cleaning the wound and removing some of the comminuted pieces, I had to use skeletal traction to keep the ankle free for dressing and to relieve the patient of the most agonizing pain on slightest movement of the joint. The infection was so severe that the whole of the bone was destroyed and had to be removed at a subsequent operation. The relief that the patient got after traction was applied convinced me of the utility of the procedure.

Since the introduction of Kirschner's wire most surgeons have given up the use of Steinman's pins for purposes of skeletal traction. There can be no denying the fact that the size of the Kirschner's wire is a decided advantage. I commenced using the Steinman's pin before Kirschner's set was available in the medical college hospitals and continued its use

helps to approximate them into a position most conducive to their union. This approximation has to be maintained by adjustments of the trough on which the limb rests and by keeping up the traction to the desired degree. It has been impressed in the strongest terms that for the healing of fractures immobilization of the bones is absolutely essential, but how often in practice we find that the maxim is forgotten and our attention is directed mainly to the treatment of the infection of the wound allowing the fractured ends to move at their own will. By the time the infection is sufficiently controlled, we rise from our slumber to find that the bone ends have moved and are nowhere near each other. Our attention should always be directed to the position of the bone ends. Constant vigilance has to be kept up to see that the trough is properly adjusted, pads being placed here and there to prevent the movement of the bone ends. Assiduous care is necessary during dressing, so that the position of the fractured ends are not disturbed.

It is seldom necessary to keep the traction pin in for more than four weeks. By that time sepsis is almost always efficiently controlled, and the bone ends adjusted in their position and held by a mass of granulation tissue with loose bone formation in it. After the pin is taken out plaster casing with a suitable window or a removable plaster casing is used with advantage. In cases of compound fracture of the type that is being discussed in this paper, sequestra of varying sizes according to the nature of the case

Fig. 2.—A case of compound fracture of the femur being treated by skeletal traction with Kirschner's wire in position.

as I found it fairly satisfactory. Incidentally, I may here mention that I use Kirschner's wire driven through the upper end of the tibia in cases of compound fractures of the femur. Steinman's pin is easy to introduce and does not require a complicated appliance for its introduction.

It cannot be forgotten that skeletal traction is only a means to an end. It serves to keep the strong muscles of the calf under tension and helps to keep the fractured ends of the bones near each other. The relaxation of the muscles is further helped by flexion of the limb at the knee. Once traction serves to bring the ends of the bones near each other, proper manipulation

Fig 3 (a, b and c) showing the condition of the bones at three stages during the treatment of a case of compound fracture of the tibia by skeletal traction. The skiagrams were taken on 26th August, 29th November, and 21st February, respectively.

ADMINISTRATION OF OPIUM TO
INFANTS IN INDIABy R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

and

GURBAKSH SINGH CHOPRA, M.B., B.S.
(Department of Pharmacology, School of Tropical
Medicine, Calcutta)

Drug Addiction Series No. 16

HABITUAL administration of opium to infants has been prevalent in India for centuries. That this custom was common in the 16th and 17th centuries is evident from some of the passages occurring in 'Ain-i-akbari'. Its use appears to have been started because of its power of allaying diarrhoea and vomiting, relieving cough and pains, such as colic, and producing sleep. Dr. Roberts in the Report of the Royal Commission on Opium (1893-94) stated that administration of opium to infants was common and that it was considered a popular household remedy for their ailments.

(Continued from previous page)

and the severity of infection will have to be removed before complete union takes place.

As in all surgical procedures this method of applying traction has its admirers as well as opponents. Wardle (1933) in his article on fractures of both bones of the leg disfavours skeletal traction and is inclined to consider it as an unjustifiable interference. His views provoked criticism and the reply by Broomhead and Roberts (1933) will be read with interest. When I come to compare the results of my cases treated by this and by other methods, I have only admiration for it, not only for the better results obtained but also for the comfort it gives to the patient.

I do not believe in using it indiscriminately, but only in those cases in which the special conditions indicate it, and when other methods have failed.

In my case the pins through the calcaneus did not cause any damage to the bone, not even in the case of compound fracture of the talus where it had to be driven in so close to the septic wound (figure 1). The movements of the ankle joint were fairly maintained in all other cases except the one with fracture of the talus. In that case the resulting immobility of the ankle was not due to the pin but to the infection and fracture requiring removal of the whole bone. In my experience, which is admittedly limited, the advantages of the method far outweigh its seeming disadvantages.

According to this authority, the custom was widely prevalent in the United Provinces, Rajputana, Malabar and in Bombay Presidency. Although this custom has declined of late years, the problem of doping of infants with opium is of considerable importance now in many parts of India and deserves investigation. During our work in the field on opium habit, we have been able to make a general survey of the problem in different parts of India and have made special study of many of its aspects particularly in the Punjab, the Central Provinces and Berar. In this paper we propose to give the result of these observations.

Incidence of the practice

Our enquiries in the field show that the habit of doping infants with opium still prevails in most parts of India. It is started when the infant is a few weeks old and is not carried on, as a rule, beyond the age of two or three years. The incidence of this custom in various provinces of India is briefly as follows:—

Punjab and North-West Frontier Province.

—So far as these provinces are concerned, although the practice was fairly prevalent twenty-five years ago, it appears to have declined considerably during the last 20 years. Even in the central districts of the Punjab, e.g., Ferozepore, Ludhiana and Jullundur, which are populated chiefly by the Sikhs and where the consumption of opium is one of the highest recorded in India, with the exception perhaps of Assam and Calcutta, the doping of infants with opium is comparatively less common now than it was two or three decades ago. The practice, however, is still indulged in all over the province, and there is hardly a town or a village in which a number of these cases cannot be detected at the present time. The practice is more prevalent in the central districts of Lahore, Amritsar, Gujranwala, Gurdaspur and in the rich canal colonies of Lyallpur, Montgomery and Khanewal in Multan district. In Hoshiarpur and Jullundur districts, where poppy cultivation is allowed and the use of unalanced capsules is prevalent, the custom of giving an infusion made from the capsules of poppy to children in the evening is met with although not to any considerable extent.

In the Frontier Province the custom is not so common except among the poor working classes in large towns like Peshawar, Bannu, Mardan and Dera Ghazi Khan, and in the villages on the border of independent tribal territory and Afghanistan.

United Provinces.—The practice of doping infants with opium in these provinces used to be much more extensive in the old days, but recent inquiries show that it has considerably declined, except in large towns and industrial centres like those of Benares, Cawnpur, Allahabad, Mirzapur, Agra, Lucknow and Moradabad. In such

places the drug is chiefly employed by women of the poor classes engaged in factories to keep the infants quiet when the mother goes to work. The habit fortunately is rapidly disappearing from the rural areas throughout these provinces although cases are still to be met with in most of the villages.

Bengal.—This province has a remarkably large urban population especially towards the west where there is a large industrial population. In the area in the neighbourhood of Calcutta, there are large factories manufacturing jute and cotton, and milling rice, while a little further away are the coal fields employing a very large number of workers.

Our enquiries in this area show that the habit of giving opium to infants is quite extensive among the workers in the industrial areas in the districts of Hooghly, Howrah and 24-Parganas. In these areas most of the labourers come from the Central Provinces (Bilaspur district) and they have brought the custom with them and use the drug extensively for administration to infants. In the mining areas the labouring class is mainly derived from the aboriginal tribes (Sonthals and Bhils) who do not themselves take opium, nor do they administer it to their children.

So far as the town of Calcutta itself is concerned, our enquiries go to show that the custom of doping infants is not uncommon among the Sikh taxi-drivers and the low class labourers hailing from Behar and Orissa, and the Central Provinces. In eastern and northern Bengal though the custom existed formerly it has now practically disappeared.

Behar and Orissa.—The custom of doping infants with opium is prevalent in the districts of Gaya, Cuttack, Balasore, Puri, Sambalpur, Hazaribagh, Ranehi and Palamau. This practice was in vogue to some extent in Manbhum district formerly, but has disappeared now as a result of propaganda work carried out by the district touring officers of the excise, education and public health departments.

Rajputana.—In Jaipur, Ajmer-Mewara and Marwar, the custom prevails on a very extensive scale. In most of these states poppy is being cultivated and opium is produced. The drug is not only largely used by the population for its euphoric effects but is also a common household remedy. The custom of doping infants with opium is prevalent among all classes of people over the whole of Rajputana.

Bombay Presidency.—The custom of giving opium to children is not uncommon in the rural areas of this province particularly in the areas adjoining the Central Provinces and Rajputana and Kathiawar. The practice is more prevalent in the industrial areas like those of Bombay, Ahmadabad and Sholapur on account of a large proportion of female labour employed in the factories. In Gujrat and Kathiawar the practice of giving opium to infants is still largely in

vogue amongst the agricultural population, although not on such an extensive scale as in former days.

Madras Presidency.—This custom is practically non-existent in the south, and only few instances could be detected among the Sawa-rashtra community in Madura district and in Malabar. In the northern parts of the presidency, that is in the Northern Circars, Agency district of Ganjam, Vizagapatam and East Godavari, this practice is very prevalent and has attracted the attention of public health and educational authorities who are doing their best to suppress it.

The Central Provinces and Berar.—In the Central Provinces and Berar the custom of giving opium to children is more widely prevalent than in any other part of India. Our enquiries show that the practice is practically universal and prevails among every community both in the rural and urban areas. The custom appears to be a long-established one and was probably introduced by the Mohammedan rulers who hailed from Persia. It has been estimated that 25 per cent of the total opium consumed in this province goes to infants, and the consumption is still higher in the cotton-growing districts where children account for as much as 40 per cent of the total consumption. In cotton-growing areas the women have to work in the fields for long hours and they naturally want their children to remain quiet during their absences from home. It therefore comes about that as many as 75 per cent of the children are doped with the drug. The practice of giving opium to children is practically universal amongst the labouring classes and agriculturists. Members of the poorer classes, such as labourers, artisans and mendicants, are more affected than the educated. The following table gives an idea of the extent of the custom in the Central Provinces and Berar :

TABLE I

Showing the proportions of opium consumed by children and adults in the Central Provinces and Berar during the year 1933

	Percentage of opium consumed by children	Percentage of opium consumed by adults	Percentage of opium consumed for smoking	Percentage for medical purposes
Central Provinces	5	75	15	5
Berar	40	35	15	10
Province as a whole	25	50	20	5

N.B.—The total amount of opium consumed in 1933 was 12,397 seers (24,794 lbs.). This figure is the lowest on record.

Is the custom declining? Even in the Central Provinces and Berar there has been a considerable fall in the opium consumed during the past few years. This is probably due to the fact that the parents have had to reduce the dose for their children, on account of the present economic depression, the fall in wages and unemployment amongst the agricultural classes. During the year 1933 the consumption for the whole of these provinces averaged 12 seers per 10,000 population, as compared with the average consumption of 27 seers thirteen years ago (1920-21). The figures for Berar are still more interesting. Thirteen years ago the average amount of opium consumed per ten thousand of population was as much as 45 seers while during 1933 the amount fell to 9 seers. The doping of infants has also declined along with the consumption by adults, or is it that only the average dose has decreased? Probably both these factors are coming into play.

The factors responsible for this remarkable decrease are partly the tremendous increase in the price of opium and the prevalent economic depression, and partly also the widespread propaganda which is being carried out against its use by medical and public health authorities. In the industrial areas in the Central Provinces this propaganda has taken a practical shape and, in some of the large factories, nurseries have been provided for the working mothers who can leave their babies when they go to work where due care is taken of them. The women are allowed leave at particular hours to go to the nursery and feed their infants. When the disadvantages of giving the drug to the infants are explained, most of the Indian mothers quickly give it up. The belief that it is good for the babies' growth seems to be also rapidly disappearing.

From a general survey of different parts of India we are convinced that, although opium is still given extensively to infants in some of the large industrial centres where women have to do long hours of work in the factory, this custom is decidedly waning and has considerably declined in the rural areas. It has entirely disappeared from many parts of India where it existed before and is rapidly disappearing from the others.

Analytical study of cases of the administration of opium to infants

Age when started.—The practice is begun during the first few weeks of a child's life. Among the series of children examined by us the earliest time to commence administration of the drug was the age of 3 weeks and the latest was three months, but occasionally the doping may be started at a later age when necessity arises.

TABLE II

The starting age in 100 infants studied

Third week and under	Fourth week	Eighth week	Twelfth week	Total
58	32	4	6	100

It will thus be seen that in about 90 per cent of infants the drug was started before the 4th week of their lives and that only in 10 per cent was it started later than this age. In the rural areas the drug appears always to be administered to those infants who are weakly and ailing. Those who have no trouble during this difficult period are rarely given the drug by the labouring classes.

Duration.—When the child attains the age of 2 or 3 years the practice is usually discontinued. Analysis of a series of 100 children examined at random showed that there is no child who gets opium habitually after the age of 3 years.

TABLE III

Duration of the doping period in 100 children examined

Up to 1 month	2 to 6 months	6 to 12 months	12 to 18 months	18 to 24 months	25 to 36 months
2	26	30	18	18	6 = 100

It will be seen that 66 per cent of the infants get opium up to from 6 to 24 months and that none get it beyond 3 years of age. There is, however, no hard and fast rule regarding the age when the doping is definitely stopped. The practice is generally given up when the child begins to play about and can live on ordinary food such as rice, *dāl* and vegetables.

Ætiology.—As we have shown above both in the Central Provinces and the Punjab the main reason for administering the drug is economic, it is given to keep the children quiet and to allow the mother to do her work unhampered. In Berar and certain parts of the Punjab (Simla Hills) custom forbids the child to be taken out and the mothers have to work for long hours. Cases have also been met with when the drug has been given to appease hunger among the poverty-stricken masses and to keep the baby warm in cold weather.

For disease and minor ailments opium is considered as a sovereign household remedy. It is specially given to children during their teething period to allay diarrhoea, peevishness and salivation. There is a deep-rooted belief amongst the parents in many parts that opium acts as a

preventive against cough, cold, diarrhoea and other minor ailments. The palliative properties of the drug in these conditions cannot be denied and the ignorant people consider it a necessity for their children and are quite unconscious of the harm it does. A large number of parents start giving the drug on account of some disease or minor ailment, and its frequent repetition leads to its habitual administration to the children as in the case of adults.

Table IV shows the diseases and ailments for which opium was started in 100 cases examined at random.

TABLE IV

Disease for which administration of opium was started in 100 children selected at random

	Number of cases
1. Cold with sneezing, coughing, watering of the eyes and nose ..	20
2. Boils all over the body (called 'Charu' in the Punjab) ..	7
3. Diarrhoea, particularly infantile diarrhoea with green stools ..	30
4. Teething and other such troubles ..	10
5. Colic and other pains ..	18
6. Sore eyes, pain and watering of the eyes, otitis media with purulent discharge from the ear (opium is believed to dry up the discharge and allay pain) ..	10
7. To cause loss in weight ..	1
8. For polyuria and anuria ..	1
9. For infantile convulsions ..	1
10. As general tonic and euphoric ..	1
TOTAL ..	100

A perusal of table IV will show that in 48 per cent of the infants the drug was given as a cure for abdominal discomfort, diarrhoea, and colic; in 30 per cent for relief of catarrh of respiratory passages and conjunctivitis, and in 10 per cent for troubles associated with dentition. It is interesting to note that only one child was given the drug because of its virtues as a tonic.

Dosage.—The dose is very small in the case of children so that opium worth a pice or two may suffice for a week or even longer. The dose given is often said to be equal in weight to that of a poppy seed. Experience has taught the mothers to keep the dose as small as possible, because infants usually develop tolerance to the drug very slowly.

TABLE V

The dose administered to 100 children selected at random

Daily dose	Number of cases
Up to $\frac{1}{4}$ gr. ..	40
" $\frac{1}{2}$ grs. ..	44
" $2\frac{1}{2}$ " ..	8
" 3 " ..	8
TOTAL ..	100

The dose is usually three-sixteenths to three-eighths of a grain to begin with, and is gradually increased to one and a half grains; we have recorded cases in which a child between 2 and 3 years received as much as three grains daily, but such large doses are rarely given. In all cases the dose has to be gradually increased to obtain the desired effects. We have observed that the parents are likely to increase the dose whenever the child gets an attack of some ailment, such as diarrhoea, cold or cough. Table V shows that in quite a large majority of cases (84 per cent) the dose is kept below $1\frac{1}{2}$ grains a day and that only in about 16 per cent are larger doses given.

Table VI shows the daily dosage according to age in 100 cases investigated.

TABLE VI

Daily dose	Up to 1 month	2 to 6 months	7 to 12 months	13 to 18 months	19 to 24 months	25 to 26 months	Total
$\frac{1}{4}$ gr.	2	16	14	2	6	..	40
$1\frac{1}{2}$ grs.	2	10	12	8	3	4	44
$2\frac{1}{2}$ "	2	2	4	..	8
3 "	2	2	2	2	8
	4	26	30	14	20	6	100

Age incidence.—From table VI it will be evident that 56 per cent of the children taking opium were between the ages of 2 to 12 months and 94 per cent were below 2 years. Only 6 per cent were between 2 to 3 years and no child took opium after the third year. It is thus clear that children between the ages of 2 to 24 months are more liable to be doped, probably because this is a critical period of life in India when the child is more likely to suffer from troubles associated with dentition and other disorders associated with the alimentary and respiratory tracts.

The approximate dose with age and the yearly consumption by a child was worked out in a series of cases in Berar and is given in the following table :

TABLE VII

Age in years	Daily dose limits	Approximate average daily dose	APPROXIMATE ANNUAL CONSUMPTION	
			In tolas	In grains
1	$\frac{1}{8}$ to $\frac{1}{4}$ gr.	$\frac{1}{4}$ gr.	1	180
2	$\frac{1}{4}$ to 2 grs.	$1\frac{1}{4}$ grs.	2	360
3	2 to 3 "	1 gr.	2	360

Table VII shows that a child consumes 5 tolas (900 grains) of opium during the total period of its childhood. The annual consumption of opium by children in Berar is estimated to be 40 per cent of the total yearly consumption.

Frequency.—The dose is generally administered twice daily, i.e., in the morning and in the evening. It may be given only once a day to begin with and when the use of the drug is about to be stopped. We have not met cases where the drug has been administered oftener than twice daily.

Modes of administration.—The drug is administered in the form of crude bazar opium. The usual practice is to buy a week's ration at a time and keep it in a small tin box. The size of a pin's head is broken off and is put into the child's mouth and the child is put to the breast. In Bombay Presidency, especially in Gujrat and Kathiawar, small pills are made which are called *bala golis* or children's pills which are commonly sold by quacks. One of these is dissolved in a little water or milk and given to the child. Sometimes the suckling mothers smear their nipples with opium and thus administer it to the infants.

Sex incidence.—In our series of cases there was a preponderance of female over male children 65 per cent as compared with 35 per cent. The reason for this is not clear.

Symptoms and effects.—The majority of the parents are unanimous with regard to the effects produced by the habitual administration of opium upon their children. They state that after the dose the child keeps quiet, smiles, plays and sleeps well. These infants when examined after their usual dose lie quietly sleeping or half sleeping close to the spot where the mother is working. The narcotic effects of the drug generally last from 4 to 6 hours during which period the child remains undisturbed. An important result of the practice is constipation which is, however, desired and encouraged by the parents to save themselves the trouble of cleaning the child frequently. We have seen infants whose bowels were said to move once or twice a week only. In those infants who have daily movement of the bowels the stools were always hard. The general physical condition and health of the majority of these children were poor as is seen by the following analysis:

TABLE VIII

Showing health of 100 children taking opium

Daily dose	Poor	Fair	Good	Total
Up to $\frac{1}{2}$ gr.	16	16	8	40
" $1\frac{1}{2}$ grs.	24	10	10	44
" $2\frac{1}{2}$ "	2	6	2	8
" 3 "	2	6	..	8
	42	38	20	100

It is difficult to say how far this poor state of general health physique is due to opium alone and how far to other causes, viz, insufficient nutritious food, unhygienic surroundings and general lack of care. There is no doubt, however, that, as compared with children under similar circumstances who were not getting the drug, the doped children looked leaner and more unhealthy.

It is difficult to estimate the immediate and remote effects produced by opium on the mental faculties of the children. We are carrying out detailed studies by following these infants into different stages of childhood and boyhood including their school career. During the period when they are receiving the drug they have a peculiar drowsy appearance and are physically less active.

The parents in many places fully believed in the beneficial and wholesome effects of giving opium to their children. This belief they said was based on the accumulated experience of many successive generations who had used the drug. Further, the harmful effects of opium, such as constipation and intoxication, which may be considered as the cause of poor health, are actually regarded by the parents as being beneficial and health-giving. There is no doubt that some of the children did look quite healthy despite the large doses they were receiving but such cases are not common.

Another danger of the use of the drug is that unless the dose is properly regulated there may be accidental poisoning. Doctors and nurses working in the mill dispensaries have often noted children brought in a state of somnolence from an overdose of opium. The toxic syndrome consists in the child being unusually sluggish and drowsy, the pupils contracted, and the reflexes diminished. The symptoms may pass off without any treatment, but deaths from overdose do undoubtedly occur though not frequently. Continued use of the drug appears to make the child more liable to attacks of epidemic diseases. Most of these children are continuously ailing and our inquiries show that the mortality rate among them is comparatively high.

We have observed that children soon get addicted to the drug and develop withdrawal symptoms. If the drug is not given about the due time, the child cries, its eyes and nose water, it does not take its nourishment well, and it gets looseness of the bowels. All these symptoms subside when a dose of opium is given. This rapid disappearance of the symptoms certainly accounts for the deep-rooted belief regarding the beneficial effects of opium in the parents' minds. The question as to whether the children become addicted to the drug in the same way as adults is under investigation and will be dealt with in a separate paper.

Physical effects.—Opium appears to hinder the normal growth of the child probably on account of the toxæmia it produces. The children

are as a rule smaller for their age, are thin, anæmic, and emaciated; their conjunctivæ are dull and their pupils contracted; and they have a general unhealthy appearance. Conjunctivitis, corneal ulcers and opacities, and otitis media with purulent discharge are frequent occurrences among these children. About 40 per cent of the children were found to be suffering from enlarged tonsils, adenoids and discharge from the nose. The tongue is often coated with fur. The abdomen was prominent on account of the sluggishness of the bowels and accumulation of the gut content and production of wind. The liver was enlarged and palpable in 20 per cent of the children and all of them had a relaxed skin on account of the paucity of subcutaneous adipose tissue, and were under weight. The bones were prominent owing to wasting of the overlying muscles. The chest was thin-walled and the ribs were prominent on account of the wasting of the intercostal muscles. The cardiac impulse was forcible, and the heart sounds loud and could often be heard all over the chest.

Strength of the habit.—It does not have the same hold over children as over adults. In most of the children the drug can be stopped without any great inconvenience. Cases have been recorded, however, where a child showed most of the abstinence symptoms occurring in adult addicts.

Seventy per cent of the parents believed that opium was beneficial if administered in proper doses before 3 years. The balance recognized that it was harmful, but considered its use essential to enable them to do their daily work. The habit unlike that in adults is not expensive, and furthermore could be easily discontinued.

Discontinuance of the practice.—The weaning of the child from the opium habit is generally done gradually, and any resumption of it in adult life is entirely disconnected from the habit in childhood. When for want of a dose the child cries or becomes restless a heavy meal of rice or milk stops the discomfort. The period taken for the complete withdrawal of the practice varies from a few weeks to one or two months. When a child is irritable from discontinuance of the drug, two or three minims of tincture of belladonna with two to four grains of potassium bromide are very effective in controlling any untoward symptoms that may arise from abstinence. The child is quietened down at once and may fall asleep.

Summary and conclusions

(1) Habitual administration of opium to infants at certain periods of their life has been prevalent in India for many centuries. The habit appears to have been started because of the drug's power of allaying diarrhoea and vomiting, relieving cough and pain, and producing sleep.

(2) The custom although it is still met with in almost every part of India has greatly declined during the last two or three decades. The drug is however still employed extensively in the industrial areas and in the Central Provinces and Berar. The practice is undoubtedly becoming less and less common in the rural areas. It has entirely disappeared from many parts of India where it existed before and is disappearing from others. The incidence of the custom in different parts of the country has been discussed in detail.

(3) An analytical study of a large number of infants receiving the drug has been made, and various factors, such as age of commencement, duration of administration of the drug, causes leading to the custom, dosage given, methods of administration, and symptoms and effects produced, connected with the custom have been discussed.

(4) The main reason for administering the drug is economic, the drug being given to keep the children quiet so as to allow the mother to carry out her work, whether in the factory or the field, unhampered.

(5) The practice is begun during the first few weeks of the infant's life, the earliest time to commence being 3 weeks and the latest period 3 months. The drug is usually discontinued when the child attains the age of 2 to 3 years, that is when it begins to play about and can live on ordinary food. The dose varies from $\frac{1}{8}$ to 3 grains daily.

(6) The drug affects the child's health adversely and hinders growth. The children receiving opium have an emaciated, unhealthy and toxæmic appearance. They are more liable to catch infections and attacks of epidemic diseases and the mortality rate among them is comparatively high.

(7) Although deaths from overdosage are not frequent they do occur. Non-fatal overdosage is not uncommon.

FACTORS INFLUENCING THE SPREAD OF LEPROUS INFECTION

By E. MUIR, M.B., F.R.C.S. (Edin)

Working under the Indian Research Fund Association,
and the School of Tropical Medicine, Calcutta

K. R. CHATTERJI

Bankura Leprosy Investigation Centre

IN this paper certain definite hypotheses are set forth. Evidence is brought forward in their support based chiefly upon two grounds: the leprolin test, and careful investigation into the histories of affected families at the Bankura Leprosy Investigation Centre.

Our hypotheses may be summarized as follows:—

1. Most healthy human adults possess (perhaps in varying degree) natural resistance to leprosy.

2. Subliminal infections with *Mycobacterium lepræ* tend to increase resistance to the disease.

3. Resistance to leprosy is lessened by three main factors:—

(a) *The age factor*—in young children resistance to leprosy is lowered.

(b) *The debility factor*—any disease, habit, physiological condition, or anything else which debilitates the patient, lowers the body resistance to leprosy during the period that debility lasts.

(d) *The hyperinfection factor*—the multiplication of Hansen's bacilli in the body beyond a certain amount lowers the resistance to leprosy, even though the patient may otherwise enjoy excellent health.

The leprolin test

If an autoclaved suspension of ground-up leproma, containing large numbers of Hansen's bacilli, is injected into the human skin, certain reactions take place which may be studied clinically and histologically. A standard suspension (Hansen's leprolin) is used and 0.2 c.cm. is injected intradermally.

Clinical appearance.—A weal about 10 millimetres in diameter is raised which disappears in a short time and may be followed by the appearance of an area of slight erythema, wider in diameter than the weal; this also disappears after a day or two. If the reaction is positive, there appears after a period varying from 4 days to 2 or 3 weeks a slightly raised, erythematous area round the point of inoculation. On picking up the affected skin between the finger and thumb an indurated nodule is felt varying in thickness from 3 to 10 millimetres. This induration generally reaches its maximum about the third or fourth week, and then gradually subsides, though it may take several months before it entirely disappears. In some cases necrosis takes place at the centre and a small

pustule appears and discharges, this being followed by more rapid resolution of the nodule.

The indurated nodule described above is caused by Hansen's bacilli, and the reaction is the same whether the suspension injected is first subjected to heat or not. A similar reaction is caused in healthy adults by other acid-fast bacilli such as rat leprosy bacilli, tubercle bacilli or saprophytic acid-fast bacilli. For a reason which will appear later, in carrying out the test we generally use as a control a suspension of rat spleen and liver, taken from a rat inoculated several months previously with *Mycobacterium lepræ muris*. This suspension (rich in Stefansky's bacilli and generally called Stefansky's leprolin) is standardized so that 0.2 c.cm. produces, in a healthy, non-leprous adult, at the end of the third week, an indurated nodule of approximately the same size as is produced by the same amount of Hansen's suspension. The end of the third week is chosen as in many cases the reaction to *Mycobacterium lepræ* suspension (Hansen's leprolin) takes place more slowly than that to the control; but at the end of the third week the former has generally caught up on the latter. The degree of reaction may be conveniently read by picking up the nodule between the finger and thumb and measuring it in millimetres with a pair of sliding calipers (figure 1). The test should always be carried out in the thin skin of the medial side of the arm.

Fig. 1—Measuring leprolin nodule with sliding calipers.

So far we have considered the leprolin reaction in the healthy adult. We shall now study the variations in leprous patients:

1. In patients who have been in contact with infectious leprous patients and have received subliminal infections the reaction to Hansen's leprolin tends to be enhanced, while that to Stefansky's leprolin remains the same. This is true whether or not visible lesions are present.

2. In patients in whom hyperinfection has taken place, i.e., in whom bacilli have multiplied to more than a certain concentration, the

reaction to Hansen's leprolin is less, and in C-2 or C-3 cases no indurated nodule forms. Provided however that the patient is an adult and in good health the control reaction to Stefansky's leprolin is positive as in healthy non-lepers.

3. In young children, especially in the first year of life, the reaction to both Hansen's and Stefansky's leprolin is reduced or negative. An exception to this is sometimes found in children who have had slight contact with a highly infectious case, or more close and prolonged contact with a less infectious case, and have thus acquired subliminal infections; in these children one may find the reaction to Hansen's leprolin stronger than that to Stefansky's.

4. In debilitated patients the reaction to both forms of leprolin is reduced or may be clinically negative. Debility in the sense referred to may be caused by various diseases, dietary deficiency, climatic and many other conditions; even such physiological conditions as pregnancy and lactation must often be included.

5. Any two or all of the three factors which lower resistance may exist together and enhance each other, or they may follow each other successively. Thus a child in contact with a highly infectious mother may on account of the age factor acquire a high infection during its first few months or years. Later, as the child grows older, the hyperinfection factor comes into play and prevents the increase of resistance which would naturally have accompanied elimination of the age factor. For further references to the leprolin test see Chiyuto (1932), Hayashi (1933), and Muir (1933, 1934 and 1934a).

The histological study of the reaction to Hansen's leprolin shows a cellular response very similar in nature to that of lesions already present in the skin. In patients with raised indurated macules containing few or no bacilli but showing dense formation of epithelioid cells and frequent giant cells, the reaction to Hansen's leprolin is always strong. If the leprolin nodule is excised some three weeks after inoculation, sections show the same features as are found in the lesions present in the skin, viz, dense grouping of epithelioid cells, disappearance of the bacilli injected, and numerous giant cells.

In contrast to this we take a C-2 case and, choosing a region of the skin where bacteriological examination fails to show any acid-fast bacilli, inject Hansen's leprolin. Clinically there is no reaction. Sections taken two or three weeks later show either no cellular reaction or only a comparatively loose and mild cellular response causing slight thickening of the capillaries; the injected bacilli have almost all entirely disappeared, having apparently been removed by the lymph flow.

Discussion.—At the beginning of this paper we put forward the hypotheses that resistance to leprosy is present in different degrees in the majority of healthy adults; that this resistance

is enhanced by slight (subliminal) infections, but is diminished by heavy infection, by all conditions of debility and in early childhood. These hypotheses are based primarily upon a careful clinical study of large numbers of leprosy cases, but these are confirmed by the results obtained with the leprolin test.

There appears to be no doubt that the leprolin test gives a reliable indication of the degree of resistance to leprosy. It is strongly positive in cases which all leprosy workers are agreed in regarding as resistant cases, viz, those in whom there are a few limited, indurated, highly anæsthetic lesions, chronic in nature, with few or no acid-fast bacilli and with little or no tendency to increase in size or number. There is much reason to believe that lesions showing a strong, compact epithelioid reaction, often with numerous giant cells, as found in sections both of the natural lesions and of the leprolin nodule, may be rightly regarded as a sign of high systemic resistance to leprosy.

In contrast with this is the strong, healthy, adult leper (C-2 or C-3 type), with a negative leprolin test; cellular response to the injected bacilli is comparatively weak. Similarly in young children and in debilitated persons the cellular response to Hansen's leprolin is low and the bacilli are not rapidly destroyed at the site of inoculation. It is justifiable to consider that these three factors render the system non-resistant to leprosy.

It is well known that conspicuous swollen leprosy lesions often disappear during acute febrile fevers, and in other conditions which produce rapid debility. During convalescence however these lesions reappear in their former sites, generally extended in size and often accompanied by new lesions of similar appearance. The explanation of this phenomenon is that during the period of debility cellular reaction to the bacilli lying in the skin is held in abeyance, though the bacilli, undeterred by tissue response and phagocytosis, multiply rapidly. During convalescence the power of the cells to react is gradually restored, marked cellular response to the bacilli in the skin once more takes place, and hence lesions reappear larger and greater in number.

All authorities on leprosy are in agreement that while conjugal infection from infected wife or husband is comparatively uncommon (given variously as from 2 to 4 per cent), infection of children by leprosy parents is exceedingly common, averaging round about 40 per cent. It is generally found (note cases described below) that, in a family where young children, older children and adults are in contact with an infectious case, the younger children tend to develop a generalized form of the disease, at first inconspicuous, but later showing itself in multiple lesions of the cutaneous or non-resistant type. On the other hand those who have passed their tender years when infectious contact first takes

place tend (if the disease appears at all) to develop fewer lesions, and these are more of the resistant, neural type. These facts corroborate the evidence that the resistance in young children to leprosy infection is lower than that in adults.

Spread of infection.—The practical bearing of our hypotheses on the nature of the spread of leprosy may be made clear by presenting it in diagrammatic form (figures 2 and 3).

Fig. 2.

Fig. 3.

The key to the diagrams is as follows:—large disc = adult; small disc = child; white disc = non-leper; crossed disc = non-infectious leper (resistant type); black disc = infectious leper; smooth-margined disc = non-debilitated; wavy-margined disc = debilitated; arrows = degrees of infectious contact; = indicates the result of this infectious contact. Degree of infection depends on the closeness and length of contact and on the grade of infectiousness of the transmitter of infection.

It will thus be seen that, on the basis of the arbitrary standard that we have adopted, two degrees of infection are not sufficient to induce the disease in the healthy adult, but three degrees produce a non-infectious or resistant case, and four degrees an infectious case. On the other hand three degrees of infection are sufficient to make a debilitated adult into an infectious case. In the case of young children, however, one degree of infection may turn a healthy child into a non-infectious case of leprosy, and two degrees a healthy child into an infectious case, while one degree may be sufficient to make a debilitated child into an infectious case.

Leprosy investigation centre evidence

The truth of these hypotheses can only be checked by careful study of the spread of infection in families and communities. Investigations which are being carried out at the Bankura Leprosy Centre furnish considerable confirmatory evidence. The following six charts with explanatory notes illustrate the nature of this evidence.

In the case of healthy individuals the disc of the sex symbol is white, in infectious lepers

black, and in non-infectious lepers crossed. The numbers above each sex symbol indicate (from above downwards) year of birth, year of first clinical signs, year of becoming an infectious case, and year of death. If any of these is not known, a ? is inserted; if any has not yet occurred, a dash is inserted. The century figures are omitted as far as possible to save space, 1920 being written 20. If other families have been infected by the original family the contact is indicated by a dotted line, the year when contact began being marked along this line. When there is more than one case in a family, each case is marked by a serial number in brackets.

CHART I

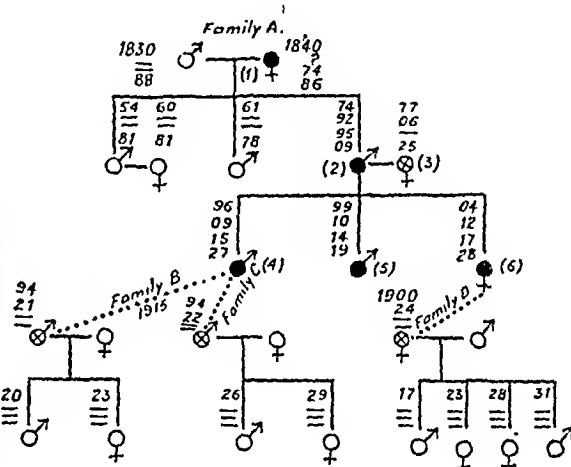

CHART I. Family A.—Gendu (1) when 34 years of age became an infectious case of leprosy after the birth of her third son, Pranannath (2). At that time her first son had married and was living in his father-in-law's house, and her second son was about 13 years old; the latter died in his 17th year without any sign of leprosy. Gendu remained an infectious case for another 12 years and died in her 46th year. Pranannath (2) the third son of Gendu (1) had infectious contact with his mother from birth. He showed his first visible lesion in his 18th year, one year after his marriage. Three years later he became a nodular case and remained in that condition for 14 years, dying in his 35th year. Pranannath's wife (3) was 18 years old when her husband became an infectious case; she developed a few patches in her 29th year, but died in 1925, without further developing the disease, in her 48th year. Jati (4), the first son of Pranannath, was in infectious contact with his father from birth; his first visible lesion appeared when he was 13; he became an infectious case in his 19th year and died at the age of thirty-one. Mati (5), the second son of Pranannath, was likewise in infectious contact with his father from birth. He showed an initial lesion when 11 years old, became infectious in his 15th year and died in his 21st year. Pranannath's third child Gati (6) was a daughter; she also was in infectious contact with her father from birth onwards; her first visible lesion appeared when 13 years old and died as such in 1928 in her 24th year.

Family B.—Paran, a friend of Jati (4) of family A, was in infectious contact with Jati from his 21st year. His first lesion appeared in his 27th year and still persists. He is now 40 years of age and an N-1 case. His wife and two children show no sign of leprosy.

CHART IV. Parimal (1); aged 14, used to play about with cotton swabs from leprous cases, he also used to drink milk supplied by an infectious leprous woman who herself milked the cow; the first sign of disease appeared when he was 4 years old; after repeated attacks of malaria he became an infectious case when 5 years old, and is now a C-3 case at the age of fourteen. His sister (2), aged 11, had infectious contact with her brother from her second year; her first lesion appeared when 10 years old; she is still an N-1 case. Another sister (3), aged 9, also had infectious contact from birth; she first showed signs of leprosy when 8 years old and has now four hypopigmented, anæsthetic patches; she is thus an N-2 case; her leprolin test shows increased resistance to leprosy. Parimal's cousin (4), a boy of five years, had infectious contact from birth; 6 months ago he developed a lesion which is positive on bacteriological examination.

CHART V

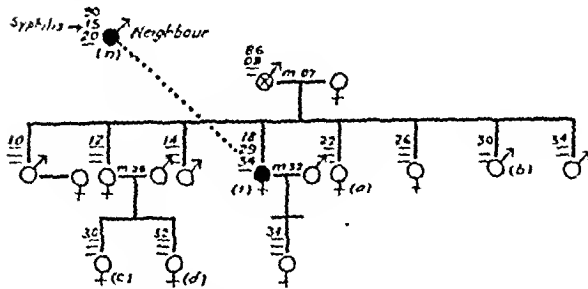

CHART V. A Brahmin, now aged 48 years, noticed about 26 years ago a depigmented anæsthetic patch on his chest. This patch is still present and has during this period undergone no change. It is bacteriologically negative and seems to be a scar. He gives no definite history of contact. His daughter S. B., aged 16, used when a child to be carried about by a neighbour, an infectious case of leprosy, who is still alive and still an infectious case. When she was 11 years old, hypopigmented patches appeared on her body, which however disappeared at puberty. She was married at the age of 14 years 9 months, and 13 months later bore a female child. During this period she was free from any signs of leprosy, but 1½ months after the birth of her child a number of bacteriologically-positive thickened patches suddenly appeared in different parts of the body, including the sites of former lesions. The leprolin test shows slightly increased reaction in the near relatives marked (b), (c) and (d).

CHART VI

CHART VI. Fulkumari (1) was in contact from her birth up to the age of 3 years with her cousin, an infectious case of leprosy who used to carry her about in his arms. She was married at the age of 13. In her 19th year after the birth of her first daughter, she developed two anæsthetic patches which however disappeared during her second pregnancy. But three months after the birth of her second daughter, many erythematous thickened patches appeared all over her body. She is now 22 years old, a C-1, N-2 case.

We have used the terms 'infectious' and 'non-infectious' for lesions according to whether they were found positive or not on routine bacteriological examination.

Discussion.—We find that, out of the 17 cases which had infectious contact beginning from birth or before the sixth year of life, 10 have already become infectious cases; the average period between their first possible infectious contact and their becoming infectious was 14.7 years. Of the remaining 7 cases one is only 4 years old, and she has already developed

a non-infectious lesion. The remaining 6 are all of one household; one child is already an N-1 and another an N-2 case; in this household the source of infection was a boy who was known to be suffering from leprosy and was kept partly isolated; moreover, in this family the average period between first possible infectious contact and the present time is 5.5 years, or a little more than one-third of the average period required to produce infectiousness in the 10 cases mentioned above which have already reached this stage.

Of the remaining 16 cases, whose first infectious contact occurred at ages varying from 11 to 25 years, only one has become infectious; and there was in his case a very distinct history of marked debility due to malaria and dysentery. Of the 16, however, 8 have developed the non-infectious type of the disease, the period between possible first infection and first appearance of signs averaging 10.5 years.

It will be observed that in no case was there any reason to believe that infection had taken effect through contact with a so-called non-infectious case; this tends to show that this name is a justifiable one for patients who give negative routine bacteriological results.

It is fully realized that the number of family records is too few to form any basis for conclusions. Also, while all members of the families have been included in the survey, only those contacts outside the family who acquired the disease have been included. For the information about some of the cases we had to rely almost entirely upon the results of cross examination of villagers; but, as far as we are aware, no data were entered which were not at least approximately correct. Those 6 families have been selected as typical of many others, and we have recorded them fully in order to show a method of investigation which may usefully be taken up by other workers. As statistics based upon such surveys accumulate the hypotheses put forward will be thoroughly tested.

The present records, as far as they go, tend to confirm our hypotheses, at least regarding the nature of the factors which raise and depress resistance to leprosy.

Two points are brought out clearly by these family records: (a) the importance of the infectious case in transmitting leprosy within the house and among neighbouring contacts; and (b) the importance of the child who within the first few years of life comes into close and prolonged contact with an infectious case. For this child not only acquires the disease, but generally develops it in the cutaneous and infectious form, and thus becomes the transmitter to the next generation. Although adult contacts sometimes become cutaneous or infectious cases, especially if exposed to some severe and lasting source of debility, this occurrence

is comparatively rare; and there is reason to believe that if in any community all infectious cases could be effectively isolated from children under 10 years of age, leprosy would disappear from that community in one, or at most in two, generations.

Summary

1. Most healthy adults are naturally resistant to leprosy. This resistance is increased by small infections, but it is low in young children, and is decreased in debilitated persons and in those who have become hyperinfected with *Mycobacterium lepræ*.

2. Evidence in favour of the above is found in the leprolin test, the use of which is explained.

3. Similarity is found between the clinical and histological appearances of a patient's leprous lesions, and those of the nodule produced by the leprolin test when this test is carried out in the same patient.

4. The factors influencing the spread of leprosy are given in diagrammatic form.

5. The histories of six typical leprous families are examined in detail. These tend to confirm the above hypotheses concerning the spread of infection.

DENTAL MYIASIS

By D. N. ROY, M.D., D.T.M. (Cal.)

Assistant Professor of Medical Entomology, School of Tropical Medicine, Calcutta

A CASE of dental myiasis in a person with a badly carious tooth was reported by Strickland (1929).

We have now received maggots from a second case, notes of which have been sent by Dr. Chakrabarty, assistant medical officer, Ambootia Tea Estate, Kurseong, as follows:—

'A patient had inflammation of the gum which went on to abscess formation. Pus was noticed round the tooth, the tooth itself not being carious. It was extracted and a large number of fly maggots emerged and were collected. The patient made an uneventful recovery'.

Evidently the odour of pus had attracted a fly which deposited its eggs in the vicinity of the peri-dental abscess while the patient was

A COMPARATIVE RECORD OF ANTHELMINTIC TREATMENT WITH TETRACHLORETHYLENE AND OIL OF CHENOPODIUM

By D. MANSON, M.B., Ch.B., F.E.S., F.Z.S.

Medical Officer, Jorehaut Tea Company, Limited, Cinnamara, Assam

TETRACHLORETHYLENE has been used as an anthelmintic in the treatment of hookworm infections in various parts of the world since 1925 and a considerable number of papers, some favourable and some adverse, on its efficiency and toxicity have been published by research workers, mainly in the United States of America, since that date.

Articles on its use have appeared in this journal (Maplestone and Chopra, 1933, and Maplestone and Mukerji, 1929 and 1933); in these were embodied the results of researches conducted at the Calcutta School of Tropical Medicine. In the last of these articles a careful résumé of the effects of treatment with tetrachlorethylene was given; the workers concluded that tetrachlorethylene was safer than, and at least as efficient as, carbon tetrachloride.

By the courtesy of the workers at the Calcutta School of Tropical Medicine, I was furnished with a quantity of tetrachlorethylene (Parke, Davis and Co.) in December 1933 and the present paper incorporates the result of treatment carried out since that time in ordinary tea-garden hospital routine on the estates of the Jorehaut Tea Company, Limited. From past experience with carbon tetrachloride the necessity for an equally efficient, but considerably safer type of standard treatment was clearly realized. It was hoped to find this more suitable remedy in tetrachlorethylene.

In spite of all precautions, carbon tetrachloride occasionally produces untoward symptoms, due either to the drug itself, or to one or other of its impurities. In a recent quotation in the *British Medical Journal*, carbon tetrachloride is indicted as the offender and the chemical impurities are exonerated from blame.

One fairly definite fact is that carbon tetrachloride is apt to produce symptoms of toxæmia in cases of severe roundworm infection. Its use in alcoholic subjects has also been arraigned and there is a large mass of evidence that this charge is a true bill.

(Continued from previous column)

asleep. The eggs hatched out and the maggots led to the further trouble.

The larvæ were identified as those of a species of chrysomia, probably of *C. bezziana*.

- Strickland, C. (1929). A Case of Myiasis of a Carious Tooth. *Indian Med. Gaz.*, Vol. LXIV, p. 386.

Tomb and Helmy (1933) express the opinion that carbon tetrachloride is capable, even in therapeutic doses, of causing fatal intoxication, accompanied by acute degeneration of the liver. They also point out that delayed symptoms are due to non-elimination of the drug. In this connection, the method of administration of carbon tetrachloride simultaneously with an effective dose of magnesium sulphate, as advocated by Maplestone, is undoubtedly the safest plan to follow.

In tea-garden practice here, it has always been the rule to exclude alcoholics from treatment, to examine carefully for signs of hepatic disease, and to avoid 'bazar' days or the days following in giving routine treatment with carbon tetrachloride. A careful chemical examination of this drug was also invariably carried out to determine the presence of impurities, notwithstanding the assurances of the makers that their product was wholly reliable. It was hoped to avoid the necessity for these precautions by using tetrachlorethylene.

The number of cases treated in the present series was 300 and this was regarded as a sufficiently large number to justify or condemn tetrachlorethylene as a satisfactory anthelmintic for general use on tea gardens. Tetrachlorethylene supplied by Messrs. Parke, Davis and Co. was used at the beginning, and later Merck's preparation of the same drug, as further supplies of the former maker's product were not at the time available.

Chemistry of tetrachlorethylene

The production of tetrachlorethylene and similar organic chlorides is carried out in the following way. Dry and purified HCl gas is compressed and mixed with pure dry CO under a pressure of 1,000–3,000 lbs. per square inch and then treated with a catalyst such as NiO, Al₂O₃, and CuO at a temperature of about 230–400°C.

The resultant, as far as tetrachlorethylene is concerned, is expressed by the formula CCl₂:CCl₂ or C₂Cl₄. It has a density of 1.6558 at 0°C. and 1.6311 at 15°C. B.P. is 121.2°C. and M.P. is 22.35°C.

Zuckermundil recommended that a small proportion of a paraffin hydrocarbon, such as liquid petrolatum, be dissolved in it to inhibit decomposition. The amount suggested is 0.1 to 1 per cent of liquid paraffin. Parke, Davis and Co. recommended that the drug should be put up in red capsules to prevent the action of actinic light.

From a study of the literature of the pharmacology of tetrachlorethylene, it is clear that it should be administered, preferably, after a fat-free diet for twenty-four hours and after combination of the drug with liquid paraffin in the dosage recommended as a stabilizer. The drug should be kept excluded from light and preferably in a brown-tinted bottle.

As the object of the investigation was to test the drug under field conditions little attention was paid to the diet factor, but care was taken to prevent the exposure of the drug to

light, and liquid paraffin was added in the proportions recommended.

With the organic chlorides, it is possible that chlorine atoms may be set free and lead to hypocalcæmia. The inference from this is that calcium gluconate might be a useful addition to the diet of patients under treatment. This was not carried out here, but is worthy of note and would be a rational mode of procedure in cases that exhibited signs of toxæmia. It was not used as no cases of this kind occurred during the trial.

Mode of treatment

Before starting routine treatment on the coolie population, a trial of tetrachlorethylene (hereinafter referred to as TCE) was made on three dogs with a maximum dose of 5 c.cm. for a seventy-pound bulldog. The results were excellent. As regards the symptoms produced, the exhibition of the drug caused a train of events closely resembling complete intoxication. No ill effects ensued and the dogs were perfectly normal in three hours. Symptoms generally ensued about one hour after the dose was given. In these three cases, capsules (Parke, Davis and Co.) were used.

Preliminary series

In treating the labourers on these gardens, the dosage suggested by Maplestone was employed for a preliminary series, 4 c.cm. of TCE along with two ounces of saturated solution of magnesium sulphate being given to adults. The TCE was carefully shaken up with the magnesium sulphate in a four-ounce bottle and given before separation took place. A hundred cases were treated in the preliminary test and no case showed toxic symptoms.

Present series

After this initial trial, which was found to be entirely satisfactory, it was decided to give TCE in different doses, alone and also with oil of chenopodium. For comparison, a separate series of cases were treated with oil of chenopodium alone.

The following four treatments were therefore administered to four groups of labourers:

Group I.—Tetrachlorethylene 4 c.cm. only (TCE/4).

Group II.—Tetrachlorethylene 3 c.cm. only (TCE/3).

Group III.—Tetrachlorethylene 3 c.cm. (TCE/CHEN) plus oil of chenopodium 1 c.cm.

Group IV.—Oil of chenopodium 3 c.cm. only (CHEN).

These were maximum doses for adults. The cases treated were mainly adults and in the children treated proportional doses were used.

No preliminary selection of cases was made, and as far as possible the same type of labourer was treated in each group. In all cases, Tallqvist readings were taken before and after treatment. In order to eliminate the possibility of confusing subsequent symptoms due to the drug with those due to the presence of any inter-current malaria, blood films (thick and thin) were taken prior to the commencement of treatment. Spleen findings were also noted on each case. By these means, it was hoped to avoid errors in compiling the symptomatology of the effects produced by TCE alone.

Symptoms following the administration of TCE

The symptoms produced by 3 c.cm. and 4 c.cm. were similar; the difference in dose did not seem to influence their nature or severity, noticeably. These usually were vertigo, which rapidly subsided, giddiness of about one hour's duration, slight tendency to sweating, which ceased when the patient sat down, and a general feeling of *bien être*. In fact, the symptoms were those of a mild, but not unpleasant, degree of intoxication. In a few cases only, there was transient nausea, immediately following the dose, with occasional complaint of a burning sensation in the throat. These quickly subsided when the patient rested. Very few cases of actual sickness occurred. The symptoms, in the main, were exactly those induced by a hearty jorum of neat raw whisky in the unaccustomed.

In all cases, the labourers preferred TCE to oil of chenopodium as evidently the slight intoxication produced was ranked by them, not as a deficiency, but as a real merit. They manifestly enjoyed the short and pleasant respite from the workaday world. This point is of considerable importance, as any treatment that is effective and at the same time acceptable to the patient is obviously indicated as a routine measure. Several hardened toppers returned after a week and asked for a second helping. With chenopodium, I have never seen this happen, nor has carbon tetrachloride ever enjoyed this salutary popularity.

In no case were there any adverse symptoms and there was no evidence of toxicity either immediately or delayed.

So far as symptomatology goes, TCE is therefore an improvement on carbon tetrachloride, chenopodium, and beta-naphthol.

The following table gives the symptoms produced by each form of treatment with percentages and totals.

Vertigo was common in all the groups including the group treated with oil of chenopodium only. The percentage showing no particular symptoms is fairly even in each series, except that the chenopodium group shows a somewhat higher incidence of negatives. Symptoms of intoxication were common to all the TCE groups but absent in the chenopodium series. The highest percentage of intoxication is in the

TABLE I
Symptoms following treatment

TREATMENT	TCE/4		TCE/3		TCE/CHEN		CHEN		Total	
	Cases	Percentages	Cases	Percentages	Cases	Percentages	Cases	Percentages	Cases	Percentages

Jaundice	1	1.25	1	0.33
TOTALS ..	80	100	74	100	74	100	72	100	300	100

TCE/4 group. Nausea and giddiness were present in a small number of TCE cases, but not in the chenopodium group. Sleepiness was common to the TCE/4 and chenopodium groups only. There were a few cases of vomiting in each series including the chenopodium cases. Abdominal pain occurred in 1.33 per cent of the TCE treatments, but may have been due to intercurrent causes.

In only one case (TCE/3) was jaundice noted. This ensued on the second day after treatment and was transient in character. Previously, in using carbon tetrachloride, I have observed quite a number of cases of jaundice, some of which were of a severe type which necessitated considerable care in treatment.

Mode of checking the results of treatment

In all cases treated, the stool was examined the day before and again ten days after completion of treatment. Egg counts were made of (a) roundworm ova, (b) hookworm ova, and (c) whipworm ova. The presence of any other intestinal parasites was also noted on each case sheet.

Egg counts in all cases were given per cubic centimetre of stool examined. In order to eliminate the personal factor, all counts were carried out by one assistant.

Method of egg count

A suitable test-tube was taken with marks at 17 c.cm. and 20 c.cm. The tube was filled with 0.4 per cent sodium hydrate to the mark 17, and the sample of stool to be tested was added to raise the level to the mark 20 c.cm.

The contents were mixed and placed in a wide-mouthed bottle to which was added another 70 c.cm. of the same solution of NaOH, to bring the total content to 90 c.cm.

Several glass beads were placed in the bottle which after corking was vigorously shaken for five minutes to emulsify the contents completely.

0.15 cubic centimetre of the emulsion was transferred to a slide and a 22 by 40 mm. cover-glass placed over it.

The specimen was then examined microscopically, a no. 3 objective, and a 8×B ocular being used.

All the ova were then counted and the totals of each type were multiplied by 200: this gives the egg count per cubic centimetre of stool examined. If the specimen of emulsion overflowed and spread on to the slide outside the limits of the cover-glass, the excess fluid was also examined and the ova count included in the total in each class.

Equivalence of groups

Parasite rates, spleen rates, and hæmoglobin percentages (Tallqvist) were taken for each case treated. As noted above this was done primarily as a check to obviate the inclusion of symptoms due to another disease appearing in

the symptomatology of TCE, but the data obtained were of value as an index to the homologous character of each group: they are given below :—

TABLE II
Malarial parasite rate

Treatment	No. of cases	POSITIVE FINDINGS		MALIGNANT TERTIAN		BENIGN TERTIAN	
		No.	%	No.	%	No.	%
TCE/4	80	11	13.75	7	8.75	4	5.0
TCE/3	74	9	12.15	6	8.11	3	4.05
TCE/CHEN.	74	9	12.16	8	10.81	1	1.35
CHEN.	72	8	11.11	3	4.17	5	6.94
TOTALS	300	37	12.33	24	8.0	13	4.33

No quartan parasites were found.

Spleen rates.—The average spleen rate of the 300 cases was 14.6, and of each of the groups 1 to 4 it was 14.86, 15.00, 16.22 and 12.50, respectively.

Hæmoglobin (Tallqvist scale).—The average readings of the four groups were, respectively, 61.35, 61.43, 62.16 and 60.41; of the whole 300 cases the average was 61.30.

Other worms found.—Threadworms in considerable numbers occurred in 7 cases in the series. Tapeworms (*Tænia saginata*) were found in two cases only. Threadworms were expelled in two cases treated with TCE/4, in two cases after oil of chenopodium, and in three cases after the mixed treatment. Tapeworms occurred in one case treated with TCE/4 and in one case having mixed treatment.

Condition of worms after treatment

The passing of live worms was reported, as follows :—

TCE/4	9 cases.
TCE/3	10 cases.
TCE/CHEN	7 cases.

No reports were made regarding the cases treated with oil of chenopodium only.

The above results cannot be regarded as entirely conclusive as in a large number of cases no reports were made of the effects on the worms.

Classification of results

The results of treatment in each group were classified in four divisions according to the egg counts. These divisions were as follows :—

1. Completely negative. No ova in samples.
2. Below 600 ova per cubic centimetre of stool. This light degree of hookworm infection is not likely to produce symptoms of anæmia.

3. 600 to 5,000 ova per cubic centimetre of stool. This degree of infection may possibly cause symptoms of anæmia.
4. Above 5,000 ova per cubic centimetre of stool. This degree of infection is almost certain to produce symptoms of anæmia.

[Note.—The above standards are generally accepted as the best for classifying hookworm infections roughly, and are those used by Dr. P. A. Mapstone at the Calcutta School of Tropical Medicine.]

Results obtained

The following table gives the results of each treatment in detail. Cases negative before treatment for any particular worm are excluded from that type in the table.

The same scheme of classification was used for roundworms and whipworms to obtain uniformity in comparison. The part that roundworms play in producing pathogenic symptoms is not so definite as in the case of hookworms, but its ill effects in children have been proven without doubt. It can also cause serious illness in adults when the infection is heavy. As regards anæmia, the part played by roundworm infection is somewhat obscure. Whipworms are generally regarded as non-pathogenic, but they have recently been accused of causing oxaluria. However non-pathogenic it may be, it is certainly better to clear out whipworm infection than to leave them alone. So far no line of treatment has proved effective against the whipworm, probably owing to its choice of position in a sheltered portion of the gut.

No evaluation of other egg infections was made, but the effects of the various treatments on other intestinal parasites are noted in a later section of this paper. The number of such cases was too small to allow of any conclusions on the efficacy of any of the treatments used.

TABLE III

Comparative table showing the results of treatment by four different methods. Number of cases treated in each group and percentage distribution of these cases according to intensity of infection after treatment

	Course of treatment	TCE/4	TCE/3	TCE/CHEN	CHEN
Roundworm	Number of cases in each group.	70	59	57	62
	No ova ..	60.00	44.07	59.65	51.61
	Below 600 ..	15.71	15.25	19.30	11.29
	600 to 5,000 ..	21.43	33.9	17.54	35.49

TABLE III—concl'd.

	Course of treatment	TCE/4	TCE/3	TCE/CHEN	CHEN
Hookworm	Number of cases in each group.	65	58	58	63
	No ova ..	64.61	55.17	68.97	47.60
	Below 600 ..	26.16	17.24	18.96	23.80
	600 to 5,000 ..	9.23	27.59	12.07	28.60
	Above 5,000
Whipworm	Number of cases in each group.	75	64	70	65
	No ova ..	41.3	35.94	45.71	33.85
	Below 600 ..	29.3	29.69	37.14	26.15
	600 to 5,000 ..	29.3	34.37	17.15	40.0
	Above 5,000

Roundworm.—From the table, it will be evident at a glance that the mixed treatment and TCE/4 produce a high percentage of complete cures, the mixed giving 59.65 and the TCE/4 60.00. The other two types of treatment give a considerably lower percentage of cures.

Hookworm.—The percentages of negative results are again high for the mixed and TCE/4 treatments, and lower for the other two treatments.

Whipworm.—The results are more even and, although there is a slight advantage in favour of mixed treatment and TCE/4, the difference is much smaller than in the other infections. Whipworm is believed to be non-pathogenic and, on this account, and, in view of the small difference in the means, it is not proposed to investigate this group further.

Further consideration of the results

In noting the results it must be borne in mind that the mere percentages of cure do not indicate the extent of the original infections in each patient. These vary within very wide limits and, in order to indicate clearly which type of treatment is statistically the best, some methods of comparison which takes into account the extent of the infection per cubic centimetre of stool before and after treatment must be applied.

The 't' statistical method of Fisher (1932) was therefore applied to the results and the 't' values determined for hookworm and roundworm.

Hookworm.—The very small infections were not included; the series was determined for all egg counts above 3 and under 25 per 0.005 cubic centimetre of stool. The limit 24 was chosen so as to get representative groups under each treatment. 0.005 cubic centimetre of stool was taken instead of 1 cubic centimetre so as to reduce the amount of arithmetic by using the common divisor, 200.

The results obtained are expressed in the following tables :

TABLE IV
Hookworm eggs per 0.005 c.cm. of stool

[illegible]

TABLE V

Hookworm. After-treatment infections in cases with initial infections over 3 and under 25 ova per 0.005 c.cm. of stool

		Ova	Cases	Mean
(a)	TCE/3	56	26	2.151
(b)	CHEN	91	41	2.220
(c)	TCE/CHEN	31	29	1.069
(d)	TCE/4	38	35	1.086

TABLE VI

Table of comparisons

(a) and (c)	(a) and (d)	(b) and (c)	(b) and (d)
S = 2.40	S = 2.231	S = 2.62	S = 2.482
t = 1.67	t = 1.51	t = 1.81	t = 1.98
P = 0.11	P = 0.141	P = 0.078	P = 0.051
Odds on = 9-1	Odds on = 7-1	Odds on = 13-1	Odds on = 19-1

The odds on significance being 20-1, therefore :—

Four c.cm. tetrachlorethylene is nearly significantly better than chenopodium 3 c.cm.

Mixed treatment is better than chenopodium 3 c.cm. alone.

Mixed treatment is almost possibly better than tetrachlorethylene 3 c.cm.

Four c.cm. tetrachlorethylene is not definitely better than 3 c.cm. tetrachlorethylene.

Mixed treatment and 4 c.cm. of tetrachlorethylene are almost equally efficient.

Roundworm.—The same procedure was followed but the count included all cases with egg count of 4 per 0.005 c.cm. of stool and over. The roundworm infections were much greater than the hookworm and the numbers are more evenly distributed so that no upper limit was necessary.

The results* were as follows :—

TABLE VII

Roundworm. After-treatment infections in cases with initial infections above 3 ova per 0.005 c.cm. of stool

		Ova	Cases	Mean
(a)	TCE/3	391	40	9.775
(b)	TCE/CHEN	183	41	4.463
(c)	TCE/4	180	42	4.285
(d)	CHEN	196	49	4.000

TABLE VIII

Table of comparisons

(a) and (b)	(a) and (c)	(a) and (d)	(b) and (d)	(c) and (d)
S = 11.64	S = 10.9	S = 10.5	S = 7.96	S = 6.99
t = 2.05	t = 2.26	t = 2.58	t = 0.34	t = 0.24
P = 0.050	P = 0.034	P = 0.016	P = ...	P = ...
Odds on = 20-1	Odds on = 29-1	Odds on = 62-1		

[* It has been necessary in the interest of space to omit the table for roundworms which corresponds to table IV.—Editor, I. M. G.]

The odds on significance being 20-1 or over, therefore :—

Mixed treatment is significantly better than tetrachlorethylene 3 c.cm.

Tetrachlorethylene 4 c.cm. is significantly better than tetrachlorethylene 3 c.cm.

Chenopodium 3 c.cm. is very significantly better than tetrachlorethylene 3 c.cm.

Mixed treatment and chenopodium 3 c.cm. are about the same value.

Tetrachlorethylene 4 c.cm. and chenopodium 3 c.cm. are about the same value.

Discussion

A method of comparison which would include all the results is not demonstrated in any of the standard works on statistics, and the method chosen, using Fisher's 't', is the best available at the moment. It is hoped that a better method may be evolved in the near future when a résumé of the comparisons may be given in a future paper.

The fallacy of accepting conclusions on mere percentages is made apparent, and much medical work in the past has no mathematical value as exact methods of comparison have not been used and conclusions have been arrived at which would not bear exact investigation.

In giving these results, much of the tedious working out has been omitted and it is hoped that this omission does not obscure the issue. To include all would render this paper unnecessarily long without adding to its interest for the general reader who is only concerned with the results.

A study of co-variances shows that there is some degree of correlation between initial and final egg counts, but this has not been included in the present paper.

Acknowledgments

I have to acknowledge the valuable assistance of my chief laboratory assistant, Dr. L. R. Dey, who carried out the egg counts, and the help which I received in the statistical section from H. R. Cooper, Esq., B.Sc., F.C.S., Acting Chief Scientific Officer, Tocklai Experimental Station, and from G. Walker, Esq., Deputy Commissioner, Sibesar, who assisted me with some of the tiresome arithmetic.

My thanks are also due to Doctors L. E. Napier and P. A. Maplestone of the Calcutta School of Tropical Medicine, for arranging the supply of the original bottles of carbon tetrachlorethylene and suggesting a field experiment.

Summary and conclusions

(1) Four hundred coolies were treated with four treatments of which three contained tetrachlorethylene; no adverse results were recorded. It is evident that tetrachlorethylene is a safe and reliable anthelmintic for general use, when properly administered.

(2) Tetrachlorethylene in a dose of 4 c.cm. and mixed treatment, tetrachlorethylene 3 c.cm. plus oil of chenopodium 1 c.cm., proved to be definitely the best methods of treatment for mixed helminth infections, and for hookworm infections.

(3) Oil of chenopodium 3 c.cm. proved the best method of treatment of roundworm infections, but was closely followed by mixed treatment and tetrachlorethylene 4 c.cm. All of these three proved very effective, but the smaller dose of tetrachlorethylene was inferior in this capacity.

(4) Tetrachlorethylene is safer to use than carbon tetrachloride, as it was administered to alcoholics without adverse results.

(5) The partiality of the coolie to tetrachlorethylene is emphasized as an important feature in recommending its use on tea estates.

(6) The percentage of cures with mixed treatment (tetrachlorethylene 3 c.cm. and oil of

chenopodium 1 c.cm.) and with 4 c.cm. of tetrachlorethylene was between 60 and 68 per cent after a single treatment.

(7) The necessity for statistical methods in an investigation of this nature is emphasized.

(8) In conclusion, it seems permissible to suggest that a treatment consisting of 4 c.cm. of tetrachlorethylene and 1 c.cm. of oil of chenopodium might prove more effective still; there is every indication that such a dosage could be used with impunity.

A Mirror of Hospital Practice

THREE CASES OF SUBCUTANEOUS INTRA-ABDOMINAL INJURY WITH SOME POINTS IN DIAGNOSIS

By H. A. LEDGARD

CAPTAIN, I.M.S.

(Indian Military Hospital, Quetta, Baluchistan)

My object in publishing this paper is twofold. First of all in order to emphasize the importance of certain early indications for operative interference, as so many of these cases are overlooked until it is too late; and, secondly, because I believe the condition of subcutaneous rupture of the intestine to be much more common than is generally supposed. R. P. Rowlands (1923) collected 381 cases, of which 315 were rupture of either the jejunum or ileum. Grant Massie (1923) pointed out that in the majority of cases the contusion is below the umbilicus.

The intestine is most frequently ruptured by blows, kicks and crushes on the abdomen; in many cases the blow is only slight in nature. Serious intra-abdominal mischief may be done by indirect violence such as falls on the buttock (Senn, 1904), or, as in one of my cases, by falls on the back.

Diagnosis

Extreme pain, rigidity and tenderness are present from the outset. There may be no bruising of the abdominal wall and if this sign is present it is apt to lead to a hasty and superficial diagnosis of 'contusion of the abdominal wall'.

Rigidity may be purely local at first but rapidly becomes diffuse, the abdomen becoming distended as the escape of gas occurs or as peritonitis sets in.

Shock.—This may be so severe as to prove rapidly fatal; in many cases, however, it is very slight and evanescent.

Vomiting is almost always present.

Dullness.—Shifting dullness may be present in the flanks but a diagnosis should be possible without this sign.

The pulse rate.—A rising pulse rate is an indication for laparotomy.

Auscultation.—The value of auscultation cannot be overestimated. There are two important signs. Twenty years ago Claybrook (1914) pointed out that, in cases of ruptured intestine following injury, the heart sounds can be heard as distinctly over the abdominal wall as over the cardiac area. This phenomenon is probably due to gas in the peritoneal cavity as the presence of free fluid alone is not enough to produce the sign, *e.g.*, in cases of ruptured ectopic gestation. Claybrook stressed the value of this as an indication for immediate laparotomy. More recently James (1934) has pointed out, in an excellent article, the complete absence of peristaltic sounds on auscultation of the abdomen in cases of perforated bowel. He states that this 'silent abdomen' is present often before diffuse peritonitis is established. The site for auscultation is the left lower quadrant of the abdomen.

Mainly on account of errors in diagnosis; the 'missed case' and consequent delay in operation

(for this is the only line of treatment) the mortality of subcutaneous abdominal injuries is appalling. Berry and Giuseppi (1908) reporting on 132 cases give the mortality as 80 per cent in those cases who submitted to operation. Cope (1914) gives the operative mortality of a series of cases as 77 per cent; and Grant Massie showed the mortality as 78 per cent. Without operation all cases are fatal. The latest figures of the mortality are unfortunately not available, but I know that the death rate is still too high. In these enlightened days of 'safe surgery' such a state of affairs is indeed distressing. I would, therefore, urge most strongly that all cases of abdominal injury, in which any four of the following signs are present, be submitted to immediate laparotomy.

- (i) Extreme abdominal pain.
- (ii) Tenderness in the abdomen.
- (iii) Rigidity—local or general.
- (iv) Claybrook's sign
- (v) James' 'silent abdomen' } auscultatory signs.
- (vi) Shock.
- (vii) Vomiting.
- (viii) Rising pulse rate—a rate above 90 per minute or a 'thready pulse'.

Case records

Case I.—Ruptured ileum

Mrs. F. A. G., 43 years of age, was standing on a household ladder, hanging curtains, when the ladder slipped and she was thrown to the ground, striking her abdomen on the projecting edge of the ladder. She felt severe pain in the abdomen and she vomited once. Towards evening she called in her family doctor, as her condition was not improving and he ordered her to bed as she 'looked ill'. The following afternoon she was sent to hospital.

On admission the pulse and temperature were normal, but the patient complained of severe pain over the right side of the abdomen. There was extreme tenderness and rigidity over the right rectus abdominis muscle and just below the umbilicus on the right side there was a small bruise. No other signs of injury were noted.

Operation.—A right paramedian incision was made and there was an effusion of blood into the subcutaneous fatty tissue; a large hæmatoma was present in the right rectus muscle and I hesitated in view of this to proceed further with the operation. Fortunately I did so, for on opening the peritoneum there was an escape of gas. A circular perforation about one-eighth of an inch in diameter was found in the ileum about three feet from the ileo-cæcal junction. It was surrounded by plastic material causing it to adhere to the adjacent coil of intestine. The opening was closed in two layers with catgut. No other tears were seen and, as there had been very little escape of fluid into the peritoneal cavity, the abdomen was closed without drainage.

The patient made a complete and uninterrupted recovery, although laparotomy had been delayed for over twenty-four hours, the fortunate adhesion probably saved the woman's life.

Case II.—Ruptured ileum

Sowar, N. M., 19 years of age, was grooming a horse when he received a kick in the abdomen. He was admitted to hospital immediately, complaining of severe pain in the right side of the abdomen. There was no external sign of injury. There was extreme tenderness over the whole abdomen and rigidity on the right side. Some hours later there was a complaint

from the patient that he was unable to pass flatus. Vomiting was almost continuous. The patient slept at intervals.

The next morning his condition gave rise to anxiety and he was transferred to another hospital (over 100 miles away) by motor-ambulance. On arrival he was seen by me and signs of peritonitis were definite. The temperature was 100°F., and the pulse rate 116 per minute. The abdomen was distended, rigid and extremely tender. There was also shifting dullness in the flanks.

Laparotomy was performed thirty hours after the injury. There was seropurulent fluid in the peritoneal cavity. A tear about a quarter of an inch in diameter was found in the anti-mesenteric border of the ileum about one foot from the ileo-cæcal junction; this was closed by means of a purse-string suture. The peritoneal cavity was swabbed out with warm saline and the abdomen closed with drainage. Glucose saline, pituitrin and eserine, and morphia were administered, but the patient died thirty hours later.

Case III.—Ruptured mesentery and branch of superior mesenteric artery

A. S., a Punjabi Sepoy, 25 years of age, was admitted to hospital complaining of pain in the back and abdomen of two days' duration.

He gave the following history. Whilst running down a hill, he slipped and injured his right loin. He vomited once shortly afterwards. No difficulty in micturition and no blood passed in the urine. The pain in the back persisted and there was also pain in the abdomen and inability to sit upright.

Examination.—Sitting posture caused agonizing pain in the abdomen. No bruises were seen on the back and there was no deformity of the spine or pelvis. There was extreme tenderness in the right loin and rigidity of the loin muscles. There was no distension of the abdomen but the whole of the abdominal muscles were rigid. There was board-like rigidity of the lower half of the right rectus muscle and extreme tenderness in the right iliac fossa. Temperature 103°F. Pulse rate—120 per minute. Respiration rate—20 per minute. Urine—normal. Total white cell count—13,800.

Operation.—A right paramedian incision was made and the peritoneal cavity was found to contain blood and clots. Most of this was swabbed away and the terminal part of the ileum at its junction with the cæcum was seen to be of cherry red colour. In the mesentery supplying this loop was a hæmatoma and a small tear. After careful swabbing it was seen that a branch of the superior mesenteric artery was ruptured and spurting. This was under-run with catgut sutures and the small tear was repaired. A lateral anastomosis was performed between the cæcum and the proximal part of the last loop of ileum. No resection was attempted in this difficult region, partly because it was felt that the piece of bowel might recover or at the worst a faecal fistula would form, and partly on account of the critical state of the patient. The abdomen was closed with drainage. A normal motion was passed two days after the operation and recovery was uneventful—the patient being discharged from hospital within one month.

PERI-ANAL ULCERATION COMPLICATING KALA-AZAR

By R. O. A. SMITH, D.T.M., I.M.D.,
Officer-in-Charge, Kala-Azar Enquiry,
and

CHIRANJI LAL, L.T.M., I.M.D.
(Indian Research Fund Association)

THE following case is reported as the complication which characterized this case of kala-azar is, we believe, of very rare occurrence.

N. P., a young Hindu male, 25 years of age, was admitted to hospital on 1st May, 1931, suffering with kala-azar. He gave a history of five months' duration of illness; his spleen was about six inches below the costal margin, and the liver slightly enlarged; anaemia was not marked. He had rather a muddy complexion, but was otherwise well nourished. His aldehyde test was positive, and he showed many parasites in his peripheral blood.

Shortly after admission he complained of pain about the anus during defecation, and on examination a small ulcer was seen at the posterior margin of the anus in the middle line. The patient was emphatic that he had no previous lesion there, and that the present one was of recent occurrence. His Wassermann reaction was negative.

Local treatment only was ordered, i.e., dressing with lotio nigra,* application of unguentum hydrargyri ammoniati, and later lotio acriflavina, but despite this treatment the ulceration spread rapidly.

Neostibosan treatment was begun on 8th May, the initial dose given was 0.1 gramme, then 0.2 gramme on 10th May. On the 12th May the patient was in great pain and very restless. It then occurred to the senior writer that the generalized leishmania infection from which the patient was suffering might be the main aetiological factor in producing the ulcer. When first seen the ulcer was small and coated with pus; later it spread rapidly in a fan-shaped manner involving the gluteal folds on either side. The edges were clean-cut and not raised; the base was red, and covered with a thin layer of pus; it did not bleed easily. The surrounding tissue showed no swelling or oedema.

Dr. Napier was asked to see the case as it was such an unusual one. He very kindly did so and agreed that the ulcerative condition could probably be looked upon as a complication of kala-azar, and he suggested intensive treatment with neostibosan, that is, given in full doses of 0.3 gramme every day instead of every other day. He did not think there was need in this case for gold therapy, the routine treatment in cases of cancrum oris*. The patient was treated accordingly and showed improvement within forty-eight hours.

The pain from the ulcer rapidly diminished and by the time his temperature had reached normal the ulcer had almost healed.

Ten days after his temperature was normal, on 28th May, he complained of pain in his right groin and it was then seen that a hubo was developing. This was lanced on 4th June and from the pus a culture of *Staphylococcus aureus* was grown. The wound healed rapidly and the patient was discharged to attend for dressing on 11th June.

The question now arose whether this ulcer was due solely to kala-azar or to some other factor. In the last case of kala-azar complicated with cancrum oris treated by the senior writer, there was a grave suspicion that scurvy was also present and was probably responsible for the precipitation of the ulcerating condition. The

child under consideration was neither ill-nourished nor very anæmic, but all its front teeth were loose and the gums very inflamed. Plenty of vitamin C was therefore given in addition to the routine treatment for cancrum oris. The ulcer healed rapidly, the gums soon closed firmly over the teeth, and the child made a good recovery.

Our patient, N. P., had no complication such as threadworms, piles or syphilis which might have caused proctitis, and have led to secondary anal ulceration. He admitted one previous attack of gonorrhoea and it is possible he might have exposed himself again, so that the possibility that this peri-anal ulceration might have been some venereal manifestation should not be lost sight of. Antimony has been used successfully in the treatment of such conditions as well; but the fact that there was no lesions on the penis or in the inguinal region, and that the ulcer was large, painful and rapidly-spreading is not in favour of such a possibility.

The bubo that occurred was a straightforward one and a pure culture of *S. aureus* was grown from the pus after incision. There was no involvement of any of the other glands.

Cancrum oris is reported to occur in cases of long-standing kala-azar, but in neither of these cases mentioned was the disease of long standing, we therefore suggest that some special factor was responsible for the production of the ulcerating condition in these patients whose resistance was generally lowered by kala-azar. as for instance scurvy in the child and venereal disease in the man.

A CASE OF SCHIZOPHRENIA WITH SUPERIMPOSED BENIGN TERTIAN MALARIA CURED WITH ATEBRIN

By A. K. M. ABDUL WAHED, B.Sc., M.B.
House Physician, Carmichael Hospital for Tropical
Diseases, Calcutta

A. C. R., a Bengali Hindu male, aged 33, was admitted into the Carmichael Hospital for Tropical Diseases on 9th March, 1934, in a state of somnolence with a provisional diagnosis of encephalitis lethargica.

The patient had been quite normal mentally and physically until two years ago when, having some suspicion about his wife's character, his mental attitude changed and he temporarily became morose and less communicative. Following a change in his environment, by removing from his village to Calcutta and finding employment in a mercantile firm, his mental condition cleared and he behaved normally for about a year. Shortly after he happened to hear certain remarks of some people about his wife. A severe mental depression overtook him for the second time and he tendered his resignation to the office, which a normal man of his position would never have done. He then went back to his village and became absolutely silent and his movements became limited and short. He had now a short attack of low pyrexia which was regarded as an attack of influenza and soon after he had a short attack of arthralgia of several joints. He then gradually became lethargic, somnolent and passed most of his time in bed. If he was made to sit up he would soon become drowsy. He would often go without food for a fortnight and even then he had to be fed forcibly. He had no inclination to answer the calls of nature. Only very rarely he would get out of

* Krysolgan injections, commencing with a dose of 0.0001 gramme together with some benign mouth-wash, has for sometime been the routine auxiliary treatment for cancrum oris adopted by Dr. Napier.

his bed and roam about his village but he would never talk. In this condition he had been for about ten months until his admission into the hospital.

On examination he was found to be dull and somnolent. His face was expressionless and wore the appearance of 'inanimate stupidity'. Most of the time he would keep his eyes shut but at times he would keep them open for two or three hours at one stretch with a vacant expression. If vigorously aroused he would waken up for a moment or two and then relapse into the same condition. The limbs were flaccid most of the time and became spastic during examination. He appeared to be insensitive to stimuli such as a pin prick, venepuncture, etc. The pupils reacted equally to light; there was no strabismus. The abdominal reflexes were brisk. The Babinski sign was absent. The heart and lungs were normal; the liver and spleen were not palpable. There was a slight degree of anaemia. The Wassermann reaction was negative. After two or three days' stay in hospital it was discovered that he was running a low temperature ranging between 98° and 100°F. This prompted a blood examination for malaria parasites. The smear showed benign tertian rings and trophozoites. There were no microfilaria in the blood. In the stools ascaris and hookworm ova were found; vegetative and cystic *Entamoeba nana* were also present. Bacteriological examination of the stool was negative. The urine was normal.

The patient was put on a five days' course of atabrin. On the second day after atabrin his facial appearance changed for the first time since admission; his dull apathetic expression changed to a slightly cheerful one and he would keep his eyes open for some time. After a course of atabrin the temperature became normal; he could be made to sit up, stand by the side of the bed and gradually walk round the ward with a slow dragging gait. He could now take his meals. He now took some interest in his surroundings and confided that he had domestic worries and physically was very weak. His nervous system was now examined and found to be normal. Evidently he was not a case of encephalitis lethargica.

On the seventh night after admission he suddenly absconded from hospital at about 2 a.m. The following morning he was found at the door of his old mercantile firm where he worked as a clerk a year ago. He explained that he was very much worried about his unemployment and had come to see his superior in the hope of being reinstated to his former post. On being reassured about his post, he was induced to return to hospital. He was then given the combined hookworm and ascaris treatment and he stayed in hospital for about twelve days. He was apyrexial and no longer somnolent. In all his activities he appeared slow and hesitating. He would prefer to sit still without paying much attention to his surroundings. He liked to read books. He seemed to be brooding over something.

The mental condition of the patient can be diagnosed as schizophrenia which explains the symptoms like mental depression, lack of speech and intelligence, lack of response to stimuli, inattention to calls of nature, general immobility, stupor, etc. When the patient actually contracted the benign tertian malarial infection is very difficult to answer. It is probable that the attack of fever which the patient had ten months before admission and which was regarded as an attack of influenza might have been the starting point of malarial infection which had persisted in a very low form for ten months, to be detected only at the hospital after admission. It was equally probable that the infection might have been of recent origin. The most interesting question that arises in connection with the

malarial infection is to what extent, if any, it has added to the clinical picture of the original schizophrenia? Has the lethargic condition or somnolence increased after the malarial infection and if so where is the seat of activity of the malaria parasites? None of these questions could be answered satisfactorily.

The other interesting point about the case is the sudden clearing up of the schizophrenic mental condition after atabrin. The improvement of the mental condition after atabrin leads one to think that probably the malarial infection augmented the schizophrenic condition in such a way that the clinical condition resembled encephalitis lethargica minus its neurological lesions and their complete clinical manifestations. It is possible that the malaria parasites acted deleteriously over the same regions of the brain in the same way as encephalitis lethargica without producing any organic neurological lesion.

The patient has been under observation for about three months after discharge from hospital and during this period his schizophrenic condition has been no worse.

I have to thank Lieut.-Colonel R. Knowles, I.M.S., Director, School of Tropical Medicine, Calcutta, for permission to publish this case.

A CASE OF SARCOMA OF THE UPPER JAW WITH SINUSITIS OF THE ANTRUM OF HIGHMORE

By B. SUKHAVANAM, L.M.P.

Honorary Clinical Assistant, Municipal Hospital, Nandyal

S., a female child aged 4 years, was admitted on the 25th April of this year on account of a hard bony swelling of the right upper jaw. The mother of the girl stated that the swelling was of four months' duration and rapidly increasing in size.

Condition on admission

The right eye was masked by the swelling and it was difficult to draw the lids apart. The bridge of the nose was deflected towards the left side and the right nostril was blocked. The child could breathe only through the left nostril.

Operation

An opening was made just above the alveolar margin underneath the upper lip on the right side and a little pus was drained through the opening from the antrum of Highmore. This, however, had no effect on the swelling on the face. Accordingly on the 30th March, Moore's operation was undertaken under chloroform anaesthesia. A triangular flap of skin and soft tissues with its apex at the inner end of the eyebrow was made, the bone beneath being freed and laid bare. The excess of bone was chiselled off little by little both from the above and medial aspect. The antrum was cleared of its growth. The flap was then replaced and stitched up. Meanwhile the drainage of the antrum continued through the opening previously made above the alveolar margin. The patient made an uneventful recovery, the operation wound healing by first intention. The swelling subsided, the cosmetic effect was restored and the patient discharged as cured on the 17th May.

DIETETICS

SCIENCE, and medical science in particular, is, like many other activities in life, by no means immune to the caprice of fashion. The subject of nutrition and dietetics in this respect is no exception. The wide interest displayed by the public in the subject of dietetics to-day may be due to several influences. In the first place there is on all sides a desire to know more about the attainment of health and the avoidance of disease than hitherto, and it is naturally realized that food must play an important rôle in this respect. In the second place the discovery within recent years of the accessory food substances or vitamins has stirred the imagination not only of the public but also of the medical profession. Here was a substance whose presence—in minute quantities—or whose absence, would condition the normal growth and development of, say, the skeleton. The popular interest in the vitamins is at bottom the same as that which sustains faith in patent medicines or quack cures; they possess the element of the miraculous. This interest is in great measure also due to the extensive research work which is being done in this field all over the world. It is scarcely realized that it would take between two and three hours a day to read all the literature appearing on the subject. Meantime the press and commercial firms re-echo such results as suit their purpose. Scarcely a day elapses but one sees a reference to some extra-potent vitamin extract or preparation. It is not to be denied that they are essential to a complete diet. The main point is that they are receiving undue attention.

At present there are some five accredited vitamins and one of these has been divided into at least four sub-groups while another is threatening to break up into two. To obtain a proper perspective one might do well to look back some sixty years and see what were the nutritional problems of the time and to what extent they have been solved to-day. The practical problems which confronted men like Carl Voit and Rubner were the calorie, and the quantity of protein, fat and carbohydrate in a diet. As regards protein, Voit laid down a standard of 119 grammes (approximately 4 ounces) per diem for a working man. This figure was based simply on what the average Munich labourer was in the habit of consuming. Later workers notably Chittenden in the United States would have this allowance cut down to less than half of Voit's figure. His main contention was that it placed an undue strain on the kidney.

So much for quantity. To-day one can safely recommend a protein intake which lies between that advocated by Voit and Chittenden respectively, although there is no rigid scientific proof in favour of it. The real truth of the matter lies in the fact that the protein problem is one not only of quantity but also of quality. Proteins differ in their capacity to promote growth and maintenance. A protein like gelatin for instance is totally incapable of performing those functions, while the proteins from milk are nature's finest product for the young growing animal. As a result of carefully controlled feeding experiments, a relative figure can now be given to a particular protein which expresses its relative biological value for promoting growth and maintenance. The proteins from flesh and milk have a value of about 100 while those of cereals are low down in the scale, rice being one of the lowest, approximately 30.

The significance of this point is best brought out when it is asked what are the main functions of food in the body; they are to supply energy in the form of calories and materials for growth and repair, as protein. Of all the food-stuffs protein alone can answer to both those claims, vitamins to neither. As an illustration of this, an experiment carried out in Scotland some years ago may be cited. Two groups of school children of the same economic class were given an extra ration of food through the school authorities. The experimental group received so much skimmed milk while the control group were given an equivalent amount of calories in the form of biscuit. At the end of the experimental period of four months it was found that the group receiving the milk showed a greater increase in height and weight than the controls. This result can not be attributed to the calorie intake which was equal in each group, nor to the extra vitamins which were negligible. The greater growth must have been due to an increased allowance of a good quality protein in the form of milk.

When it is realized that millions of the rice-eating classes of India have a protein consumption not more, and often less, than that advocated even by Chittenden, that the biological value of rice protein is low, that one or more vitamins may be lacking in their diets, that their physique is poor compared to that of the Northern races of India who consume a better diet, one can appreciate that the providing of an adequate diet to all would involve a wholesale reorganization of agriculture and economics.

The association of the protein intake and physique was pointed out by McKay in Calcutta some twenty years ago. This unsolved aspect of the dietary has tended to fall into the background since then.

Without in any way minimizing the importance of vitamins it will be appreciated that no surfeit of those substances can promote normal

growth and maintenance without the necessary building stones.

It is not sufficiently realized that the assimilation and metabolism of food is an active process on the part of the living organism. It is no mere stoking of the furnaces of the cells with fuel. Pflüger more than seventy years ago never ceased to stress the contention that protein after absorption became an integral part of the living cell, only to be broken down again in its turn and the effete material replaced from without—a continual flux of matter. The function of the vitamins may possibly be that of controlling or directing this flux. Rigid proof may be lacking for Pflüger's idea but it is at least a biological concept infinitely preferable to crude mechanical analogies.

The question has been asked what is the ideal

diet? The answer is—there is no one ideal diet. What is an ideal diet? The answer is—many. It is the unique property of the living organism that it can adapt itself within a certain range of environmental conditions. A change of conditions, as is well known, is stimulating. Variety may well be said to be the key-note of practical dietetics. It ensures that nothing is left out; it stimulates the palate and alters the nutrient medium surrounding the cells. To-day one hears a good deal about a balanced diet, an expression so difficult to define in rigid terms, an abstraction not readily acceptable to the practical man. This aspect however may well be left to look after itself provided the word variety is interpreted and practised on as liberal a basis as possible.

CAMPAIGN AGAINST TRACHOMA

THE Executive Committee of the International Organization of the campaign against trachoma held in Paris on the 14th May, 1934, a conference at which the following members of the Committee assisted: MM. Emile de Grosz, President, F. Wibaut, Secretary-General, A. F. MacCallan, M. Marquez, Morax, Park Lewis, Szymansky, Vice-Presidents; Brandes, de Lapersonne, Van der Hoeve, as well as M. Wagenmann, Maziny Bey and MM. Trantas, Marin Amat, Carris and Churchill.

The President made a sympathetic reference to the death of Professor Angelucci. The Secretary-General read his report from which it appears that the financial situation of the organization is very modest in that it has at its disposal about 1,500 Holland florins. The principal source of receipt is the American subvention. The Executive Committee will provide funds to a research worker desirous of investigating the ætiology of trachoma in a laboratory of a country in which this disease is present. A commission composed of MM. Morax, MacCallan and Wibaut was delegated in regard to this matter.

At the conference which will be held in Budapest in the spring of 1935 it is proposed to examine anew the question of the prophylaxis of trachoma. The rapporteurs elected were as follows: MM. Myashita (Japan), MacCallan (Great Britain), Zachert (Poland), Tewfik (Egypt) and Jitta (Holland).

The organization against trachoma held in conjunction with the International Association for the Prophylaxis of Blindness a conference on the 14th May, 1934, presided over by MM. de Lapersonne of Paris and Emile de Grosz of Budapest. The principal subject was trachoma in the Colonies and in the meridional conditions of Europe. The rapporteurs were Maziny Bey (Cairo) and MM. Maggiore (Genes), Lasnet (Algeria), Trantas (Athens), Wibaut (Amsterdam) and Cucnod (Tunis). In addition M. Morax made a statement on the rôle of gonococcus in tropical zones.

QUININE STOCKS OF GOVERNMENT OF INDIA

(From the *British Medical Journal*, 7th July, 1934)

QUESTIONS IN PARLIAMENT

ON 2nd July the Duchess of Atholl asked why the 300,000 lb. of quinine owned by the Government of India were lying idle, for how long had this been the case, and what arrangements were in contemplation for

making this stock of quinine available for those who annually suffered from malaria and could not procure it. Sir Samuel Hoare said that the Government of India habitually maintained a reserve stock of quinine for emergencies. This reserve rose to 300,000 lb. about 1926 and continued at or above that figure until 1932. Measures had since been initiated to reduce it to 150,000 lb., which was regarded as a sufficient reserve. In March 1933, it had been reduced to 282,759 lb. He had no later figure, but the Government of India was doing its best to increase sales. He would ask for a further report with reference to the last part of the question. The Duchess further asked if the recommendation of the Royal Commission on Agriculture in 1928, that the Government of India should control the production, manufacture, and distribution of quinine in the interests of those who suffered from malaria, had been held up since the first Round Table Conference. Sir Samuel Hoare said there was no foundation for this suggestion.

LEAGUE OF NATIONS' SECOND INTERNATIONAL CONFERENCE ON THE STANDARDIZATION OF VITAMINS

THE second International Conference on the Standardization of Vitamins convened by, and held under the auspices of, the Health Organization of the League of Nations was held in London from 12th to 14th June under the chairmanship of Dr. E. Mellanby, Secretary of the Medical Research Council of Great Britain.

The report of the conference recommended provisions for two years for international adoption, standards and units for four vitamins A, B, C, and D, concerned with growth and infection with beri-beri, scurvy, and prevention of rickets respectively. Since certain of the standard preparations recommended for adoption were not available for general use until 1932, the present conference had at its disposal the results of two years' experience with the provisional standards.

As in the 1931 report, standards and units are recommended only for four vitamins, the possibility of adopting standards for vitamins B₂ and E was considered at the present conference. Many hold that insufficiency of vitamin B₂ causes pellagra and that vitamin E is necessary for successful reproduction in both male and female. The conference felt that our present knowledge of these vitamins, and of the pathological results to which their absence gives rise, is still

insufficient to justify the adoption of standards and units.

The standards for vitamins A and C, provisionally adopted in 1931, have been altered. The substitution of more clearly defined and more easily reproducible chemical substances is a useful step forward. As vitamin A, pure carotene has been chosen in the place of the standard preparation of carotene recommended by the previous conference. The vitamin C standard chosen is ascorbic acid, a substance which the work of Szent-Guörgy (Hungary) showed to be identical with vitamin C. No change has been recommended in the case of the vitamin B₁ and D standards. The former has proved highly convenient in practice—of all the standards chosen by the 1931 conference the vitamin B₁ standard has perhaps proved most satisfactory—and a large stock, sufficient to last for many years, is available at the central institution from which the standards are distributed—the National Institute for Medical Research, London. The vitamin D standard remains unaltered. With the proviso that it may be replaced when exhausted (or should it become for any reason unsatisfactory) by crystalline vitamin D in suitable

solution. Large quantities of the standard solution of irradiated ergosterol are available.

The units remain the same in all cases. Where a change has been made in the standard material, the old units have been restated in terms of the newly-adopted substance. The desirability of leaving the original units unaltered is emphasized by the fact that certain of the units recommended by the 1931 conference have been adopted into the pharmacopœias of a number of countries.

Vitamin standards and units are to-day of considerable importance, not only in connection with scientific work but in the commercial field. In all civilized countries one observes the production of vitamin preparations on a large scale, and it is obviously to the advantage of both manufacturer and purchaser to have some method by which the potency of such preparations may be described. Further, the existence of standards and units facilitates control of such preparations by public health authorities who wish to protect the consumer from wasting his money on preparations which are alleged to be rich in vitamins but which are in fact quite otherwise.

Current Topics

Study of the Treatment in Acute Tetanus

By FREDERIC W. TAYLOR, M.D.

(From the *Journal of the American Medical Association*, 24th March, 1934, Vol. 102, p. 895)

THE results obtained from the treatment of active tetanus cases are far from satisfactory. Mortality statistics on this disease vary considerably from different sources but lack any constant variation that would indicate a desirability of one form of therapy over another. The only constant variation in these statistics is found in a comparison of cases with long and with short incubation periods. Calvin and Goldberg found a mortality of 84 per cent when the incubation was less than five days, of 83 per cent when it was from five to ten days, of 37 per cent when it was from ten to fourteen days, and of 25 per cent when it was from fourteen to twenty-one days.

Until the last few years much clinical investigation has been directed toward determining the most efficacious route of administering tetanus antitoxin. Most failures following any advocated method of treatment have been attributed to an insufficient quantity of serum. The result of this reasoning has been a pyramiding of the antitoxin dosage to unbelievable heights, limited only by the amount of serum available.

This specific treatment with tetanus antitoxin regardless of the route of administration or the amount given has been strangely ineffective in bringing about any marked decrease in mortality. This is remarkable, since the prophylactic use of this serum has achieved such brilliant results.

It was with the hope of gaining additional information, which might aid in the treatment of active tetanus, that this study was attempted.

The material used includes all the cases of active tetanus admitted to the Indianapolis City Hospital and the Indiana University hospitals from 1927 to 1933. These cases were submitted to a critical examination in an attempt to analyse the treatment given and the results obtained. Certain fallacies in the treatment will be pointed out and suggestions made of improvements that might well be instituted.

The patients were quite representative of those applying to a general hospital for treatment after the onset of tetanic symptoms. Their ages ranged from 4 to 63, with 59.4 per cent between the ages of 5 and 15. During the period of our study forty-two patients were treated for tetanus. Of these, five cases were not considered in the study because of a reasonable doubt

as to the correct diagnosis from either a clinical or a laboratory standpoint. The remaining thirty-seven were undoubtedly cases of tetanus. This forms a very small series but, nevertheless, one that suggests several striking deductions.

GENERAL CONSIDERATIONS

Before going further it might be well merely to mention some of the pertinent bacteriologic and physiologic aspects that the disease presents. Tetanus is a symptom and sign complex resulting from the irritant effects of tetanus toxin on the central nervous system. Toxin is elaborated from the focus of infection by the anaerobe *Clostridium tetani*. This organism will not live in healthy, sound tissue but requires either necrotic tissue or tissue that is partially devitalized. Such a devitalization is usually accomplished by the introduction of a foreign body along with the tetanus bacteria. From this focus, usually a deep penetrating wound, toxin is produced. It is believed that the toxin is picked up from the blood stream or the focus by the peripheral nerves or their lymphatics. These structures transport the toxin to the central nervous system. Here it has a particular irritative effect on the cells of the hind-brain and cord. The toxic effects are found in the cells of the lower motor neurons, but to a lesser degree. Once combined with the nerve cell, antitoxic serum cannot displace the toxin. Antitoxin neutralizes only that toxin which is free in the blood or tissues. In this limited neutralization lies its only value in cases of active tetanus.

The nerve cells of the central nervous system are hyperstimulated. These cells and the medullated nerve fibres show slight degenerative changes. However, these degenerative changes are not specific and may be seen in other toxæmias. The damage produced in the nerve cells by tetanus toxin is not permanent and in this feature contrasts with poliomyelitis, in which much of the damage is permanent. The nervous lesions of tetanus apparently are entirely reversible. With recovery, even from the most desperate cases, complete restoration of function is the rule.

Death in these patients results from exhaustion, spasm of the glottis and convulsion but not from the neurologic lesion produced by tetanus toxin. Patients do not die from the disease itself, as in bulbar poliomyelitis, but from its symptoms. The suggestion is made in this connection that if the distributing focus and symptoms are adequately handled the disease will limit itself.

The treatment of active tetanus logically falls into three phases. These are (1) treatment of the local focus, (2) administration of appropriate sedatives and general supportive therapy, and (3) administration of specific antitoxic serum.

LOCAL LESION

Much has been written about the treatment of the local lesion in tetanus. Thorough careful débridement has universally been advocated. Yet, in our experience, this phase has received but little consideration compared with that directed toward the administration of antitoxin. At least, this would seem to be true in the present series. In twenty-three of the thirty-seven cases, adequate exploration was not done on admission to the hospital. In these there were sixteen deaths (69.6 per cent).

It is a frequently noted fact that the local wound in cases of tetanus may appear quite innocent or may be 'healed'. Thus attention is detracted from this initiating cause and directed toward the patient's more active symptoms. Complete local excision of this type of wound has been rightly advocated. There are still prominent texts on the subject which teach that 'if the wound is healed it should not be disturbed'. Just such a procedure was followed in seventeen of our 'healed wound' cases. Of these patients, twelve died, a mortality of 70.5 per cent. It is thought that this disastrous outcome was largely due to negligence in appreciating the local wound as the distributing focus of the toxin and hence the cause of the entire tetanic syndrome.

As pointed out by others, it is astonishing how many foreign bodies are found in these innocent appearing or 'healed' lesions. That these foreign bodies greatly add to the danger of the disease goes without saying. The following examples taken from our cases illustrate this point:

Two of our patients in an extremely critical condition continued a stormy and downhill course after more than a week of the most intense serum therapy. Both cases appeared to be hopeless. Then quite unexpectedly foreign bodies were extruded spontaneously from the draining wounds. In one patient this occurred nearly two weeks after hospital treatment had been instituted. Immediately after the extrusion, convulsions ceased in both patients and they started on a rapid uninterrupted course to recovery.

These cases point out strikingly the importance of a foreign body in the local wound and how it may enhance local production of toxin and bacterial growth. It seems reasonable to assume that in all cases in which the severity of the disease increases with the patient's stay in the hospital there is an inadequately treated focus that is still elaborating tetanus toxin.

In the twenty deaths, only four autopsies were allowed. These are of interest because of the conditions found in the local wounds. Two of the four cases presented wounds that were 'entirely healed'. When, however, these were opened and explored each contained a small foreign body surrounded by necrotic tissue and pus containing *Clostridium tetani*. The wound in the third case was not explored by the pathologist because it was 'completely healed'. In the fourth case a foreign body surrounded by pus and necrotic tissue was removed in the ward the day before the patient reached the autopsy table. This wound likewise yielded tetanus bacilli on culture.

These examples are given to emphasize the importance of the local wound and as an argument against the dictum that 'if the wound is healed it should not be disturbed'. Tetanus is caused by the local focus and continued by it. The local lesion should therefore receive primary consideration. Active tetanus is an acute surgical emergency carrying with it a mortality far in excess of most surgical emergencies. It should be treated as such with admission to the hospital by way of the operating room.

In a discussion of the local wounds, our cases caused by 'blank cartridges' should not be omitted. There were ten of these, resulting in weeping draining wounds of the hands or fingers. It has often been noted that

this type of injury frequently introduces the gun wadding of the cartridge into the wound. The wadding acts as a foreign body, stimulating growth of tetanus bacilli carried in with it. Our cases emphasize this observation. Of the ten cases, eight were searched for gun wadding. In all eight cardboard wadding was found and removed. In the other two a search was not made and both patients died.

No comment is necessary to the foregoing except perhaps the observation that all blank cartridge wounds contain gun wadding, which should be removed.

It would seem from this discussion that the most logical treatment of the local wound in cases of active tetanus is that used by Tulloch. He advocated the complete excision of the focus without entering infected tissue. At many sites, of course, this is not feasible. Here the only alternative is ample wide exploration under general anaesthesia, with a careful search for debris and foreign bodies.

Opinions differ as to the relative merits of the various dressings or irrigating solutions that have been recommended. Tulloch doubts the value of any particular procedure over any other. He also questions the value of oxidizing agents, such as hydrogen dioxide. Since the wound is infected, it is probable that a hypertonic wet dressing best serves the requirements.

SEDATIVES AND GENERAL CARE

It may again be stated that all deaths in tetanus are the results of one or more of the following: convulsions, spasm of the glottis or diaphragm, exhaustion and respiratory failure. It is obvious that therapy directed to prevent these conditions is of prime importance.

In the past, hypnotics, narcotics and general anaesthesia have been used to control these symptoms. Before the advent of tetanus serum, sedatives used and recommended include practically all of those listed in the Pharmacopoeia and need not be mentioned. In mild cases of tetanus many of these are of considerable value. In severe cases all either lack sufficient potency or are too transient in their effect.

The ideal sedative drug should produce a quiet restful narcosis which is well sustained for a number of hours. Its physiologic effect must not be exhausting on the patient after continued use. Drugs very close to this ideal have been used in recent years as basal anaesthetics and have been advocated in controlling tetanic seizures.

Sodium amytal (sodium isoamylethyl barbiturate) has been used in this capacity. Avertin (tribrom-ethanol) has also been used and probably enjoys a greater general popularity.

Both of these drugs are relatively safe and give a well sustained narcosis. In nineteen of our cases, sodium amytal was used intravenously to control symptoms. This was quite efficient and proved far more satisfactory than any other medication. There is one point in this use of sodium amytal which is worthy of note and which likewise applies to tribrom-ethanol. The tendency was to give amytal only when convulsions become severe. The drug was then withheld until convulsions again appeared. A more rational procedure would be to continue sustaining doses, keeping the patient under moderate narcosis at all times. In this way the patient might entirely escape severe tetanic seizures and large amounts of sodium amytal or tribrom-ethanol would not be necessary to restore a restful sleep.

The time-honoured quiet darkened room is of great importance. It is too often either overlooked or not available. That the average tetanus patient is not kept sufficiently relaxed and quiet is well illustrated by our series. Of the twenty patients who died, fifteen (75 per cent) continued to have convulsions or rigidity up to the time of death. Nineteen of the twenty (95 per cent) were restless and not relaxed.

Since the tetanus patient frequently succumbs to exhaustion, all practical supportive therapy must be brought into action. The fluid intake should be maintained at a high level and elimination watched closely. As the patient usually cannot take sustaining amounts

of fluid and nutrition by mouth, these elements must be given by other routes. For this purpose the intravenous and subcutaneous use of dextrose solution and physiologic solution of sodium chloride are of invaluable aid.

ANTITOXIC SERUM

The pedestal on which tetanus serum has been placed in medicine is due entirely to its use as a prophylactic measure. Here it is surpassed by none of the specific serums. Ample proof of this was demonstrated in the World War. Because of these remarkable results, the serum has been viewed with the same faith in the treatment of active tetanus. Here, because of many complex factors, the antiserum fails to duplicate the specific action found in its prophylactic use.

The statement has been made that 'tetanus antitoxic serum has done more harm than good in the treatment of active tetanus'. This at first sounds like rank heresy. However, there is much truth in the fact that this specific has brought about practices that certainly are detrimental to the patient's welfare. Because of the fact that it has been considered a specific, it has been used in general practice to the exclusion of other phases of treatment. The local lesion has been neglected, as well as general supportive measures and sedatives.

The majority of recent writers have expressed the opinion that, in the care of patients who have already shown tetanic symptoms, tetanus serum is of doubtful value. Perhaps the most valuable statistics along this line have been those of Calvin and Goldberg. These writers found no decrease in the mortality rate at Cook County Hospital despite the ever increasing amounts of serum used. Nor could they find any advantage of administration by one route over any other. In spite of adverse evidence as to its value, the average tetanus patient continues to be loaded with massive doses of serum. Failures are still explained on the basis of insufficient serum. Again the local wound and administration of ample sedatives receive little consideration.

In our series twenty patients died, a mortality of 54 per cent. This high rate cannot be explained because of lack of antitoxic serum. The amount given ranged from 50,000 to 420,000 units. Of twenty-three patients receiving from 50,000 to 100,000 units, twelve died (52.1 per cent). Of ten patients receiving from 200,000 to 420,000 units, two died (20 per cent). These figures would seem to indicate strongly the value of massive doses of serum. On further consideration, however, it is clear that those receiving small total amounts lived but a short time after admission to the hospital. Had their span of treatment been longer, they eventually would have received the massive aggregate doses already mentioned. It is because of this fact that statistics indicating the great value of huge doses of serum should not be accepted without further knowledge of their origin.

Our patients received rather uniform initial doses of antitoxin. These consisted in from 20,000 to 60,000 units in 89 per cent of the cases.

Serum was administered by vein, intramuscularly, and beneath the spinal meninges. All three routes were utilized in the majority of cases. In the light of our own results and those of others it would seem that no particular route holds an advantage over any other, except that intravenous and intramuscular medication make the antitoxin immediately available and there is no delay caused by slow absorption. Intravenous administration is somewhat more dangerous than intramuscular medication, because of anaphylactic reactions, and probably no more effective. The intrathecal route would seem theoretically to be more desirable, since the serum causes a non-specific inflammatory reaction about the spinal nerve roots. Experimental evidence demonstrates that this reaction prevents or retards the absorption of toxin from the nerve trunks. Clinically no advantage is noted, and this route has the disadvantage of giving delayed absorption by the circulating blood.

A few of our patients received injections of antitoxin into and about the wound site. While this procedure may prevent the absorption of some toxin, it certainly destroys or interferes with the natural barrier of granulation tissue thrown up about the focus. When local injection is used, the serum should be infiltrated at some distance from the actual lesion where it cannot disturb this barrier. Local antitoxic serum nerve blocks have been advocated and would seem to be of considerable benefit.

As previously stated, serum is of value in neutralizing the uncombined tetanus toxin but can be of no aid in removing that already combined with nervous tissue. Much smaller amounts of serum than those generally used are amply sufficient to neutralize the free toxin of the body. In this light it would seem a more rational procedure to give from 30,000 to 60,000 units of serum when the patient is first seen. This dose might be repeated in a week or so, when a decrease of the amount of antitoxin in the tissues has occurred.

With the consideration of serum as an adjunct and not a 'specific' in the treatment of active tetanus, more attention will be focussed on the local lesion and general care of the patient.

COMMENT

It is hoped that the foregoing has emphasized several phases in the treatment of active tetanus cases not generally appreciated. Treatment should be directed along three well defined lines. These are, in order of their importance, (1) adequate care of the local wound, (2) sedative and general care and (3) tetanus antitoxic serum. Though mentioned separately here, these must be considered as an inseparable triad in the treatment of the disease. If emphasis is to be placed on any particular phase more than on another, I believe that sedatives and the local focus should receive that consideration rather than the use of antitoxin.

1. *Local lesion.*—Since the local wound causes the disease and continues it, prime consideration should be given to that focus. Whenever possible, immediate complete excision of the wound is recommended. When this is not possible, complete exposure and search for foreign bodies should be done under general anesthesia. The foreign body is a potent factor aiding bacterial growth and continuing the elaboration of toxin. It should not be overlooked. In active tetanus cases it must be considered that the local wound contains a foreign body until proved otherwise. This is particularly true of 'blank' cartridge wounds. The local wound of tetanus is an acute surgical emergency and should be treated as such, even though the patient is later admitted to the medical wards.

2. *Sedatives and general care.*—Patients with tetanus die from 'their symptoms and not from the disease itself'. It therefore follows that if these symptoms can be controlled adequately the patient's chance of recovery is much greater. Tribrom-ethanol or sodium amytal is recommended to induce light narcosis. The suggestion is also made that these drugs be given at regular intervals so as to keep the patient quiet and relaxed. This would seem wiser than to use them only when the patient becomes rigid and is on the verge of a convulsion. Equally important in conserving the patient's strength with sedatives is adequate supportive care. Particular attention must be given so that fluid intake is maintained at a high level and proper elimination is effected.

3. *Tetanus antitoxic serum.*—The high reputation that this product enjoys is due entirely to its prophylactic use. Here it is a specific in preventing the disease or at least in lengthening the incubation period. In active tetanus it is in no sense a specific, and its value is questioned by many. As the antitoxin is unable to withdraw toxin already combined with nervous tissue, its sole action is to neutralize uncombined toxin in the body. Here it may have considerable value and, until definite proof to the contrary, its use may well be continued. It seems unnecessary to administer the huge quantities used at present. It is recommended that from 30,000 to 60,000 units be

given when the patient is first seen. This might be repeated if the case runs a long, protracted course. The intramuscular route of injection is perhaps the most satisfactory.

The conclusion of two workers in this field nearly forty years ago is as pertinent to-day as it was then: 'An ounce of clean surgery is worth several pounds of serum therapy'.

Calcium Metabolism in Health and Disease

By FRED A. K. HERBERT, M.A., M.B., B.S.

(From the *Medical Press and Circular*, 3rd January, 1934, Vol. CLXXXVIII, p. 11)

MANY interesting problems arise in the study of the physiological regulation of calcium exchanges in the body. The outstanding physiological requirements are the maintenance of adequate solid deposits of calcium carbonate and calcium phosphate in the bony skeleton, and the maintenance of a constant, or nearly constant, level of calcium in plasma and tissue fluids, so as to secure normal excitability of nerve and muscle. Calcium is also necessary to blood coagulation; but the amount needed for this is very small, and in fact severe calcium deficiency may occur without any interference with normal blood coagulation. The main problems of normal and abnormal calcium metabolism, therefore, concern the mechanisms whereby absorption of calcium, the transport in plasma, the interchange between the plasma and the depots of solid calcium salts in bone, and the excretion by the kidneys and bowel, are regulated in accordance with the needs of the body. The normal balance between deposition and resorption of calcium salts from bone seems to be the main factor in the maintenance of the normal plasma calcium level.

NORMAL CALCIUM METABOLISM

Calcium absorption.—The main sources of calcium in food are milk, cheese, butter, eggs, green vegetables and nuts. Absorption occurs from the upper part of the alimentary tract, and the main factors governing absorption are the acidity of the contents of the upper intestine, the proportions of calcium and phosphorus in the diet, and probably the supply of vitamin D. The change from the acid reaction of the upper intestinal tract to the alkaline reaction in its lower reaches determines the solution and absorption of calcium salts in the upper part, and the precipitation and loss of calcium as phosphate in the lower part of the intestine. The proportion of calcium to phosphorus is important because an excess of phosphorus in the presence of a deficiency of calcium will lead to loss of a large proportion of the calcium as phosphate, and in the same way an excess of calcium will aggravate the ill effects of a deficiency in phosphorus. The proper proportion of the two elements is of more importance than their absolute amounts. The normal adult requires about 0.4 to 0.5 gm. of calcium in the diet; the requirements of children and of pregnant women are greater. A normal varied diet containing adequate amounts of milk will ensure an adequate supply of calcium and phosphorus in their proper proportions. When it is especially desirable to guard against calcium deficiency, as in pregnancy, the supply of both vitamin D and calcium is important. It is generally believed that the vitamin produces its effect by increasing calcium absorption, but there is no direct proof that it acts only or mainly at this stage of calcium metabolism.

Transport of calcium in the blood.—The blood corpuscles contain little or no calcium. The serum contains 9 to 11 mg. Ca per 100 c.c. This is a surprisingly high figure in view of the phosphate and carbonate content of the serum and its slightly alkaline reaction. Two important factors enabling the serum to hold this calcium in solution are the protein content and the CO_2 tension. In any protein solution containing calcium, some of the calcium becomes bound to protein, and the proportion of the total calcium taken up by the protein depends on the nature and amount of the protein and some other factors which will not be discussed

in detail. The protein-bound calcium does not pass through colloidion membranes, and it is therefore possible, by ultrafiltration through such membranes, to determine the proportion of calcium which is protein-bound. In normal serum, on the average, 5.3 mg. Ca per 100 c.c. is diffusible, and 4.7 mg. per 100 c.c. protein-bound. Normally the value for the diffusible calcium of serum is roughly equal to the values for calcium concentration in protein-free tissue fluids (œdema fluids and transudates), and in cerebro-spinal fluid. Now even this figure of about 5 mg. Ca per 100 c.c. in simple solution is much higher than can be explained by the solubility of the calcium salts concerned. Only about 2.5 mg. Ca per 100 c.c. would be expected to exist in ionized form. Some authors have therefore regarded the serum and other body fluids as supersaturated solutions. If this were so, it would be easy to understand the deposition of calcium salts in bone as a precipitation of calcium carbonate and phosphate from a supersaturated solution in the presence of the solid; but how, then, could one explain resorption of calcium salts from bone, or the normal balance between deposition and resorption which maintains the normal calcification of bone and the normal calcium level of serum? The problem of the composition of the diffusible fraction of the serum calcium is still an open question. The general belief is that about 2.5 mg. per 100 c.c. is ionic calcium, and the remainder some non-ionized but diffusible calcium complex of unknown nature. Some believe, on the other hand, that the physico-chemical conditions of serum permit a greater concentration of ionic calcium in serum than in the artificial salt solutions on which calculations of ionic calcium are based. In the absence of any reliable method of measuring ionic calcium directly, the question cannot yet be definitely settled. It is possible that the parathyroid hormone may play a part in increasing the solubility of calcium in serum, but there is no definite evidence that its action in regulating the level of serum calcium is to be explained in this way.

Storage and resorption of calcium in bone.—Little is known of the mechanisms concerned in the interchange of calcium salts between bone and tissue fluid. Wells believed that in calcification of normal bone, and in the formation of pathological calcium deposits, local changes in CO_2 content play a part. In relatively inert material, such as the matrix of bone, the CO_2 tension will be lower than in cellular tissues in which active respiration is going on. Therefore the less cellular areas will be more alkaline, and in these deposition of calcium will be favoured; whereas in areas where the CO_2 tension is higher, the solution of calcium as bicarbonate will be facilitated. There is no doubt that the administration of acids, or of those salts (such as ammonium chloride) which produce a systemic acidosis, leads to the mobilization of calcium from the skeleton.

A very attractive theory of the deposition of calcium salts in bone, developed by Robison, has much experimental evidence to support it. He has found in bone an enzyme capable of liberating inorganic phosphate from the esters of phosphoric acid. The enzyme, phosphatase, is probably present in the osteoblasts. Its action would be to produce a local increase in the concentration of inorganic phosphate which would lead to the precipitation of calcium phosphate in the neighbourhood of the cell.

CALCIUM EXCRETION AND CALCIUM BALANCE

Calcium is excreted both in urine and in faeces. The major part of the calcium lost by the body passes out in the faeces, and of this some is the residue of unabsorbed calcium of the food, and some has been excreted by the large intestine. Some loss by excretion is inevitable even when the diet is very poor in calcium, for the body seems to have no means of conserving calcium when the supply is inadequate. In this the calcium ion differs from the chloride ion. If the chloride in the diet is reduced to a minimum, chloride excretion practically ceases. On the other hand, when diets low in calcium are given, the loss of calcium in urine and faeces continues, and there is a continuously

negative balance. On diets of normal total energy value but containing only 0.10 to 0.15 gm. Ca per day, the total excretion of calcium daily is from about 0.20 to 0.40 gm., and occasionally more. Of this, from 0.10 to 0.16 gm. Ca is lost in the urine, and the remainder in the feces. The results of balance experiments in normal subjects vary very much, and other factors beside the calcium content of the diet affect the retention of calcium, but it is usually considered necessary to have about 0.1 to 0.5 gm. Ca in the diet to ensure that absorption will keep pace with excretion.

PATHOLOGICAL CALCIUM METABOLISM

Tetany.—Cases of tetany fall into two main groups firstly, alkalosis tetany with normal serum calcium values; and, secondly, the various types of tetany associated with low serum calcium. Tetany due to alkalosis may occur (1) as a result of loss of hydrochloric acid from the body by severe vomiting (gastric tetany); (2) as a result of the administration of bicarbonate; and (3) as a result of overbreathing, which causes a deficiency of H_2CO_3 .

In gastric tetany there is a marked fall in the chloride content of the plasma, and a compensatory increase in bicarbonate, causing an abnormally alkaline reaction (pH 7.5 to 7.6 instead of the normal 7.3 to 7.5). After bicarbonate administration an absolute increase in the bicarbonate is the main change, and the plasma chloride shows only a slight fall. In pulmonary over-ventilation the important change is the disturbance of the normal ratio of carbonic acid to bicarbonate as a result of deficiency in CO_2 . There is a slight secondary rise in the plasma chloride.

In all three types of alkalosis tetany, the reaction of the plasma becomes abnormally alkaline. The occurrence of tetany is explained as due to a decrease in the ionized calcium as a result of the increased alkalinity. There is no change in total serum calcium, and no significant change in the diffusible fraction, and in the absence of a reliable method of estimating the ionized calcium, the relationship of calcium to alkalosis tetany lacks experimental proof.

The cases of tetany associated with low serum calcium may be considered under three heads. firstly, tetany due to parathyroid deficiency; secondly, tetany due to nutritional deficiency, and, thirdly, tetany due to phosphate retention. In all types of low calcium tetany both the total and diffusible serum calcium are reduced. The change in the diffusible calcium is probably the primary and significant change. A fall in the diffusible fraction would lead to a secondary change in the protein-bound fraction. It is very rarely that one meets with cases of parathyroid tetany. The importance of preserving the parathyroids in operations on the thyroid gland is well recognized, and post-operative tetany is very rare. Cases of parathyroid deficiency occurring spontaneously have been described, but are extremely rare. In parathyroid tetany there is a fall in the excretion of phosphorus and of calcium, especially affecting the urinary excretion. The serum inorganic phosphorus rises, and the serum calcium falls. There is retention of calcium and phosphorus in the body. In tetany due to nutritional deficiency the conditions are quite different. Infantile and juvenile tetany are always associated with that type of rickets in which the serum calcium is low, and the cause is a dietetic deficiency, probably a deficiency in both calcium and vitamin D. In such cases there is an excess of calcium excretion over calcium absorption, and failure in calcification of the skeleton. Similarly, cases of coeliac disease or idiopathic steatorrhea ('non-tropical sprue') show decalcification of the skeleton, and a low serum calcium associated with tetany. Loss of calcium in the stools in combination with fatty acid as insoluble calcium soap may contribute to the calcium deficiency in these cases of fatty diarrhoea, but probably the main factor causing the calcium deficiency is a failure in absorption of the fat-soluble vitamin D. Such cases may, therefore, be classed with the cases of infantile and juvenile tetany, as due to nutritional deficiency.

The serum phosphorus is low or normal in cases of this type.

It is possible to produce tetany experimentally by injection of phosphate into the circulation. The rise in serum phosphate leads to a fall in serum calcium, probably because the concentrations of calcium and phosphorus cannot both be high at the same time, being limited by the low solubility of calcium phosphate. A similar condition is met with in severe renal disease associated with uræmia. In this condition the serum phosphorus rises, and the serum calcium falls, tetany may occur, and if the condition occurs during the growing period and lasts long enough, bone changes will occur—the changes of renal rickets. The cause of the skeletal changes is not fully understood. There are various therapeutic measures by which a low serum calcium can be raised to the normal with relief of tetany, but their action is different, and the choice of the most suitable measure depends on an understanding of the underlying cause of the tetany. The injection of calcium salts temporarily relieves tetany, but the calcium rapidly disappears from the circulation, and the treatment is only of value as an emergency measure.

The parathyroid hormone raises the serum calcium level, but it produces its effect by mobilization of calcium from the bones. If the tetany is due to parathyroid deficiency, then parathyroid treatment remedies the deficiency, but parathyroid treatment ought not to be used in those cases of nutritional deficiency where the skeleton is already deficient in calcium. Whenever the parathyroid hormone is used serum calcium estimations are necessary in order to avoid overdosage.

The administration of acids, or of salts which cause a systemic acidosis, will relieve the symptoms of tetany, and this relief is due to various causes. In alkalosis tetany, the administration of acid substances will act by correcting the alkalosis. In cases of low calcium tetany, the production of an acidosis will have an immediate effect on the symptoms by increasing the ionized calcium, even before any rise in total calcium occurs. The administration of acids will also raise a low serum calcium to normal, both by increasing calcium absorption and by mobilizing calcium from the skeleton. Owing to the latter effect, acids should be used with caution.

In the cases of nutritional deficiency, treatment is directed to remedying the underlying deficiency by ensuring an adequate diet, by treatment with cod-liver oil or other preparations of vitamin D, or by irradiation. Other methods of raising the serum calcium have their place only as emergency measures.

Hypocalcæmia in renal disease.—The retention of phosphorus and the fall in serum calcium which occur in severe renal failure (azotæmic nephritis) have already been mentioned. In such cases tetany may occur though sometimes the low serum calcium may exist without symptoms of tetany. The presence of acidosis may prevent the development of tetany. Abnormally low serum calcium figures also occur in nephritis with oedema. In these cases the serum proteins are low and consequently there is a fall in the protein-bound fraction of the serum calcium, the diffusible calcium remaining normal. Tetany does not occur under these conditions. The significance of a low serum calcium in nephritis can therefore only be determined when the figures for protein and phosphorus are also taken into consideration.

Hyperparathyroidism.—The effects of parathyroid deficiency have long been known and studied, but only since 1925, when Collip prepared for the first time an active extract of the parathyroid glands, has it been possible to describe the results of excess of this hormone.

The Collip extract, when administered to animals with parathyroid deficiency, will raise the serum calcium to normal, and relieve the symptoms. When administered to normal animals it produces a marked rise in the serum calcium, and symptoms occur which are fatal if the dosage is high enough. The first symptoms of overdosage are lassitude, anorexia,

vomiting and lowered muscular tone. Later the animals become emaciated, and suffer from hæmatemesis and bleeding from the bowel, dehydration, and death from collapse. Post-mortem examination shows hæmorrhage into the gastro-intestinal mucosa, and congestion of the lungs, liver and spleen. Blood analysis in the earlier stages shows an increase in the calcium, and a fall in the inorganic phosphorus, and later a rise in non-protein nitrogen and a rise in inorganic phosphorus. The hormone produces an increased excretion of both calcium and phosphorus in the urine. The source of the excess calcium in blood and urine is the skeleton; the parathyroid hormone causes a mobilization of the calcium from the bones. If animals are treated with doses of parathyroid insufficient to cause severe acute symptoms, and continued over a long period, they develop a generalized osteitis fibrosa similar to the human disease, generalized osteitis fibrosa of von Recklinghausen.

Different species have very different susceptibility to parathyroid overdosage. In man and in the dog there is great susceptibility; the cat is less susceptible, the rodents much less susceptible, especially the rat, which is able to stand very large doses.

At about the same time that Collip introduced his active parathyroid extract, and so began the experimental study of parathyroid overdosage, progress was being made in the study of hyperfunctioning parathyroid tumours in man. It had for some time been recognized that bone diseases, particularly generalized osteitis fibrosa, were associated with enlargement of the parathyroid glands, and the question was debated whether this was due to compensatory hypertrophy or an overfunctioning tumour. In 1925, Mandl attempted to treat a case by parathyroid grafting, and finding that this did harm, he later explored the neck and removed an enlarged parathyroid gland, also removing the grafts he had previously introduced into the abdominal wall. The result was strikingly successful. Since that time many cases have been successfully operated on, and diagnosis has been made easier by the discovery that in these patients there are the biochemical evidences of hyperparathyroidism: the serum shows a high calcium figure and a rather low figure for inorganic phosphorus, and there is a marked excess of calcium in the urine. (Observations on urinary calcium are usually made with the patient on a fixed low calcium diet, and can only be made satisfactorily under conditions which ensure accuracy in dieting, and in collection of excreta.)

The parathyroids in these cases sometimes show hyperplasia, sometimes adenomatous enlargement, but in either case the effect is overfunction.

Removal of the tumour has striking results. The serum calcium falls very rapidly to normal or lower; it may be necessary to give parathyroid extract and calcium gluconate for a short time after operation in order to avoid tetany. The serum phosphorus rises. Excretion of calcium and phosphorus return to normal. The patient loses the pain and tenderness in the bones almost at once; later, gradually the condition of the skeleton improves, both as regards structure and calcification. Cases are on record in which the patient before operation was a helpless, bedridden invalid, and has been walking with a stick six months later. Deformities, of course, remain, but the disease becomes arrested.

Overdosage with irradiated ergosterol.—Therapeutic doses of vitamin D promote calcification of the skeleton, but very large doses cause a quite different syndrome. This toxic syndrome resembles in all respects the effect of overdosage with the parathyroid hormone. The symptoms are the same with both drugs, and the biochemical changes—hypercalcaemia, decalcification of the skeleton and excessive calcium excretion—are the same. Also the different species vary in susceptibility to the toxic effects of irradiated ergosterol in the same way as in the case of parathyroid hormone; those species which are resistant to the one drug are resistant also to the other, and those which

are susceptible to the one are also susceptible to the other. The sensitiveness of a species to the therapeutic use of vitamin D bears no relation to its sensitiveness to the toxic effect, so that one must beware of applying the results of animal experiments to clinical work in considering the possibility of overdosage with vitamin D. Overdosage in the course of therapeutic use of the vitamin must be rare, but it probably occurs occasionally. In view of this relationship between vitamin D and the parathyroid hormone, it is of interest that in fish, which have no parathyroid glands, there are large supplies of vitamin D in the liver.

The use of calcium estimations in diagnosis.—Generally speaking, estimations of the serum calcium are required only in the following conditions: (1) in the investigation of cases of tetany; (2) in the control of treatment with parathyroid hormone; (3) in the diagnosis of generalized osteitis fibrosa with parathyroid tumour.

The changes in serum calcium which occur in renal disease are incidental, and the estimation is not likely to help in the diagnosis or prognosis; moreover, the calcium figures in renal disease can only be interpreted if the figures for protein and inorganic phosphorus are also known. In the majority of cases of rickets the serum calcium is normal; it is low in those cases which are associated with spasmophilia. The serum calcium is normal in all convulsive conditions other than tetany. Beneficial results have been described from the administration of calcium chloride in various conditions associated with effusions. The benefit is probably due to the diuretic effect of the chloride ion, and not to any special effect of calcium in the control of exudation. The serum calcium is normal in urticaria, and in angio-neurotic oedema. It is also normal in cases of 'haemorrhagic diathesis' and of hæmophilia. The amount of calcium required for blood coagulation is very small, and no condition is known in which calcium deficiency causes failure in coagulation. As regards estimations of calcium in urine and faeces, these can only be made satisfactorily under the conditions of a 'metabolism' ward, in which accuracy in dieting and in collection of excreta are assured.

The Modern Treatment of Nasal Catarrh

By A. L. YATES, M.C., M.D., F.R.C.S.

(From the *Medical Press and Circular*, 31st January, 1934, Vol. CLXXXVIII, p. 98)

THERE are many forms of nasal catarrh which clear up very rapidly with simple forms of treatment. In some of these the best results can be obtained by surgery, in others palliative measures are the best. The history of a case of nasal catarrh is generally of great importance. We can first divide all cases into acute, subacute and chronic.

The acute cases fall into two main groups from the point of view of history. In one the inflammation has produced obstruction to the ostium of the sinus, and an empyema of the sinus has formed. These cases are characterized by pain. It is important to note the presence of previous attacks which show that a case of apparent acute sinusitis is in reality an acute condition grafted on a chronic process.

In the second group of nasal inflammation the ostium of the sinus is open. No pain has therefore been present, and the history given is one of fever and malaise, which have not yielded to the ordinary forms of treatment. Nasal symptoms are often in this class of case slight. In subacute and chronic inflammation we get three forms of history. In the one the patient suffers from intermittent pain; in the second, it is the character of the discharge of which the patient complains; sometimes this is excessive in amount, and sometimes it is slight, but causes a bad taste in the mouth; and in the third, the history is one of general ill-health, which may be manifested by rheumatism, skin disease, and increased bodily or mental fatigue. This last is of considerable importance.

EXAMINATION

Acute cases.—The headache in the early stages is not markedly severe, but as the case progresses it may become agonizing and totally incapacitate the patient from his work. If it is the maxillary antrum which is the site of inflammation this will be dull on transillumination, and the mucous membrane in the middle meatus will be swollen. All practitioners have not, however, the facilities to carry out this examination, but an examination of the fauces gives material information.

In an acute case of sinusitis there can frequently be seen behind the posterior pillar of the fauces a thin white line. This is the main lymphatic from the nose, and, being superficial, is visible through the mucous membrane. The presence of this line gives us the information that examination should be conducted by someone versed in nasal treatment.

In the class of case in which there is no pain, this vessel can still frequently be seen, but sometimes the mucous membrane parallel with the posterior pillar of the fauces is so thickened and congested that it hides the vessel. The presence of this thickening of the mucous membrane is, however, confirmation of the presence of nasal inflammation.

In chronic cases nasal examination shows swelling of the strip of mucous membrane over which the pus is passing. This swelling is seen in the middle meatus if the frontal anterior ethmoidal or maxillary sinuses are the site of inflammation. In cases of sphenoidal or posterior ethmoidal sinusitis the inflammation is most marked on the upper surface of the middle turbinate.

The diagnosis of the actual sinus is, however, more readily made by a post-nasal examination with a mirror. This also shows a thickening of the mucous membrane in the region over which the pus is passing. Thus, if it is the maxillary antrum, the frontal sinus or the anterior ethmoid cells which are the site of inflammation, the mucous membrane is thickened in front of the Eustachian cushion; or if the sphenoidal sinus is the site of inflammation, the pus is passed over the highest and most central portion of the naso-pharynx, and here the mucous membrane is inflamed and thickened.

In the atrophic forms of inflammation these areas of mucous membrane are thickened, but are pallid, and in the hypertrophic states of inflammation they are thick and red. Transillumination may be a guide to show which antrum is inflamed, or if a frontal sinus is the seat of trouble, but will give no information as to the state of any other sinuses. In chronic states it is good practice to obtain a specimen of the nasal pus in doubtful cases, and examine it beneath the microscope. It is important in this examination to determine the character of the cells, and the presence of free micro-organisms.

TREATMENT

Acute cases.—Pain is the symptom which attracts attention when there is obstruction to the opening of an acutely inflamed sinus. In the initial stages the nose should be cocaineized to contract the mucous membrane, and it may be expected that the pain will cease, because the congestion at the opening of the sinus has been removed by the cocaine. The pain will frequently recur, and cocaineization should be carried out again. If by this treatment the pain is gradually lessened, it should be continued up to, but not longer than, a period of three days. If there is no relief from pain, or if the pain on its recurrence is as great as formerly, or if the pain has not ceased after three days' treatment, the sinus should be washed out when this is possible. If it is not possible to catheterize the sinus, the use of cocaine should be continued as long as it causes an improvement. If, however, the symptoms are increasing in severity it will be necessary to consider the need for operative measures.

In the case of the antrum, the bony wall between it and the nasal cavity will be punctured with a trocar, and liquid paraffin used for lavage. Watery solutions should not be used in acute cases, as they sometimes increase the inflammation. The sphenoid and posterior ethmoid sinuses can be washed out through their normal ostia under cocaine anaesthesia. The frontal sinus can often be washed out by introduction of a soft catheter through its normal ostium. In a few cases it is necessary to open the frontal sinus because the catheter cannot be introduced, but this should be deferred in acute cases whenever possible, as cocaine will generally clear up inflammation of the frontal sinus.

As to the use of cocaine, it is necessary to know how much is delivered by the spray that is employed. Certain makers of sprays, for example, Rogers, show the amount upon the spray, but if this is not done it is easy to spray the fluid into a minim measure, and to determine how many emptyings of the ball are necessary before 10 minims have been sprayed. Supposing this number to be forty, the spray delivers 10/40, or one-quarter of a minim, with each closure of the ball. If in this case a 10 per cent solution of cocaine is used, 1/40th of a grain of cocaine would be sprayed with each emptying of the ball.

In certain cases of acute sinusitis there is no pain because the ostium is open. Because these cases are afebrile and painless they are very often missed. The treatment is the same in the early stages; the cocaine generally effects considerable improvement. If the fever and the secretion from the nose continue, and the secretion is for the most part post-nasal, the sinuses can be washed out, or in certain cases filled with liquid paraffin by use of vacuum. The latter is a new method, and under trial in acute cases.

In certain of these cases the fever is maintained, and when this is so it is generally advisable to administer either large quantities of fruit juice or large quantities of sodium bicarbonate, for often when the urine becomes alkaline the temperature falls almost as if by crisis, and inflammation in the nose resolves. In other cases alkalinization does not have this effect, but it does no harm.

Subacute cases.—Many subacute cases of nasal catarrh are very trivial, and are cured spontaneously. There are a few in which treatment is required because the cases have considerable importance. This importance arises by reason of the fact that certain forms of inflammation render the mucous membrane capable of toxic absorption to an unusually high degree, and filter-passing micro-organisms may, in certain rare cases, find their way through the nasal mucous membrane. It is, for example, believed that this is the source of infection in certain cases of encephalitis lethargica.

If in a case of subacute catarrh symptoms such as diplopia, mental unrest, or failure of mental concentration are observed, it may be well to investigate the sinuses. It must be borne in mind, however, that there are many other causes for such symptoms, and many other portals of infection, and that catarrh is very common.

In the rare cases in which the nasal inflammation is the cause of such grave symptoms, lavage of the sinuses with liquid paraffin sometimes works wonders, for the liquid paraffin tends to prevent toxic absorption by covering the surface of the mucous membrane with a layer of oil. In certain cases, even though a nasal sinus may be associated with these symptoms, the lavage of the sinuses with paraffin produces little alteration in the symptoms because the micro-organisms have found their way into the cells of the mucosa.

In a few cases of subacute catarrh we meet with tonsillitis, which is secondary to the nasal inflammation. In such a case the posterior portion of the tonsil is more enlarged than the anterior, and the posterior pillar of the tonsil is much inflamed. In such a case the tonsils should not be enucleated, as the operation may

debase the power of resistance in the sinuses, and lead to an increase in the activity of the infection.

In certain cases of subacute catarrh, particularly when a mild grade of sinusitis is preventing the recovery from a cold, it may be very helpful to try and empty the sinuses by a spray of liquid paraffin, which is actuated by an electric pump. This causes a strong blast of air and paraffin to pass over the opening of the sinus, which causes a vacuum within it in exactly the same manner as the escaping steam causes a vacuum in the inner chamber of the apparatus used for sterilizing dressings. The head is placed in such a position that the partial vacuum will cause the pus to be emptied from the sinus. Sometimes this method works, and sometimes it is useless. If cases of sinusitis fail to clear up completely they should not be left alone, but should be washed out, preferably with liquid paraffin, in order to avoid the damage which otherwise will occur to the mucous membrane in the sinus.

Chronic catarrh.—Many cases of chronic catarrh are trivial; others, by reason of the excess of the secretion, or its taste or odour, call for treatment, while others are more serious in that toxic absorption causes rheumatism, skin disease or similar remote effects. Among these latter there is an important group in which the patient gradually loses mental alertness and efficiency to an extent which is not infrequently prejudicial to his business. The treatment must be designed to fit the case. Thus in a mild catarrh which is not very excessive, and in which the discharge is odourless and tasteless, some simple palliative measures are all that are desired, and generally will bring about a cure.

Of these methods of treatment, a simple nasal douche, which is sniffed from a tumbler up the nose and blown from thence into a basin, is often very helpful. This does not, however, reach the interior of the sinuses, and if a sinusitis complicates the inflammation in the nasal airway, it is desirable to fill the sinuses with oil by the method introduced by Proetz, and called displacement. If the paraffin is mixed with an oil opaque to *x*-rays, such as lipiodol, its entry can be verified from the skiagrams. This gives us the information that the ostium of the sinus is open. If we can fill a sinus in this way oil will be emptied from it by the action of the cilia, and with it the excess of mucus. If the sinus fills again, it probably should be washed out.

There are certain newer methods of displacement which are worth a trial. The *x*-ray photograph, after displacement, may show that one sinus has not filled, and this then may be washed out instrumentally if the discharge continues. In general, however, where is little need to wash out sinuses instrumentally in this mild group of inflammation, as they clear up very well by simple measures. In cases in which the discharge has an offensive taste or smell, or is so excessive as to cause considerable trouble to the patient, it is generally wise to examine the mucus in order to discover the type of cells, and whether free micro-organisms are present in these cells or in the mucus. If free micro-organisms are present it is probable that we shall not operate until other measures have been tried. If there are no free micro-organisms, then the patient must decide whether he will be treated by operative or by palliative measures.

In this class of case the results are obtained more quickly by operative than by palliative measures, and they are generally more sure, but if the patient is content to come week by week for palliative treatment, it will, in cases in which the discharge diminishes progressively, generally effect a cure. Such palliative measures as displacement frequently give good results, but they are tentative, and classified as a test treatment. Frequent washings out of the sinuses by instrumental means can be employed if the patient will permit them, but, generally, patients want some less disagreeable method, and simple displacement followed by nasal douching at home is generally the first choice, and if this fails, an operation is considered.

Before an operation is performed an *x*-ray examination of the sinuses should be carried out. If the *x*-ray shows thickening of the mucous membrane in all the sinuses, it is necessary to consider whether the case is one of allergy or whether the mucous membrane has been thickened as a result of inflammation. This is a very important decision, because allergic cases withstand operation extremely badly. When the sinus mucous membrane is thickened as a result of inflammation, the master sinus, that is to say the one which causes the initial inflammation which has spread to all the other sinuses, shows a greater thickening of its mucous membrane than the others. If the mucous membrane is thickened equally throughout the sinuses, the case is generally one of allergy, and vaccines should be tried. These should be given by the intradermal route, and the degree of reaction of the skin controls the doses, which must be extremely small. In cases in which the thickened mucous membrane is confined to the antrum, and the discharge has not lessened as a result of a reasonable period of treatment, the antrum should be opened by Caldwell-Luc approach, and the mucous membrane carefully removed.

If the frontal sinus shows thickening of the lining mucous membrane, no operation should be carried out unless there has been pain which has not yielded to displacement, but if displacement has failed the sinus can be catheterized or opened. The catheter will generally cause a remission of the symptoms, but will not cure in any but the mildest cases, but it is advisable to give test treatment in these cases before an operation is decided on.

If the inflammation is centred in one sphenoid, or one posterior ethmoid, the lavage can be easily accomplished through the normal ostium, but the opening of the sinus can only be effected by removal of the middle turbinate. If this is diseased, and the lining mucous membrane of the sinuses is seriously affected, operation may give the best results. In the majority of cases instrumental lavage of these sinuses is all that is required, and if there is recurrence it can be easily repeated.

In certain cases the hypertrophy of the mucous membrane, which has been produced by the inflammation, leads to obstruction of the nasal cavity. This obstruction is frequently increased in degree by reason of deflection of the septum. If an examination of the history shows that the nasal airway previous to the inflammation was comfortable, it is probable that removal of the focus of infection will restore the airway. If, in spite of treatment, the airway remains obstructed, the question of straightening of the septum and diminution of the hypertrophied turbinates will have to be considered, but this measure is generally inadvisable as a first procedure.

The only condition in which an operation has invariably to be carried out is that in which the mucous membrane has undergone polypoid degeneration, and when this is the case the altered mucous membrane around the base of the polypi must be removed. In addition, it may be said that the trend of opinion to-day is in favour of conservatism in nasal surgery, and that operation is reserved for those cases which have resisted the various forms of test treatment that are now in vogue.

Dietary and Medical Management of Diseases of the Gall-bladder

By JOHN RUSSELL TWISS, M.D.

and

CARL H. GREENE, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CI, 9th December, 1933, p. 1841)

Progress in any field of medicine is not a uniform process. The introduction of new points of view for the study of the disease process, the developments of

new technical methods of examination, or advances in any of the medical sciences may lead to renewed interest, intensive study and rapid progress, at least for a time. The last decade has seen such an interest in the anatomy, physiology, chemistry and pathology of the liver and biliary tract.

It is desirable at the present time, therefore, critically to review this literature and to point out the application of these newer points of view in improving the therapeutic management of the patient with disease of the liver or biliary tract.

Mann has reported, in summarizing both the literature and his own studies, that he has come to consider the gall-bladder as a part of a mechanism whereby the secretory activity of the liver is correlated with that of the gastro-intestinal tract. In the fasting state preceding a meal, the liver is active but the amount of bile secreted is relatively small. The gall-bladder is partially filled with concentrated bile, of which the bile salts are a most important constituent. The sphincter at the end of the common duct allows amounts of bile to escape into the duodenum only at infrequent intervals and most of the bile secreted by the liver passes into the gall-bladder. As soon as the ingested food passes the pylorus the chyme causes the sphincter to relax and, co-ordinately with this, the gall-bladder expels a portion of its contents. The bile salts are quickly absorbed from the intestine and stimulate the liver to increased activity. With the increased secretion of bile there is an increased flow of bile to and from the gall-bladder. With the stomach empty and chyme no longer pouring over the papilla, the sphincter opens less frequently, and gradually the secretory activity of the liver is reduced to that of the fasting state. It therefore appears that the function of the gall-bladder is to provide a reserve of concentrated bile which is of value both in digestion and as a means of stimulating the liver to increased activity at the time the gastro-intestinal tract is most active.

The data on which this hypothesis is based are varied and, in many particulars, still a subject for controversy. The ability of the gall-bladder to concentrate the bile from several to tenfold, suggested by the work of Kemp, Hammarsten and Hohlweg, was conclusively proved by Rous and McMaster and by Mann and Bollman. Whether substances other than water and inorganic salts are absorbed, however, is still under debate. Examination of the gall-bladder of a dog several days after the ligation of the common bile duct shows the surface lymphatics to be distended with bile-stained fluid, while two or three months later the contents of the gall-bladder are reduced to a small amount of inspissated mucus that may fail entirely to give the chemical tests for unchanged bilirubin or bile acids. Mann has reported experiments indicating absorption of bile salts from the gall-bladder, and Andrews and his associates think that such absorption and the consequent ratio of bile salts to cholesterol is an important factor in the deposition of cholesterol crystals from the bile. There would seem, on the one hand, to be some evidence for assuming that the gall-bladder is able to absorb bile salts from the contained bile. On the other hand, the fact that the gall-bladder bile normally contains several times as much bile salts as hepatic bile suggests that such absorption usually is small in extent, at least when compared to the accompanying absorption of water.

The deposition of lipids or, more particularly, cholesterol in the mucous membrane of the gall-bladder noted by Naunyn has been termed the 'strawberry gall-bladder' by MacCarty and, more recently, 'cholesterosis' by Mentzer. The pathogenesis of this condition is now a source of acute controversy. Some investigators, *e.g.*, Sweet and Halpert, hold that it is evidence of absorption of cholesterol from the bile by the epithelium of the gall-bladder; others, *e.g.*, Elman and Graham, hold to the earlier view of Naunyn and Aschoff that the gall-bladder secretes cholesterol into the bile. Others, *e.g.*, Wilkie and Doubilet, insist that

the wall of the gall-bladder behaves as a semipermeable membrane and that passage of cholesterol in or out depends on the relative concentration in the blood and bile. In any case, as emphasized by Twiss and Killian, the concentration of cholesterol in gall-bladder bile as compared to that in hepatic bile is relatively much greater than that of other biliary constituents. That the gall-bladder epithelium has some secretory activity, apart from the secretion of mucus, is indicated by the experiments of Mann with rose bengal.

Until recently it was a question as to whether the gall-bladder ever really empties. For a long time Sweet and Halpert have insisted that it never empties at all. The introduction of cholecystography by Graham and Cole has done much to answer this question. When cholecystography is combined with duodenal drainage, the results in normal individuals may be dramatic. In such an experiment the patient is given the dye in the usual way. The following morning, duodenal drainage is started. If successful, dilute bile (the A bile of Lyon) is obtained. This bile contains little if any dye. Roentgenograms show the tip of the tube in place in the duodenum and a distended gall-bladder. Stimulation by magnesium sulphate or olive oil then produces a flow of dark concentrated bile (B bile) containing much dye. This is followed by a flow of light bile (C bile) containing little dye. Roentgenograms at the end of the experiment show a marked reduction in the size of the gall-bladder. While such experiments show that the gall-bladder does empty, there is an extensive experimental literature which indicates that it perhaps never empties completely, as does the urinary bladder, and several days may elapse before the entire content at any one particular time is removed.

Once it is accepted that the gall-bladder does empty into the duodenum, the question of the mechanism involved becomes paramount. The effect of respiratory movements, changes in intra-abdominal pressure, the elasticity of the viscus, variations in the tonus of the duodenal wall or of the sphincter of Oddi, and the existence of a reciprocal innervation between the sphincter and the gall-bladder have been discussed at length. More recently, attention has been focused on the rôle of the intrinsic musculature of the gall-bladder. Various observers from Doyon to Potter and Mann have noted that when the gall-bladder or common duct is connected to a manometer there are small rhythmic variations in pressure that could be interpreted as due to contractions. Boyden, Whitaker, and Higgins and Mann have conclusively shown contractions in the gall-bladder of various species from fish to guinea-pigs, cats and dogs. Cholecystography furnishes at least presumptive evidence that similar contractions may occur in man. Furthermore, Ivy and his students have shown the presence in animals of a hormonal mechanism (cholecystokinin) which produces contraction of the gall-bladder. They believe that the efficiency of such fatty substances as cream, egg yolk, olive oil and oleic acid in producing contraction and emptying of the gall-bladder is to be explained by their action in stimulating the production of cholecystokinin in the mucosa of the duodenum rather than to a specific stimulatory effect of these materials either on nerve endings in the duodenum before absorption or on the wall of the gall-bladder after absorption. Ivy has also shown the effectiveness of cholecystokinin in causing emptying of the gall-bladder in man.

The importance of the sphincteric mechanism at the duodenal end of the common duct, as pointed out by Giordano and Mann, must not be minimized. Ivy, Voegtlin, and Greengard have recently reported experiments on a human subject in whom, after the injection of the cholecystokinin solution, gall-bladder pain was produced by the contraction of the latter viscus concurrently with the development of spastic obstruction of the intramural portion of the common bile duct. In this case the intraduodenal administration of magnesium sulphate was effective in relieving the

spasm and distress. Since cholecystokinin is formed after the eating of fats, functional disturbances analogous to those in the subject reported by Ivy, Voegtlin and Greenard may explain some of the intolerance to fats, which is a frequent complaint of patients with chronic cholecystitis.

It is manifestly impossible at the present time to discuss, in detail, the pathologic lesions involving the biliary tract. Chronic cholecystitis with or without an accompanying cholelithiasis greatly exceeds all other lesions in frequency and medical importance. The problems concerned with the cause and formation of gall-stones are by no means settled. It is now recognized that the gastro-intestinal disturbances, which Moynihan considered the 'inaugural' symptoms of gall-stones, are the symptoms of cholecystitis and have no direct connection with the presence of stones. Whether gall-stones are the result of an antecedent cholecystitis or by mechanical irritation are responsible for the development of a subsequent cholecystitis is not a question that can be answered at the present time. In special cases it can be shown that one or the other of these two mechanisms is presumably responsible for the troubles of the patient, but in general they can be discussed together. However, if medical therapy is ever to supplant surgery in this field of medicine it will be necessary to recognize and correct disturbances in the biliary tract before the formation of calculi.

There are various predisposing causes that must be considered in relation to the production of either cholecystitis or cholelithiasis. Particular emphasis is placed on the effects of (1) biliary stasis, (2) infection, (3) disturbances in pigment excretion, or (4) cholesterol metabolism, (5) obesity and (6) pregnancy.

Biliary stasis with stagnation of the bile in the gall-bladder is important. Such stasis presumably permits greater concentration of the bile and so favours deposition of insoluble matter. It is further assumed that stasis favours the development of both infection of the bile and inflammatory processes in the wall of the gall-bladder.

Infection may involve either the bile or the gall-bladder, or both. Bacteriologic studies have found streptococci, which have been considered to result from focal infection arising primarily in the teeth, tonsils or appendix. Cholecystitis is a frequent complication in typhoid, and a residual infection of the biliary tract is responsible for many typhoid carriers. This is a cause of disease of the biliary tract, which we hope is of diminishing importance. These two types of infection are usually thought to be blood borne, though whether the organism reaches the gall-bladder through the bile, through the cystic artery or by lymphatic extension from the liver is a source of controversy. Hurst believes that the majority of cases of cholecystitis are due to infection with the colon bacillus and are the result of an ascending infection to the gall-bladder from the duodenum.

Metabolic disturbances may affect the excretion of either bile pigment or cholesterol. Small, irregular, dark brown or almost black stones composed of pigment and calcium with only slight, if any, degree of accompanying cholecystitis are frequently found in patients with congenital hæmolytic jaundice. According to Giffin, they occur in 58 per cent of such cases. In this condition it is recognized that there is a marked pleochromia of the bile as a result of the excessive excretion of bile pigment. Greene and Snell found in dogs that the intravenous injection of bilirubin or of hæmoglobin increased the excretion of pigment in the bile but that significantly this augmented rate of excretion was brought about primarily by an increase in concentration. They report two experiments in which the concentration of bilirubin in the hepatic bile rose to 1,000 mg. per hundred cubic centimetres, or from six to twenty times the usual normal values. Similarly, concentrated bile has been observed in dogs following the experimental production of anæmia by

the administration of phenylhydrazine. If such concentrated bile remains in the gall-bladder long enough to undergo much further inspissation, it would not be surprising if deposition of the excess pigment and calculus formation should occur.

Disturbances in cholesterol metabolism frequently result in the formation of gall-stones. The waxy, glistening gall-stone composed of a radiating mass of cholesterol crystals is most characteristic, but, according to McNee, only some 6 per cent of gall-stones are of this type. Twenty per cent are combination stones in which a cholesterol stone serves as a nucleus for the subsequent deposition of pigment and calcium; 64 per cent are mixed stones built up of concentric layers of cholesterol, pigment and lime salts. It is frequently assumed that the pure cholesterol stone is deposited as the result of a primary metabolic disturbance which may be independent of any element of cholecystitis. The effect of infection in causing the deposition of pigment and calcium is evidenced in the mixed types of stones. Pickens, Spanner and Bauman have recently pointed out that gall-stones, on the average, consist of 91 per cent of cholesterol with only some 3 per cent of pigment and 1 per cent of calcium present. Under these conditions the importance of cholesterol and of disturbances of cholesterol metabolism in the formation of calculi is obvious.

A tremendous amount of work has been done on different phases of cholesterol metabolism, but here also there is no final agreement as to the origin, function or fate of this material. According to the recent review of Muller it is probable that the cholesterol in the body is both endogenous and exogenous in origin. The relative importance of these two sources has not been finally determined, though most observers consider that the greater proportion of the cholesterol is absorbed from the food and is excreted in the bile. A smaller amount is excreted in the bowel. The presence of bile in the intestine favours the absorption of cholesterol but is not essential thereto.

According to this view the liver has a regulating function and is active in maintaining the cholesterol content of the blood at a fairly constant level. In some types of hepatic disease, especially when biliary obstruction is present, the cholesterol content of the blood is increased, while that in the bile is reduced. Normally, apart from the diurnal variations pointed out by Bruger and Somach, it is difficult to affect the cholesterol level of the blood, though slight and transient increases may be produced by a meal rich in cholesterol, particularly if fats are fed in addition. There is considerable evidence that, with the prolonged use of foods rich in cholesterol, hypercholesteremia develops and is accompanied by an increased excretion of cholesterol in the bile. Independently of the cholesterol intake, diets rich in fats or any other measure that produces an increase in the fat content of the blood also produce hypercholesteremia. Diets low in cholesterol, especially if they are low in fat as well, lead to a reduction in the cholesterol content of the blood. If hypercholesteremia is present, such diets frequently produce a return to normal but do not reduce the cholesterol content of the blood below normal. We have found hypercholesteremia in a large proportion of patients with chronic cholecystitis or cholelithiasis without biliary obstruction. The bile cholesterol is increased in some but not all cases. In these cases a diet low in cholesterol and at times the use of repeated duodenal drainages frequently results in a return toward normal of the blood cholesterol, associated with an improvement in the clinical condition of the patient.

There is a definite sex difference in the incidence of cholecystitis and cholelithiasis, and various factors have been proposed to explain the greater frequency in females. Two of the most important of these are obesity and pregnancy.

In obesity there seems to be a disturbance in cholesterol metabolism, but a definite relation between the cholesterol content of the blood and the degree of

obesity has not been established. Rapid weight reduction or starvation with mobilization of fat apparently liberates considerable quantities of stored cholesterol and produces a resultant hypercholesteremia. Under these conditions it should be emphasized that while weight reduction is important in the obese patient it should be gradual, and care should be taken to avoid stasis during the period of reduction.

Hypercholesteremia also occurs in pregnancy; apparently this is due in part to retention for, according to Pribram and to Baumeister, the bile cholesterol is at first reduced. In the later months of pregnancy and postpartum the retained cholesterol was found by McNee and Baumeister to be eliminated in part in the bile. Bodily activity is apt to be reduced during pregnancy and constipation is usual. In addition, Mann and Higgins have recently shown that the muscular activity of the gall-bladder is diminished in pregnant animals. All these factors promote biliary stasis and so favour the formation of calculi and the development of biliary infection during pregnancy.

The fundamental requirement for satisfactory results in the treatment of gall-bladder disease is a correct initial diagnosis. A careful and complete diagnostic work-up is essential, for there is no one method of diagnosis that is infallible. In the majority of patients, symptoms are usually indefinite. Typical colic is by no means always associated with stones. Physical examination is frequently of little assistance, except in acute conditions or in cases of jaundice. The limitations of cholecystographic study must be recognized, for a diseased gall-bladder may visualize and empty normally even though stones are present. Conversely, there may be no visualization on repeated cholecystographic examination and still laparotomy may reveal an apparently normal gall-bladder. We have found non-surgical biliary tract drainage a valuable supplementary method of diagnosis, provided the drainage is properly performed and the results are correctly interpreted, particularly in regard to the absence of concentrated bile or the presence of pathologic elements in the biliary sediment.

The selection of a group of 500 patients as having gall-bladder disease has been made in the clinic for diseases of the biliary tract at the New York Post-Graduate Hospital, in accordance with the complete diagnostic routine described elsewhere. In addition to the examination of the biliary tract, other tests such as urine analysis and blood counts have been done as a routine. When indicated, roentgenologic studies of the gastro-intestinal or urinary tracts have been made. The patients who gave evidence of biliary tract disease only have been studied over a period of three years, the initial diagnostic study being repeated periodically to determine the effects of treatment and to correlate these observations with the clinical course of the disease.

The general plan of medical treatment followed in these patients has been based on consideration of the foregoing principles and may be considered under the heading of (1) prevention of biliary stasis, (2) prevention or treatment of inflammation of the gall-bladder or bile ducts, (3) diet and (4) removal of calculi when once formed. So far, progress other than surgical in this last type of therapy has been nil and need not be considered further.

The value of attention to the general hygiene of the patient, of regular habits, moderate exercise, deep breathing, avoidance of constipation, freedom from mental strain and worry and the like has been amply demonstrated by experience. In the past this improvement has been ascribed largely to the relief of biliary stasis. Horseback riding has long been favoured to stir up a sluggish liver and cause emptying of the gall-bladder. In the light of present knowledge of the physiology of the biliary tract, it would seem now that the value of such measures is to be ascribed as much to the improvement in muscular tone and the state of

the general health of the patient as to any specific action on the gall-bladder. This remark, however, is not to be interpreted as in any way minimizing the importance of such general measures.

Removal of foci of infection, particularly as regards the teeth and tonsils, is important as a means of preventing or treating infection in the biliary tract. Hurst, among others, has emphasized the importance of attacks of indigestion or acute gastritis in permitting ascending infection of the biliary tract, particularly with colon bacilli. He also stresses the value of methenamine as a biliary antiseptic in such cases.

Various spas have long been favoured for the treatment of diseases of the liver and biliary tract. Apart from regulation of the hygiene of the patient and the use of diets, this type of therapy depends on the use of mineral waters. These contain saline cathartics in varying amounts, the active agent usually being magnesium sulphate, sodium sulphate, sodium phosphate or a mixture of these salts. It is now accepted that saline cathartics as well as the ever popular calomel have little action in stimulating the secretion of bile, but they prevent constipation, ensure regular action of the bowels, and favour emptying of the gall-bladder. The use of such a procedure, but questions of time and expense lessen its value as a routine therapeutic measure.

Alkaline powders when given before meals frequently relieve reflex gastric symptoms. Sedatives such as phenobarbital or bromides give excellent results, especially in nervous or neurotic patients. The use of these drugs with antispasmodics or alkalis at times is especially effective. We have used cholagogues with symptomatic relief in some cases, sodium dehydrocholate being the preparation usually given.

While the occurrence of a typical biliary colic followed by jaundice is diagnostic, it usually indicates the presence of gall-stones and the need for surgical rather than medical management of the patient. The early symptoms of cholecystitis, the 'inaugural symptoms of cholelithiasis' of Moynihan, are not localized to the biliary tract. Much of the epigastric fullness and distress, the flatulence and nausea of which these patients complain is due to disturbances in the activity of the stomach, duodenum and bowels, produced partly as a result of secondary reflex disturbances and partly as a result of interference with normal digestion. This relationship has been pointed out by von Noorden and Salomon, Chester Jones, and recently discussed in detail by Alvarez.

Von Noorden has called attention to the secretory disturbances of the stomach and intestinal tract which he attributes to catarrhal conditions. He states that gastric hypo-acidity may not produce any symptoms but nevertheless has an effect on the biliary tract, particularly in regard to the loss of protective action against external bacterial invasion. Hyperacidity, he feels, is more frequently associated with pain and furthermore produces excessive stimulation of the bile flow. This can be prevented by regulation of the acidity. Von Noorden also calls attention to the frequent association of the 'lazy colon' with gall-bladder disease. The importance of the spastic sigmoid is emphasized particularly, for it sometimes causes colic which may be mistaken for biliary colic.

The value of frequent small meals and of a bland, non-irritating diet that is free from coarse fibre and leaves only a small residue is generally accepted as basic in the treatment of chronic cholecystitis and the associated gastro-intestinal disturbances. The various topics previously discussed in this paper, however, show that no single diet is applicable to the management of all patients.

When the patient is obese, reduction in weight is imperative. In this case, fats should be eliminated from the diet and the intake of cereals and starches reduced to keep the total intake of food below the caloric requirements.

A certain proportion of patients with disease of the biliary tract complain of intolerance to food. Some have been literally 'afraid to eat' and are semistarved and underweight in consequence. In such cases the bland diet is important. In addition, when the patient is underweight every effort should be made to increase the calorie intake. Frequent feedings, either four or five small meals daily or the use of intermediate nourishment between the usual three meals, a liberal intake of starches and cereals, and, if possible, the addition of cream, butter or olive oil to the diet is desirable to facilitate gain in weight.

In some instances the intolerance to food is due to reflex gastric disturbances with the development of the syndrome of hyperacidity, which is usually considered characteristic of peptic ulcer. In such cases a modified ulcer type of management with or without the use of alkalis is indicated.

Many patients show a definite intolerance to fats. The importance of bile in the absorption of fats has long been known. This is partly due to its action in activating the pancreatic lipase, partly to the action of the bile salts favouring emulsification and solution of the fats and partly, as more recently emphasized by Wieland and Sorge and by Verzar and Küthy, to the formation of addition compounds between the bile salts and the fatty acids, which are thereby absorbed directly into the portal blood stream.

Friedrich von Müller long ago showed the great diminution in the absorption of fat that occurs in the presence of complete biliary obstruction. Many patients with cholecystitis complain of discomfort following a fat meal, which is probably best explained by the effect of fats in stimulating the formation of cholecystokinins. This stimulates the gall-bladder to contract and, in the presence of active inflammation or of any disharmony in the reciprocal action of the gall-bladder and the sphincter of Oddi, may well cause pain. On the other hand, if there is no intolerance, cream, egg yolk, olive oil or oleic acid are valuable additions to the diet, for in the presence of a functionally competent gall-bladder they stimulate the formation of cholecystokinins and aid biliary drainage.

The significance of hypercholesteremia in relation to the possible formation of gall-stones has already been discussed. The routine determination of the cholesterol content of the blood is a valuable procedure in these patients. When this value is increased, foods rich in cholesterol, such as brain, eggs, butter, goose, duck,

liver, sweetbreads or cream, should be excluded from the diet.

This represents a compilation of the majority of values given in the literature for the cholesterol content of food. Many of the analyses are old. The need for an accurate and comprehensive series of analyses of the cholesterol content of food is obvious. In the past, beans and peas have been proscribed, but Schoenheimer has recently pointed out that while they contain considerable amounts of sterol the latter is not cholesterol but phytosterol, which is not absorbed by the mammalian intestine. These vegetables may therefore be included in the diet.

GENERAL DIRECTIONS FOR USE WITH THE GALL-BLADDER DIETS

Meals.—Meals should be small in amount and taken at the same time each day. Large meals and overeating are detrimental. Chew all food carefully; the teeth must be in good condition.

Rest.—A rest of a half hour lying down should be taken after the noon and evening meals. This allows the food to digest, which is impossible with mental or physical work immediately following meals.

Bowel movements.—An effort should be made to move the bowels every day after breakfast, regardless of inclination. If the bowels do not move every day this should be reported to the physician so that medication may be prescribed.

Exercise.—A proper amount of outdoor exercise is essential for the proper functioning of the gall-bladder and all other organs. A walk of at least forty blocks should be taken every morning, deep breathing being taken at this time to stimulate the action of the gall-bladder.

Water.—At least eight glasses of water are to be taken daily. A glass of water, preferably hot, should be taken on arising in the morning. The other water should be taken between meals rather than with meals.

Medication.—As directed by the physician.

CONCLUSION

If due attention is given to the physiologic disturbances responsible for the symptoms of which the patient complains and if physiologic principles are kept in mind during the treatment, improvement is possible in the present medical management of diseases of the gall-bladder and biliary tract.

Reviews

A HANDBOOK ON DIABETES MELLITUS AND ITS MODERN TREATMENT.—By J. P. Bose, M.B. (Cal.), F.C.S. (Lond.). With a foreword by Major-General Sir John Megaw. Second Edition. 1934. Thacker, Spink and Company (1933), Limited, Calcutta. Pp. xviii plus 232. Illustrated. Price, Rs. 6-8

THERE are few parts of the world in which diabetes does not occur so that it cannot be considered in any way a tropical disease. 'Why then', one might ask, 'is the disease being studied in a tropical diseases institution?' The answer is that though it is a universal disease, diabetes as it occurs in India presents very special features that merit special investigation. This constituted the *raison d'être* for the foundation of a scholarship for diabetes research at the Calcutta School of Tropical Medicine—the other essential was provided by the generous endowment of this research post by Mrs. M. Mitra, in memory of her husband the late Rai Bahadur Dr. Ashutosh Mitra of Kashmir.

One of the most important results of the foundation of this scholarship was the publication by Dr. Bose, the first occupant of this research post, of a *Handbook*

on *Diabetes Mellitus*. The urgent need for such a book was obvious, as, of the scores of books that had been published on this important disease, none fulfilled the requirements of the practitioner, or dealt with the special aspects that it presented, in this country. It is not surprising that this book was very popular and that the edition was soon exhausted; the book under review is the second edition of this book.

The whole subject of diabetes is dealt with in a systematic and practical manner. All the advances in our knowledge of this disease that have been made in Europe and America have been carefully followed and interpreted in terms of the problem, as it presents itself in India, and to these have been added Dr. Bose's own contributions to the problem in the form of his researches into the subject during the last thirteen years. Perhaps one of the most important points emphasized is that the discovery of insulin has placed a very valuable instrument into the hands of a well-informed medical man but a very dangerous weapon into the hands of the ignorant one; with this little book available no medical man has any excuse for remaining in the second category.

This second edition has been completely revised and a chapter or so added. An important addition is the chapter on diabetes in children, which appeared not very long ago as an article in this journal.

The book is worth its purchase price for the appendices alone, as here is to be found information about standard diets for Indian patients of different ages and about the composition of different articles of Indian dietary that will be found collected together nowhere else.

It has become a habit in this country for writers of books to persuade the occupant of a high administrative post, who may know nothing about the subject-matter of the book, to write a foreword: the argument being that a wine of doubtful quality requires the largest possible bush. Here the case is quite different, the writer of the foreword is primarily a physician and a scientist, only incidentally occupies a high administrative post, and his praise can do nothing but add to the confidence of the reader.

The book is of course written primarily for the medical man but it contains information which the patient himself should have at his disposal and we suggest that it would be a good book for the doctor to recommend to his well-to-do and more intelligent patients.

The author has a straightforward and clear style and his English is irreproachable; the publishers have played their part well and have produced a handy and neat volume; the paper is thin but fully opaque, and the type is clear. This second edition will certainly enhance the established reputation of the book.

THE PRACTITIONERS' LIBRARY OF MEDICINE AND SURGERY. Volumes V and VI. Volume V:—Traumatic Surgery, and Volume VI:—Obstetrics and Gynaecology. 1934. D. Appleton-Century Company, New York and London. Volume V:—Pp. xiv plus 1080. Illustrated, and Volume VI:—Pp. xiv plus 900. Illustrated. [Available from Messrs. Butterworth and Company (India), Limited, Calcutta.] Price, Rs. 37-8 per volume

THE fifth and sixth volumes of this very ambitious and, so far, very successful encyclopædia of medical practice have now been published. The division of the subject of surgery into non-traumatic and traumatic was an original idea, and appears to have been a successful one. The volume of non-traumatic surgery has already been reviewed in these columns. Volume V, on traumatic surgery, necessarily covers the whole subject of orthopædics, but its scope is much wider than this, and it naturally includes injuries to the soft tissues and to the various organs. The subjects fall under the main headings: trauma to the skin and subcutaneous tissues—including burns, fractures, dislocations, amputations, injuries to joints, bursæ, muscles and tendons, and injuries to head and neck, thorax and thoracic viscera, abdomen and viscera, genito-urinary tract, spine and spinal cord, nerves and blood vessels; the surgery of the hand is given a special chapter, and there are concluding chapters on traumatic shock, on post-traumatic states, and on the industrial aspects of the subject.

Each subject has been dealt with under the headings, definition, ætiology, anatomy, physiology and pathology, symptoms, diagnosis, prognosis, and treatment.

The subject of this volume is one that has seen very great advances during the last twenty years; for example, the whole principle of the treatment of fractures has undergone a change, largely brought about by war and immediate post-war experiences, and a better knowledge of the anatomy of the fascial layers of the hand has led to improved treatment of injuries and infections of this important member.

The subjects lend themselves to illustration and have been illustrated freely and efficiently; one series of illustrations will appeal to the practitioner for ready reference when he is faced with a case of injury to the

spine; this series shows the areas of anaesthesia following injury to the spinal cord at different levels.

It is difficult to offer any special criticism, but the general impression made is that, though the book no doubt summarizes the best American teaching, that of the European school might have been incorporated now and then with advantage, especially that of Böhler in Vienna.

In certain ways volume VI, on obstetrics and gynaecology, will be the most important volume in the series. As the editors say, the profession, to its credit, is becoming more and more maternal-mortality conscious each year. Obstetrics is not a subject in which dramatic advances are registered very frequently; the physician usually plays a very secondary part during the physiological process of bringing children into the world, but though he does little what he does is of the very greatest importance; it is therefore essential that he should keep his knowledge up-to-date, in order that he may keep the maternal mortality in his own practice down to an irreducible minimum.

The subject of obstetrics is divided into large chapters with the following titles:—The physiology of pregnancy—this includes the diagnosis of pregnancy, prenatal care, and presentation and position, the physiology of labour—including the mechanism of labour, the management of normal labour, and the newborn child, the physiology of the puerperium, the pathology of pregnancy, the pathology of labour, the pathology of the puerperium, and obstetrics surgery. The second part of the volume is devoted to gynaecology; here the subject is dealt with regionally.

In a volume of this size it is of course possible to treat the subject fairly fully, and the writers have attempted to describe in detail all the procedures that the general practitioner is likely to have to carry out himself in the course of his practice, but at the same time they have not excluded specialist subjects, as they feel—and we agree with them—that it is important for the practitioner to know something about the special procedures which he would not normally undertake, because, unless he does, he cannot advise his patients intelligently or give them any idea of what the result of their visit to the specialist is likely to be.

There is one minor criticism; we notice that under the heading of ulceration of the vulva the recent advances in our knowledge of the ætiology of the conditions now grouped under the heading lymphogranuloma inguinale, or poradenolymphitis have not been included, and these different conditions are not grouped together.

In conclusion it may be said that these two new volumes are quite up to the standard set by their predecessors, which was a high one.

Butterworths are the agents in India and the whole set may be obtained from them on the extended-payment system.

DISEASES OF THE EYE.—By Sir John Herbert Parsons, C.B.E., D.Sc., F.R.C.S., F.R.S. Seventh Edition. 1934. J. and A. Churchill, Limited, London. Pp. viii plus 695, with 21 plates and 353 text-figures. Price, 18s.

THIS excellent and popular textbook of ophthalmology which first appeared in 1907 needs no introduction and the new edition must receive the welcome it so rightly deserves.

Since the appearance of the last edition in 1930 our knowledge of ophthalmology has considerably advanced and the author has incorporated the most important advances. The chapter on the physiology of the eye has been re-written in the light of our present knowledge.

Too much praise cannot be given to the book which is written in a clear lucid style and well illustrated with text-figures and plates.

As the book is immensely popular and largely used in all parts of India, the only criticisms that the

reviewer would like to make are that there are no references to the ocular complications of leprosy, and superficial punctate keratitis of Fuchs which is so common in epidemics during and after the rainy season. No mention is made of Webster's mucous graft operation for the radical cure of ectropion and trichiasis resulting from trachoma.

To medical practitioners and students the book is strongly recommended as the best medium-sized textbook of its kind and should be indispensable to every medical man working in India where so much eye disease is everywhere to be found.

E. O'G. K.

ATLAS OF EXTERNAL DISEASES OF THE EYE.—By H. Neame, F.R.C.S. 1934. J. and A. Churchill, Limited, London. Pp. 111, with 51 plates. Price, 15s.

THE subject of external eye diseases lends itself so readily to the atlas form of treatment that we are surprised that it has not been adopted before. The book consists of fifty-one coloured plates depicting different eye diseases of which there is external evidence of the changes that have occurred; opposite to each plate is a short description of the condition, under the headings: synonym, symptoms, diagnosis, ætiology, pathology, prognosis, and treatment. The description never occupies more than one page, so, it will be gathered, the subjects are treated concisely, often in one line; this of course is just what is required.

The illustrations, which have been collected from a number of sources, are excellent. We can imagine this book having a very wide sale amongst final-year medical students and house surgeons, who will find it invaluable in an outpatient department and will treasure it all their practising lives. It really is a book for which there has been a 'long-felt want'; we foretell a great future for it, and both author and publishers have our best wishes as they have shown great enterprise; coloured illustrations are expensive to reproduce and to issue a book containing fifty-one at the modest price of this volume is an achievement.

SURGICAL ANATOMY AND PHYSIOLOGY.—By Norman C. Lake, M.D., M.S., D.Sc. (Lond.), F.R.C.S., and C. J. Marshall, M.D., M.S. (Lond.), F.R.C.S. 1934. H. K. Lewis and Company, Limited, London. Pp. lx plus 888, with 238 illustrations. Price, 30s.

THE book is divided into two sections, general and regional. The general section consists of nine chapters, describing 'the main physiological and pathological principles underlying surgical treatment'.

These chapters are exceedingly well presented, evenly balanced, and thoroughly up-to-date. The regional section consists of forty-five chapters and covers the whole of the body. The scope of each chapter is given 'whenever appropriate' as follows:—'development, anatomy, structure, physiology, pathology, operative and practical application'. It will be seen that this book is something more than a textbook of surgical anatomy and physiology.

The illustrations are good. There are several minor criticisms. Firstly, figure 141 showing a diverticulum of the lesser curvature of the stomach as seen through a gastroscope is somewhat out of place, also figure 235, vasography. In place of these, an illustration of a development of the palate and one showing cerebral localization might have been inserted. A student will have some difficulty in following figure 114 showing Kanavel's palmer space.

A word must be said concerning the index. The authors have overcome the students' difficulty with anatomical terminology by giving both the old and new anatomical names. Such an arrangement must save time and annoyance when looking up a subject hurriedly.

The paper is good and the printing bold. This is a book for which there has been a definite want, and should be in the hands of students during their final year.

F. J. A.

MANIPULATIVE TREATMENT FOR THE MEDICAL PRACTITIONER.—By T. Marlin, M.D., M.B., Ch.B., D.P.H., D.M.R.E. 1934. Edward Arnold and Company, London. Pp. vii plus 133. Illustrated. Price, 10s. 6d.

THAT there is a definite want amongst the profession at the present time for works on the subject of manipulation is shown by the publication recently of several books. In order not to overburden the subject, the author has omitted 'theories and explanations which are commonly adduced'.

The reviewer many years ago had several manipulative demonstrations to him by what was known in those days as a 'bone-setter', nowadays as an osteopath.

It is the first time as far as we know where an author has stated in print his debt to the osteopath. There is no doubt that many patients are improved and some cured by the manipulations of osteopaths. The busy practitioner can do the same if he will spend a few hours in mastering the manipulations which are very clearly represented in this book. He will be well repaid for the time spent when he sees the rapid response to manipulation of the vague pains around the shoulders, neck and head.

The author re-introduces to the profession the 'scapular hold' and the 'leather strap'. The latter is of great service to the practitioner working alone; the manipulations themselves are also rendered less arduous. Whether the busy practitioner should be recommended to manipulate some of the larger joints is a matter of opinion. Many will no doubt feel very dubious and rightly so.

We recommend this book to the profession.

F. J. A.

AIDS TO OPERATIVE SURGERY.—By C. P. G. Wakeley, D.Sc. (Lond.), F.R.C.S. (Eng.), F.R.S. (Edin.). Second Edition. 1934. Baillière, Tindall and Cox, London. Pp. viii plus 225, with 3 figures. Price, 3s. 6d.

MR. WAKELEY'S *Aids to Operative Surgery* is a handy book on the subject. It consists of eleven chapters and its arrangement has been brought into line with the bigger textbooks. It is remarkable that within such a small compass, so little of importance has been left out. For the student, desirous of rapid review in preparation for examinations, this little book will be of assistance. The inclusion of illustrations has definitely added to its value. An adequate index is appended.

P. N. R.

THE RELIEF OF PAIN IN CHILDBIRTH.—By F. Neon Reynolds, M.C.O.G., F.R.C.S. (Ed.). 1934. Medical Publications Limited, London. Pp. 114. Price, 10s. 6d.

THIS small book gives a clear and detailed account of methods which can be used for the relief of pain in labour. These methods are not confined to the use of drugs alone. Dr. Reynolds points out that careful treatment of the minor disabilities of pregnancy, so often neglected, will greatly increase the patient's chances of a safe and easy delivery. The successful treatment of these will conserve the patient's physical and nervous energy, will tend to allay fear, and will give the patient confidence in the ability of her medical attendant to see her safely through her confinement. The author has found that heartburn which is a very common and distressing complaint can usually be relieved by the use of alkalis, or, when they are not

successful, by the administration of small doses of dilute hydrochloric acid, particularly in the latter months of pregnancy. He suggests that on this question there is a useful field for minor research. Turning to drugs a concise yet full account is given of the more useful ones, including the newer anaesthetics. A note of warning is sounded in regard to the barbiturates, which are dangerous drugs not suitable for routine administration, though they may be of use in individual cases in experienced hands.

Drugs are divided into those suitable for the first stage when the object should be to give sleep between the pains, and those suitable for the second stage when pain should be relieved but when it is also desirable for the patient to return quickly to consciousness between pains. For the first stage a preliminary dose of morphine and hyoscine followed by the rectal injection of paraldehyde in olive oil is recommended for primiparae, while paraldehyde alone will nearly always be sufficient for a multipara. The drug for the second stage is chloroform, or nitrous oxide and oxygen if available. A chapter is given to the vexed question of anaesthetics for midwives' cases. The method of giving paraldehyde would be suitable for administration by midwives. The author also holds that a practically fool-proof apparatus for the administration of chloroform by midwives could be devised, but this has not yet been done.

J. M.

HANDBUCH DER CHEMOTHERAPIE.—By Viktor Fischl and Prof. Dr. Hans Solossberger. Vol. II. Metallerivatives. Publishers: Fischl'sche Medizinische Buchhandlung, Leipzig. 1934. Pp. xi plus 540. Price, 55 Marks

THE review of the first volume of this work appeared in the *Indian Medical Gazette* (Vol. LXVII, p. 593), and it was pointed out that the work was more comprehensive than any other volume that had appeared so far. The present volume is a continuation of the previous one and deals with the metallic compounds used in chemotherapy. The subject is discussed under the following sections: (1) Arsenic; (2) antimony; (3) bismuth; (4) iodine; (5) copper; (6) silver; (7) gold; (8) mercury; (9) rare metals, and (10) other elements. In the case of each element, the history, the chemistry, the use of the metal, the inorganic derivatives, the complex organic salts and the different metallo-organic derivatives, their toxicology, therapeutic results, mode of action, etc., have been described; this is followed by a register of the literature. The second volume also furnishes a complete index for the first and second volumes, besides including the contents of both the volumes. The issue of this volume thus completes the collection of all the useful information on the subject and will be welcomed by all interested in the advances of chemotherapy and also in problems connected with it.

Abstracts from Reports

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1932. VOLUME II

PRINCIPAL DISEASES AFFECTING THE BRITISH ARMY

Dengue, sandfly fever and pyrexia of uncertain origin

MORE than 60 per cent of the cases of dengue come from the garrisons stationed in ports, and of these Calcutta, as usual, supplies the lion's share. There have however been no severe outbreaks, and the admission ratio shows a decline.

Sandfly fever continues to be a source of considerable anxiety. Although the mortality rate is nil, and the stay in hospital which this disease occasions is short, the morbidity rate during the season of incidence is high and the incapacitating effect is serious. The majority of cases occur in the North-West Frontier Province and in Northern Punjab, and, by reducing considerably the number of effectives, adds greatly to the discomforts and worries of the hot weather.

It will be recalled that in 1925 an investigation was made under the auspices of the Indian Research Fund Association into the problem of sandfly breeding at Landi Kotal, a garrison in the Khyber Pass which usually shows a high incidence of sandfly fever. Extensive breeding grounds were discovered in nullahs which intersect the camp, and methods for their destruction were devised. For the first few years thereafter the sandfly fever incidence dropped, and it appeared that something had been achieved. Of late, however, sandflies and cases of sandfly fever have been as numerous as ever, and this in spite of the fact that the breeding grounds in question are still very effectively treated, and are not now the source of the trouble.

Certain observations suggest that infection is not being acquired in the barrack-rooms, but during night duty while manning the trenches guarding the perimeter. If so, this considerably widens the problem.

The question of the habits and bionomics of the sandfly have again been taken up, with the assistance of the Indian Research Fund Association, and further investigations into the location of the breeding grounds

and other practical points of importance are being made, from which it is hoped that good results will accrue.

Fever of the typhus group

The diagnosis of sporadic cases of this condition is becoming much more common, probably due to a more universal recognition of the symptoms of the disease rather than to an increased incidence, as in the past there is little doubt that many cases of this disease were included in the P. U. O. series. In all, 34 cases were reported among all ranks and families, British and Indian, entitled to hospital treatment, with 4 deaths.

The Weil-Felix reaction has been positive in a proportion of cases, but hitherto the technique has not been sufficiently standardized to permit of conclusions being drawn therefrom. Efforts are now being made to carry out in all cases a series of tests with 'O' emulsion of *B. proteus* X2, X19, and Kingsbury. Attempts are also being made to isolate strains of *B. proteus* from these cases in the hope that one giving a specific reaction may be discovered.

The question of aetiology is of interest. While the general picture of the cases corresponds to tick typhus as described by Megaw and others, in the majority of cases it has been impossible to obtain a definite history of tick bite. In many cases, however, there was a relationship between the onset of the disease and recent residence in forest bungalows, camps, etc., which is in keeping with the hypothesis that this is a disease of the wilds, normally occurring in some lower animal which constitutes the reservoir of infection, and conveyed to man by some parasitic arthropod which occasionally selects him as a host. In a few cases there was a suggestive local adenitis. Louse infection can be definitely excluded in the majority of cases. The suggestion of the vector is receiving special attention.

In a small group of five cases which occurred in one cantonment louse infestation was suspected, although not proved. It was not specifically noted that the patients were lousy, but subsequent investigations revealed this condition in certain of their comrades. These cases showed 'no recent movements', and were

of a very severe type, two of the five patients dying (one British and one Indian soldier).

Enteric fevers

British troops.—There is an increase from 1931 of six admissions for typhoid fever and seven for paratyphoid A fever, and a decrease of one for paratyphoid B and seven for enteric group, there being an increase of five for the whole group.

Indian troops.—There is a decrease of twenty-one admissions for typhoid fever, four for paratyphoid A fever, three for paratyphoid C, and twenty-eight for enteric group, while paratyphoid B fever shows an increase of one. This gives a decrease of 55 cases in the group.

Dysentery, diarrhoea and hepatitis

There is a well-marked decrease in the total admissions for these bowel diseases, which would be much more noticeable were it not for the exceptionally high incidence in one station (Quetta).

Carriers

The examination of food handling menials prior to enlistment and at intervals during their first month of service continues. In all, 13,681 menials were examined with a total of 42,705 bacteriological examinations and 32,645 microscopical examinations, resulting (as far as dysentery is concerned) in the discovery of *B. dysenteriae* Flexner in thirty-five of these men, *B. dysenteriae* Shiga in five and *B. dysenteriae* Schmitz in three, while cysts of *E. histolytica* were found in 388 (2.83 per cent).

In view of the fact that no appreciable decrease in the total dysentery and diarrhoea figures has occurred during the five years in which an extensive search for dysentery carriers has been in operation, the question of the value of these examinations has recently been considered and the following facts emerge.

Bacillary dysentery

There is no record of the discovery of a true carrier of bacillary dysentery (i.e., a normal individual who, while suffering from no symptoms, regularly or intermittently excretes dysentery bacilli). In supposed cases which have been carefully investigated, the so-called carrier has proved to be an individual who has had the misfortune to be called up for examination at a time when he was suffering from an attack of dysentery, either primary or, in a chronic case, relapse.

There is no doubt that for every one case found in this way during 'carrier' tests, innumerable others occur at other times of which nothing is known. It is obviously both unjust and illogical to penalize the unfortunate who happens to be discovered when it is well known that there are many others who differ only in that they have not been detected. Further, a sequel of the present system is, that whenever possible the disease is concealed, and the man continues at work during the only period when he is definitely infective.

It is proposed to change this policy, and to direct attention towards encouraging the active case to report sick and be struck off duty until non-infective. Intrac-table chronic or relapsing cases will be discharged.

Amoebic dysentery

The relationship of the *E. histolytica* carrier to the occurrence of frank cases of amoebic dysentery is a question which merits close attention. During the years in which the search for these carriers has been in vogue in India various anomalies have come to light.

In the first place it is well known that, despite the precautions taken, many carriers escape the net and are employed in duties which involves food handling. The percentage of carriers who are detected varies within wide limits from district to district, and in certain cases from year to year, in a way which makes it clear that

in many localities the number of undetected carriers must be much higher than in others. The incidence of amoebic dysentery, on the other hand, pursues a steady course, and in no way reflects the variations which exist in this supposed reservoir of infection.

Again, in one large station careful records have been kept of the incidence, by units, of cases of amoebic dysentery. In no time has the distribution suggested infection from a carrier; on the contrary, it has been roughly proportionate to the numbers at risk.

Another anomalous finding is that the annual number of carriers detected is in excess, and in some stations greatly in excess, of the number of cases of amoebic dysentery. This has its counterpart in the state of affairs in the United Kingdom, where considerable numbers of the population are cyst-passers but where there is no amoebic dysentery.

The only conclusion which can be drawn from these observations is that the carrier is only one of many factors concerned in the spread of amoebic dysentery.

Admittedly the complete protection of an individual from infection with cysts would eliminate amoebic dysentery. Such a measure of protection has been the goal of the system in vogue, but in Indian circumstances has proved impossible of attainment. The half measure of success which has been realized has produced no results, and, on the other hand, has in many cases resulted in grave injustice to the individual and much inconvenience to his employers.

In view of these facts, the conclusion has been reached that the present policy is not a practical proposition: routine investigations for the exclusion of carriers will therefore be abandoned.

An interesting feature of the year is the marked increase in dysentery which took place in Quetta, the ratio being for British troops 64.3 as opposed to 22.9 in 1931 and an average of 19.5 for the three years 1929 to 1931. This increase occurred in the amoebic as well as in the bacillary type, but was relatively more marked in the former.

The outbreak was more or less equally distributed among all units and also amongst families. Bacillary dysentery reached its peak in June and July; a wave of amoebic dysentery occurred four to five weeks after the July rains, and another a similar period after some heavy spates which occurred in August.

The cause of this outbreak was the subject of much investigation. The year was an unduly dry and dusty one in its early months, and the possibility of the outbreak being associated with irritation from dust was carefully considered but the findings were inconclusive.

There was no notable increase in the number of flies. This observation is interesting when compared with the state of affairs in Poona, a station which has normally a relatively high dysentery ratio, and which this year showed therein a marked reduction accompanied by a corresponding freedom from flies.

Tropical abscess of liver and hepatitis

In all 112 admissions were made for the above condition.

A scrutiny of the case cards shows that of these 69 were probably amoebic in origin. In this figure are included one case which relapsed once and another which relapsed twice.

The difference between amoebic abscess and amoebic hepatitis is one of degree only. Of the above cases, 16 were sufficiently advanced to be called amoebic abscesses, and of these three died. The majority of cases responded readily to emetine treatment.

Cysts of *E. histolytica* were discovered in the faeces of only four of these cases. (This statement is difficult to understand.—Editor.)

Malaria

The incidence for the years 1931 and 1932 are shown in the table.

TABLE
Malaria ratio per 1,000—British

Year	Fresh	Relapse	TOTAL
1931	64.8	47.7	112.5
1932	49.2	34.9	84.1

From these figures it will be seen that malaria maintains its pride of place as the scourge of the army in India. In 1932 admissions for this disease formed 14.5 per cent of the admissions for all forms of injury and disease; and this percentage only represents hospitalization; it neither includes out-patient attendance, nor indicates the degree to which the disease adversely affects general physical efficiency.

It is, therefore, impossible to regard these figures with equanimity; but although, in an absolute sense, they are profoundly disturbing, in a relative sense they are not without a certain amount of comfort and encouragement, since the situation seems to maintain the steady, if somewhat slow, improvement which has been a feature of recent years. This is especially evident in the case of the Northern Command, in which malaria plays more havoc amongst the troops than in any other area in India. In this command, a steady decline is shown in the admission rates (per 1,000) during the past eight years from 291.00 in 1925 to 91.15.

During the past ten years the all-India figures have varied much, from those of 1924—the worst year—to those of 1932, the best.

Prophylactic quinine

As regards the prophylactic value of quinine, the usual conflict of opinion is found in the annual reports of districts and commands. On the whole, army medical opinion of to-day is not enthusiastic. Peshawar District experienced an unusually low malarial incidence, and the health officer there made the following remarks on the subject:—

'This measure of malaria prevention or, rather, early cure was practised throughout the district in all plains stations as regards both British and Indian troops from August to November. The dose given was ten grains of quinine sulphate daily with a small dose of magnesium sulphate with the exception of Sundays when nothing was given.

A considerable amount of work has been carried out in previous years in the Peshawar District, particularly by Major T. Young, R.A.M.C., in connection with quinine prophylaxis, and, apart from his findings which indicated definitely a lower incidence of malaria in troops given prophylactic quinine than in others, a large body of expert opinion is in favour of the measures.

It is thought that until some more satisfactory means of protection of troops is found, quinine prophylaxis must continue to be adopted in special circumstances such as years likely to produce an epidemic or very high incidence of malaria and in special conditions such as on field service, when mosquito nets cannot be used, and practically no other method of prevention is available'.

However, these opinions would not be accepted in their entirety by every military medical officer in India. The more usual experience is reported from another district in which a heavy malarial incidence occurred, thus:—

'Prophylactic quinine was issued in the three biggest stations in the district. No apparent benefit followed. In one station certain units were kept as controls, but in these the malarial incidence was no higher than in the protected (*sic*) units.

Atebrin was introduced into army practice too late in the malaria season of 1932 to permit of definite

conclusions being reached regarding its comparative value. Reports on which to base such conclusions will not be available until the middle of 1933. In the meantime preliminary reports indicate that the clinicians are impressed with the efficacy of this drug. It is generally held to be as powerful in action as quinine; but most observers report that it is slower in getting to work. They prefer to start a course of atebriplasmaquine treatment with a preliminary administration of quinine for the first two days—although this is not in accordance with the latest report on the subject'.

Again there has to be recorded a marked decline in the numbers admitted to the Malaria Treatment Centre, with a consequent shortage of clinical material. Undoubtedly this reflects the more efficient methods of treatment in vogue in the hospitals outside.

Experimental trials of an outfit designed for the field diagnosis of malaria and dysentery are now nearing a successful conclusion.

There is no doubt that the appearance of plasmaquine and atebriin has re-awakened interest in the whole subject of malaria in the army in India; and credit is due to all the clinicians and epidemiologists who have been working on the problem throughout the year: they have risen to the occasion.

Effects of heat

Recently there has been a revival of interest amongst medical officers in the interesting conditions which are included under this heading. Fresh observations and methods of treatment are in train, the results of which may be published later.

Ophthalmology.—The enlistment of recruits suffering from mild trachoma continues to give successful results. The opinions of recruiting medical officers are in conformity with that of a distinguished ophthalmologist in civil practice, who writes:—

'I can speak from 33 years' Indian experience and I am quite convinced that there are many mild cases of trachoma which are not only amenable to treatment, but which will eventually clear up without treatment. One sees hundreds of these cases each year.

Regarding the contention that these are not cases of trachoma at all, but forms of chronic conjunctivitis, it is not possible to be dogmatic—for only experience can enable one to diagnose between early cases of trachoma, angular conjunctivitis and follicular conjunctivitis.

But in my opinion it is perfectly safe to accept recruits with mild trachoma; in fact, in some parts of India, especially in Sind, there are few eyes that do not show some signs of trachoma and yet give rise to no symptoms at all; and these signs are only found in apparently healthy eyes on evertng the upper lids. If all recruits are rejected because they have some signs of mild trachoma, the field for recruiting will be enormously curtailed. Furthermore, in mild cases of trachoma at the age at which recruits are taken, the risk of infection is so small, as to be almost negligible'.

BENGAL PUBLIC HEALTH REPORT BY DR. R. B. KHAMBATA, D.P.H., DIRECTOR OF PUBLIC HEALTH, BENGAL. REPORTS OF THE BENGAL SANITARY BOARD AND THE CHIEF ENGINEER, PUBLIC HEALTH DEPARTMENT, FOR THE YEAR 1931

THE report for the year 1931 of the Public Health Department which has just come to hand contains an immense amount of data covering a wide field in public health matters. It is impossible in a small space to do more than touch on some of the more important topics of direct medical interest.

Population.—According to the census of 1931 the population of the Bengal Presidency, excluding the Bengal States and the Chittagong Hill Tracts, is 49,901,030, which is 3,378,787 in excess of the population enumerated in the preceding census of 1921. The

natural increase of the population during the decade was, therefore, approximately 337,878 per annum.

The largest increase was recorded in the Chittagong Division (excluding the Hill Tracts) and the smallest in the Rajshahi Division. Six districts, showing the largest percentage increase of population during the decade, are Noakhali (+15.9), Tippera (+13.3), Darjeeling (+13.0), Bakarganj (+12.9), Murshidabad (+12.0), and Chittagong (+11.5). Of these, three districts belong to the Chittagong Division. Only two districts, namely Jessore (-3.0) and Rajshahi (-4.6), recorded decrease of population during the decade.

Provincial births and birth rates.—Excluding still-births, the number of children born during the year 1931 was 722,091 males and 666,125 females or a total of 1,388,219 against 613,885, 591,046 and 1,237,931, respectively, in 1930. The birth rate is 27.8 per mille of population in 1931, against 26.6 per mille in 1930. Thus during 1931 the birth rate shows an increase of 1.2 per mille of population as compared with the corresponding figures for 1930. The birth rate is 26.2 per mille in the previous quinquennium, the birth rate for 1931 being 27.8 per mille. There is an increase of 1.6 per mille of births in 1931 as compared with that of the previous quinquennium. The number of males born to every 100 females in 1931 was 108 and in 1930 the corresponding figure was also 108.

Provincial deaths and death rates.—During the year 1931, 1,113,312 deaths were registered in the province, representing a death rate of 22.3 per mille from all causes. The corresponding figure for the year 1930 is 1,044,256 or 22.4 per mille and 22.7 during the previous quinquennium. The death rate was still further reduced by 0.5 per cent as compared with 1930. It was reduced by 1.8 per cent when compared with the quinquennial figure. It was thus lowest on record since 1900. Five hundred and seventy two thousand, eight hundred males and 540,512 females died during the year 1931, while 539,260 males and 504,996 females died during the year 1930. One hundred and five males died to every 100 females. The death rate from various causes is shown below:—

six months and 16.0 per cent at the age period of between six and twelve months.

Cholera

Cholera accounted for 79,073 deaths, giving a death rate of 1.6 per mille in 1931 against 54,963 deaths and a rate of 1.2 per mille in 1930, thus showing an increase of 33.3 per cent. It was 11.1 per cent less than the average of the previous quinquennium (1.8). 7.1 per cent of the total deaths in the province in 1931 were due to cholera. Deaths from cholera were reported from 605 out of 654 circles of registration and from 14,952 out of 86,360 villages in the province against 617 out of the 654 circles and 13,183 out of the 84,748 villages, respectively, in the previous year.

Smallpox

General prevalence.—Smallpox claimed 9,207 victims in the province in 1931 against 11,268 in 1930. The death rate was 0.2 per mille in 1931 being the same as in 1930, and 0.6 the mean of the previous five years, showing a reduction of 66.7 per cent against the latter, being stationary in the former. Smallpox was responsible for 0.8 per cent of the total provincial mortality against 1.1 per cent in 1930. Two thousand, three hundred and thirty-two villages out of 86,360 were affected with smallpox in 1931 compared with 4,565 in 1930.

Plague

Only one death from plague was reported from Calcutta in 1931.

Fevers

General prevalence.—Deaths from fevers in 1931 amounted to 731,784 against 705,066 in 1930. The death rates were 14.7 for 1931, 15.1 for 1930 and 15.2 during the last quinquennium. The death rate in the year under review was thus reduced by 2.7 per cent compared with the previous year and by 3.3 per cent compared with the quinquennial average. There were slight increases under the following sub-heads (a) enteric fever and (b) relapsing fever. On the other

Causes of deaths

Years	Cholera	Smallpox	Fevers	Dysentery and diarrhoea	Respiratory diseases	Injuries	All other causes	All causes
1931	1.6	0.2	14.7	0.9	1.2	0.4	3.3	22.3
1930	1.2	0.2	15.1	0.8	1.2	0.4	3.4	22.4
Percentage of difference	+ 33.3	±	- 2.7	+ 12.5	±	±	- 3.0	- 0.5

Thus there is an increase in cholera, dysentery and diarrhoea, while there is a diminution in fevers and all other causes. Smallpox, respiratory diseases and injuries remain stationary.

Mortality according to age.—The death rate for every age period was reduced in 1931 compared with that during the previous year except in the case of the periods between (1) 5 to 20 and (2) 40 years and above. In the age period 60 years and above the increase is by 22.9 per cent. In the age period 5 to 10 years the increase amounts to 25.8 per cent.

Provincial infant mortality.—241,552 infants under one year, of whom 129,740 were males and 111,812 females, died in 1931. During 1930, 231,872 infants under one year died, of these 124,212 were males and 107,660 females. The death rates for the two years were 174.0 and 187.3 per 1,000 births, respectively. 21.7 per cent of the total deaths occurred among infants below one year. 57.3 per cent of the total infant mortality was recorded among infants under one month, 26.7 per cent among those between one and

hand there was a decrease under the following sub-heads (a) malaria fever, (b) kala-azar and (c) other fevers. The death rate from measles remained the same as in the previous year. Fevers accounted for 65.7 per cent of the total provincial mortality against 67.5 per cent in the previous year.

Dysentery and diarrhoea

General prevalence.—The total number of deaths reported from dysentery and diarrhoea was 42,764 with a death rate of 0.86 in 1931 against 39,367 and 0.84 in 1930. The death rate was thus increased by 2.4 per cent against 1930 and by 22.8 per cent against the previous quinquennial average (0.7). Twenty-two thousand, five hundred and fifty-four males and 20,210 females died from this cause. Taking these two diseases separately, 24,014 deaths were due to dysentery and 18,750 to diarrhoea, against 22,252 and 17,115, respectively, in 1930, the corresponding ratios being 0.5 and 0.4 in 1931 against the same in 1930. Dysentery and

Analysis of fever deaths in 1930 and 1931

Causes	NUMBER		DEATH RATES PER MILLE		Percentage of increase + or decrease — in 1931	PERCENTAGE OF TOTAL FEVER MORTALITY	
	1930	1931	1930	1931		1930	1931
Malaria fever ..	336,879	349,111	7.2	7.0	— 2.8	47.8	47.7
Enteric fever ..	11,144	12,608	0.24	0.25	+ 4.2	1.6	1.7
Relapsing fever ..	4,767	5,705	0.10	0.11	+ 10.0	0.7	0.8
Measles	2,963	2,954	0.06	0.06	± 0	0.4	0.4
Kala-azar	10,914	10,199	0.23	0.20	— 13.0	1.5	1.4
Other fevers	338,399	351,207	7.3	7.0	— 4.1	48.0	48.0

diarrhoea accounted for 3.84 per cent of total deaths against 3.77 in 1930.

Respiratory diseases

General prevalence.—Respiratory diseases claimed 62,351 victims in 1931 yielding a death rate of 1.24 per mille against 56,082 and 1.20 per mille, respectively, in 1930 showing an increase of 3.3 per cent. The death

question of birth control. The increase in population and child death rate are in all probability no unconnected. (3) The death rate from cholera as compared to 1930 has increased from 1.2 per mille to 1. per mille, i.e., a 33.3 per cent increase.

The value of vital statistics does not lie in the possession of interesting records of past events, but as a guide to future action.

Diseases	NUMBER		DEATH RATES PER MILLE		Percentage of increase + or decrease —	PERCENTAGE OF TOTAL DEATHS FROM RESPIRATORY DISEASES	
	1930	1931	1930	1931		1930	1931
Influenza	3,171	4,714	0.07	0.09	+ 28.6	5.65	7.56
Pneumonia	25,784	27,599	0.55	0.55	± 0	45.98	44.26
Phthisis	11,576	12,238	0.24	0.24	± 0	20.64	19.62
Other respiratory diseases	15,551	17,800	0.33	0.35	+ 6.0	27.73	28.55

rate was higher by 37.8 per cent than the provincial quinquennial average (0.9). The death rate from pneumonia and phthisis remained the same, while other sub-heads showed increases when compared with 1930. 5.60 per cent of total deaths were due to respiratory diseases against 5.37 in 1930.

Part I of the report deals further with the progress made by maternity and child-welfare centres, school hygiene, inspection of school children and vaccination centres. Part II of the report, written by the chief engineer of the public health department, comprises details of expenditure on, and improvement of, water supplies and sewage disposal, etc.

From a general survey of the vital statistics in the report we should like to draw attention to three salient points: (1) The increase in population in Bengal, more marked in some districts than others. The increase is of course not confined to this Presidency alone. (2) The death rate for each life period compared to 1930 is reduced except for those between 5 and 20 and above 40 years of age respectively where an increase is recorded. This increase in the death rate of children and adolescents should impress on all the necessity of child-welfare schemes and, taken along with the increase of population mentioned above, the desirability of the community taking some definite standpoint on the

SEVENTY-FIRST ANNUAL REPORT OF THE GOVERNMENT CINCHONA PLANTATIONS AND FACTORY IN BENGAL FOR THE YEAR 1932-33

General.—The outstanding feature of the year in the quinine market was the sudden drop in price of the commodity from about Rs. 26 to Rs. 19-8 per pound. The fall occurred at a time when currencies were shaken, just before America went off the gold standard, and, while quinine is still linked to gold in the sense that its price fluctuates from day to day with the cost of the precious metal, there is a discernible tendency on the part of those in power in the quinine world to show a more accommodating spirit towards markets where currency has become alienated from gold. The break, coming as it does after years of steadiness, must be all the more welcome to those countries and governments which rely on quinine for the maintenance of a standard of health among their peoples. Looking back it is surprising that the fall did not occur earlier, for quinine has held an almost unique position in a world of falling prices. It may be taken as a mark of confidence in the future of the drug that, with prices of other commodities falling all round, it has maintained its level so long. And this too while the gulf between

New anti-rabic centres were opened at Goalpara, Sibsagar, Golaghat and Hailakandi hospitals. Some private centres for treatment of anti-rabic cases were also started at Lumding (Assam-Bengal Railway) and Dhamai and Mahina tea estates under the supervision of the medical officers at these places.

Yaws.—The campaign against yaws was continued during the year. Two hundred and sixty cases were treated in civil hospitals and dispensaries, against 300 in 1932, while 1,215 cases were treated by the public health staff in charge of dispensaries under that department.

Goitre.—The great prevalence of goitre in the villages situated on the banks of the Dihin river in the Sib-sagar district was brought to notice during the year, and action was taken to institute a survey of the villages situated on the banks of this river. According to McCarrison, the prevalence of goitre along a river is an indication of heavy sewage pollution; and the object of the survey is to ascertain how far up the river the goitre incidence extends, to enable us to say what can be done. Up to date 37 villages have been examined and 938 cases of goitre detected.

The Pasteur Institute and the Assam Medical Research Society.—Government continued to give a grant of Rs. 25,000 to the Assam Medical Research Society. The activities of the society were chiefly confined to malaria, cholera and dysentery. The work on anaemia of pregnancy and pneumonia had to be discontinued for want of funds.

Malaria surveys were carried out in 28 different areas in the province, 19 of which the malaria officer was able to visit in the year. The staff employed by the Research Society on Malaria numbered 51. The expenses were met by contributions from the Assam Government, the Indian Research Fund Association, the Indian Tea Association, the Assam Oil Company, the Assam-Bengal Railway, 5 Municipalities, 4 Local Boards and 3 Town Committees who asked for assistance.

Field experiments on the value of plasmoquine in reducing malaria were carried out. The results of these experiments are still indecisive, and more experimental field work is required to assess the true therapeutic value of this drug. In the plains of Assam where often the vector mosquito incidence is high and their infectivity rate also high, treatment with plasmoquine to reduce gametocyte carriers is of doubtful value owing to constant reinfection. In one area, however, where the mosquito incidence has been reduced, plasmoquine appears to have been of value in reducing the numbers of gametocyte carrier children.

Bacteriophage continued to be used for the treatment and prevention of cholera. Nowgong district, where bacteriophage is systematically distributed to the headmen of villages, had a mortality of 0.036 per 1,000. This is the fourth year in succession in which this district has had no outbreak of cholera. The previous longest period of freedom from cholera since 1906 is 1 year and 9 months in 1920-21.

As mentioned in last year's report a second experiment was undertaken in Habiganj subdivision. By July 1933 bacteriophage had been distributed to every village in Habiganj. The northern half of Habiganj forms part of the delta of the Barak river; the rest of the delta being formed by Sunamganj, North Sylhet and Karimganj. In September cholera broke out in Cachar on the banks of the upper reaches of this river. The infection swept down the valley into the delta. Karimganj had 923 cases with 381 deaths, North Sylhet 955 cases with 493 deaths and Sunamganj 2,586 cases and 1,361 deaths. Habiganj had only 106 cases and 45 deaths. These figures contrast graphically with an exactly similar epidemic in 1927 when Sunamganj had 1,443 deaths and Habiganj 1,500.

Technical researches in the laboratory clearly show that the changes brought about on the cholera vibrio

by bacteriophage go far to explain the results obtained in the prevention and treatment of cholera in the field.

TRIENNIAL REPORT ON THE WORKING OF HOSPITALS AND DISPENSARIES UNDER THE GOVERNMENT OF BENGAL FOR THE YEARS 1929, 1930 AND 1931. BY MAJOR-GENERAL W. V. COPPINGER, C.I.E., D.S.O., M.D., I.M.S., SURGEON-GENERAL WITH THE GOVERNMENT OF BENGAL

Medical education.—This has progressed during this period, teaching up to university standards being given at the Medical College, Calcutta, and Carmichael Medical College, Belgaehia, and the following numbers graduated in medicine in the triennium:—

	Men	Women
1928-29	233	3
1929-30	193	1
1930-31	161	2

the corresponding figures for the membership of the State Medical Faculty being 1928-29 6 men, 1929-30 11 men, and 1930-31 8 men, no woman taking this qualification.

This diminution in numbers was probably partly due to the increasing difficulty of the course and also to economic conditions.

The similar figures for the State Medical Faculty licence are as follows:—

	Men	Women
1928-29	309	5
1929-30	306	2
1930-31	411	2

and the membership figures follow these closely.

The diplomas in Tropical Medicine and in Public Health continue popular.

An important change has been the introduction of inspection of the schools and examinations of the State Medical Faculty by a committee of the Bengal Council of Medical Registration. This has led to an improvement in the teaching of the schools and the methods of examination and should tend to equalize standards all round by improving those in the weaker schools. The principle has been recognized by the Calcutta University, but is not carried into effect.

A marked feature of the triennium has been a falling off of the number of qualified candidates entering the Medical Colleges. This is due probably to the prevailing economic distress, the lengthening and greater cost of the medical course and its recognition by parents and the diminishing emoluments of those who qualify, and this applies to a good deal of India. There has been a good deal of agitation throughout India and especially in Bengal for the raising and stiffening up of the licentiate course and standards towards that of the university so as to maintain a single register for licentiates, members and graduates. This is generally recognized as very desirable, but the cost both to parents and schools of the extra time and money required renders this change practically impossible in these times of financial stringency, as it has been found that the introduction of even small changes in the teaching of chemistry for the licentiate students has been impossible to give effect to, on account of the expense involved in the improved practical work.

Much, however, has been done to improve the facilities for post-graduate study. In addition to the teaching provided at the School of Tropical Medicine both in Public Health and Tropical Diseases, post-graduate facilities are now available at the Medical College Hospitals for work in almost every branch of medicine by the introduction of a system of Clinical Assistants and House Officers.

School of Tropical Medicine and Hygiene, Calcutta.—The high reputation of this school as a research and

also as a teaching institution was maintained throughout the triennium. The institution attracted a larger number of candidates from the different parts of the country, viz, 321 against 254, during the previous triennium. The candidates trained during the period under report were as follows:—

1928-29	102
1929-30	112
1930-31	107

The number of students who passed out of the school during the last three years is also shown below:—

	1928-29	1929-30	1930-31
D. T. M.	.. 34	30	30
D. P. H.	.. 12	14	17
L. T. M.	.. 24	39	35
TOTAL	.. 70	83	82

Diseases—Cholera.—The disease prevailed in the town in a mild form throughout the triennium, there having been 3,735, 2,772 and 2,427 attendances with 801, 489 and 464 deaths in 1929, 1930 and 1931, respectively, in comparison with 2,208, 3,269 and 3,855 cases with 480, 717 and 860 deaths in 1926, 1927 and 1928, respectively. These show a steady decrease in the incidence of cholera cases in the Calcutta hospitals. As usual, the Campbell Hospital, which has the greatest amount of accommodation for cholera cases, maintained its high reputation for treatment and recorded the largest number of attendance of patients, viz, an average of 1,765 as compared with 3,110 patients in the preceding triennium.

Kala-azar.—Formerly kala-azar cases were difficult of diagnosis, but with the advent of improved methods of investigation and the modern method of treatment the disease is now under control. The newer antimony preparations for kala-azar appear definitely to have a greater value in curing of the disease than the older. It is very satisfactory to note that the disease is steadily decreasing year by year. In the Calcutta hospitals 10,640 patients were treated in 1929, 6,922 in 1930 and 6,322 in 1931, total 23,884, as compared with 35,443 patients in the previous triennium. The Medical College group of hospitals afforded treatment to the largest number of patients, viz, 3,840 in 1929, and 1,931 in 1930, while the Campbell Hospital showed the largest in 1931, viz, 1,364. The Carmichael Medical College Hospital, Belgachia, treated only 1,086 cases in 1929, 401 in 1930 and 208 in 1931.

Malaria.—The total number of malaria cases during the triennium was 167,500 against 162,078 in the preceding triennium, an increase of 5,422. Most of the patients were dealt with in the Medical College Hospitals in 1929, while Taltola Municipal dispensary treated the largest number in 1930 and Sree Vishudhanda Saraswati Marwari Hospital in 1931. The total number of deaths was 250 against 244 in the previous triennium.

Plague.—The town of Calcutta was practically free from plague, only two cases occurred during the triennium, viz, one case was recorded as out-patient in the Ultadanga Municipal dispensary in 1929 and another in the Lady Dufferin Victoria Hospital in 1930. The Howrah General Hospital also treated two cases of plague during the year 1931.

Smallpox.—This disease may be said to have prevailed in a rather milder form during the triennium under report as compared with the previous triennium. In 1929 altogether 269 patients were treated with 41 deaths in the Calcutta hospitals. In 1930, 616 cases with 203 deaths and in 1931, 501 with 140 deaths, a total of 1,386 cases as compared with 2,496 in the preceding triennium.

The Campbell Hospital is the only smallpox hospital in Calcutta where in-door patients are treated and has

got separate and adequate accommodation for the treatment of such patients. It has treated the largest number during the triennium, viz, 188 in 1929, 514 in 1930 and 404 in 1931. Most of the persons suffering from this disease do not come to hospital for treatment but prefer to remain at their homes and get themselves treated by private practitioners.

Influenza.—The number of influenza cases steadily increased during the triennium. In 1929, 1930 and 1931, 18,321, 20,263 and 25,733 patients, respectively, were treated as compared with 10,207, 15,069 and 15,683 in 1926, 1927 and 1928, respectively. Deaths from this disease were comparatively small in number, viz, a total of 181 as compared with a total of 366 in the previous triennium.

Tuberculosis of the lungs.—The total number of patients treated in the Calcutta hospitals from this disease was 6,062 in 1929, 7,318 in 1930 and 8,525 in 1931, or a total of 21,905 as compared with 4,117, 6,358 and 6,200, or a total of 16,675 in the previous triennium. The figures show that there was an increase of 5,230 patients in the triennium under report.

Veneral diseases.—The total number of patients treated for all sorts of venereal diseases was 82,260 in the triennium under review; of this 59,866 were males and 22,394 females against a total number of 75,615 patients (51,965 males and 23,650 females) in the preceding triennium. Of the total number 33,514 patients (24,633 males and 8,881 females) were treated for gonococcal infection, 33,486 patients (24,268 males and 9,218 females) for syphilis and 15,260 (10,965 males and 4,295 females) for other diseases of venereal origin.

Epidemic dropsy.—The prevalence of this disease was markedly increased in 1929 and 2,788 cases were treated in the Calcutta hospitals during the year alone against 1,055 in 1928. Most of the cases are associated with the use of badly stored rice and other adulterated articles of food. In 1930 the disease was somewhat of a milder type and 1,454 cases were admitted in the hospitals. The number in 1931 again rose to 1,854.

In the in-door department a total of 276 cases was treated in the triennium. The incidence of death was, however, not much, it being only 29 against 217 in the preceding triennium.

Diphtheria.—A separate arrangement for the treatment of diphtheria cases exists only in the Medical College Hospitals. A small block is situated on the roof of the main building of the Medical College Hospitals where accommodation for 10 beds exists, viz, 8 for children and 2 for adult females. There is a small operation theatre for the relief of urgent dyspnoea. Scrum is always kept in sufficient quantity in the ward, in an ice chamber owing to the effect of excessive heat of tropical climate. The total number of cases treated was 190 in 1929, 223 in 1930 and 213 in 1931. The total number of tracheotomy operations performed was 76 in 1929, 68 in 1930 and 100 in 1931. Out of 213 cases in 1931, 73 died, i.e., a mortality of 34.2 per cent, which is higher than the mortality rate of the two previous years, viz, 23.3 per cent in 1930 and 26.3 per cent in 1929. The high mortality in the year 1931 was due to the fact that a large number of cases were brought very late with urgent dyspnoea and on no less than 100 cases tracheotomy had to be performed. The death rate in tracheotomy cases is always higher than that of the cases treated without this.

Hospitals for the treatment of leprosy.—There are only three asylums for the treatment of lepers in Bengal, viz, (1) the Albert Victor Hospital for the Treatment of Leprosy, Gobra, Calcutta, (2) Raniganj Leper Hospital in the Burdwan district and (3) the Bankura Leper Hospital.

The first is maintained by Government and the latter two are under the management of the Mission to Lepers, maintained by their funds and subscriptions with Government aid.

The number of beds and of patients treated in the three hospitals during the triennium under report is separately shown in the table below:—

	1929		1930		1931	
	Number of beds	In-door patients	Number of beds	In-door patients	Number of beds	In-door patients
Gobra ..	181	359	181	400	181	382
Raniganj ..	182	239	174	195	174	193
Bankura ..	226	239	226	240	226	243
TOTAL ..	589	837	581	835	581	818

Malaria.—As in the previous triennium this disease accounted for the largest number of patients treated, viz, 7,196,318 as compared with 6,167,877 during the previous triennium—an increase of 1,028,441. The figures for the individual years are 2,227,502 in 1929, 2,271,740 in 1930 and 2,697,076 in 1931. The incidence of death was 863 among the in-patients against 866 in the previous triennium.

Kala-azar.—The total number of patients treated for this disease was 179,202 as compared with a total of 246,981 during the previous triennium—a decrease of 67,779. The figures for each individual year were 64,066 in 1929, 55,053 in 1930 and 60,083 in 1931. There was a total of 696 deaths among the in-patients treated for this disease.

Cholera.—The outbreak of cholera in the triennium under report seems to be of a mild character. The total number of patients treated for this disease was 31,252 against 47,972 in the previous triennium. The mortality amongst the in-patients was also lower, viz, 1,156 against a total of 1,538 in the triennium ending 1928.

Smallpox.—As compared with the previous years smallpox appears to have been less prevalent. There was a total of 2,137 cases against 4,291 in the previous triennium. There were altogether 113 deaths from this disease during the triennium under report.

Influenza.—The total number of patients treated for this disease was 390,313 as compared with a total of 256,551 during the previous triennium—an increase of 133,762. In 1929, 93,780 patients were treated and the number increased rapidly to 119,780 in 1930 and to 176,753 in 1931. The type of the disease, however, does not appear to be severe as the death rate was very small, viz, a total of 180 during the triennium under report.

Epidemic dropsy.—There had been a steady decline in admission and attendances for this disease in the mofussil hospitals and dispensaries, the numbers being 6,101, 3,469 and 1,349 for 1929, 1930 and 1931, respectively.

Tuberculosis of the lungs.—The total number of patients treated for this disease during the triennium under report was 34,233 as compared with 28,428 during the previous triennium. The figures for the individual years indicate a gradual annual increase in attendance and admission for this disease, and this has been the condition for the last several years. The prevalence of this disease is thus very apparent.

Mention may here be made of the Tuberculosis Hospital at Jadabpur in the 24-Parganas district under the auspices of the Calcutta Medical Aid and Research Society. The institution made improvements in its buildings, equipment and in its working during this triennium. At the end of the period under report there were 45 beds, viz, 33 for males and 12 for

females, for the accommodation of tuberculous patients and in all there were 27 patients treated in 1929, the same number in 1930 and 114 patients in 1931. Excluding the opening balance, the total receipts of the institution was Rs. 2,22,853 during the triennium, of which Government contributed Rs. 1,00,000 in 1929 and the Calcutta Corporation Rs. 55,000 in 1931. The expenditure during the triennial period was Rs. 2,15,817.

Veneral diseases.—The total number of patients treated for venereal diseases was 218,363 as compared with 235,288 during the previous triennium. Of gonococcal infections, the total was 112,594 against 119,607, and the number of patients treated for syphilis was 73,499 against 79,906 during the previous triennium. Other diseases of venereal origin accounted for 32,270 cases as compared with 35,775 during the previous triennium. The number of deaths occurring among the in-patients treated for these diseases was 130 against 120 during the three years 1926-28.

Leprosy.—Apart from cases treated in the special hospitals for the treatment of this disease, the total number of patients treated in the mofussil hospitals and dispensaries was 8,907 as compared with 6,831 during the previous triennium. The figures for individual years were 2,815 in 1929, 2,867 in 1930 and 3,225 in 1931.

General remarks.—This has been a period of much difficulty in this as in other departments, the continuance of the period of financial stringency, with the extensive changes in organization necessitated by the approaching changes in methods of Government, and the economic and political disturbances of this period, have rendered work exceptionally difficult. There has been nearly a breakdown in our nursing services in the larger hospitals in connection with the shortage of the usual contributions for their upkeep, and the officers in charge of the larger hospitals have had great difficulty in arranging for adequate dieting and ordinary consumable medical and surgical supplies during the period and have managed to curtail expenditure under these heads without seriously interfering with the comfort and treatment of the patients in their charge, though this has involved a great deal of extra labour. Buying supplies of all kinds on a large scale and locally has been extensively introduced and with good effect, but the indents for new equipment, especially for surgery, have had to be reduced. The new wing of the Eden Hospital, though ready for occupation, could not be opened up to date on account of the extra expenditure involved and the partial and temporary closure of beds in certain hospitals had to be seriously considered. The system of charging fees for patients who could afford to pay has been considered, and steps are being gradually taken to introduce this system where possible. It is already in existence in some of our hospitals, notably the Presidency General Hospital for most of its beds, and the District Board of Nadia has introduced this system in the dispensaries under it with considerable success. The records and figures in the early part of this report will show the great increase in popularity of our hospitals and the increased attendance, and I have no doubt that the next triennium will show a larger increase owing to improvements now in progress in our out-door departments, especially in Calcutta.

There has been a great increase in demand for electrical and x-ray treatment during this triennium partly due to new methods and partly due to the provision of more facilities and the popular appreciation of their utility. This and some of the newer methods of treatment, especially the more extensive use of sera and vitamin preparations, have proved very expensive and have thrown a heavy load on our financial resources.

Two new medical schools have been opened during this period and will, I hope, prove a success. Much interest is being taken in them locally and efforts are being made to improve the hospitals on which they are based. The inspecting committee of the State Medical Faculty has been a great help to me in matters connected with the medical schools by their advice and helpful criticism.

Correspondence

ATROPINE IN STRANGULATED HERNIA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—The following case may interest some of your readers.

H. B., a Mohammedan male, aged about 60 years, was brought to this hospital with a strangulated inguinal hernia of the left side at 7-30 p.m. on the 10th June, 1934. The duration of this condition was about five hours; the patient was in severe pain; his temperature was normal and pulse 68 per minute; he was constipated. The serotal swelling was irreducible, hard, tense and tender with no impulse on coughing; it was of elongated shape, measuring ten inches by six inches. The patient had been suffering from chronic bronchitis.

Ice was applied to the swelling and atropine sulphate, 1/50th of a grain, was injected subcutaneously; within forty minutes the hernia slipped in on slight manipulation with immediate relief to the patient.

Yours, etc.,

H. L. MUKERJEE,
Resident Sub-Assistant Surgeon.

E. B. RAILWAY HOSPITAL,
LALMONIRHAT,
18th June, 1934.

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I shall be very glad if you will kindly publish the following few lines in your esteemed journal:—

P. C. D., a Hindu male, aged 55 years, while passing along the street in front of the Astanga Aurved Hospital, suddenly felt severe pain in the right inguinal region. He was brought into this hospital for treatment. On examination, I found the patient suffering from strangulated right inguinal hernia. The swelling in the serotum was very tense and did not yield to taxis. The patient was in extreme distress and perspiring profusely. The patient was questioned closely, but he never admitted of having ever suffered from hernia.

I remembered having read in the *Indian Medical Gazette* that atropine had been used with good results on two similar cases. I injected atropine 1/100th of a grain and applied ice over the part.

Within twenty-five minutes' time, without any sort of manipulation on my part externally, the whole of the descended gut returned to the abdominal cavity, and the patient was thus relieved promptly.

I am grateful to Dr. D. P. Ghosh, B.A., M.B., for permission to publish the notes of this case.

Yours, etc.,

AMAL CHANDRA DEY, I.M.F. (Cal.),
Senior Assistant Medical Officer
and Pathologist.

ASTANGA AURVED
MEDICAL COLLEGE HOSPITAL,
CALCUTTA,
21st July, 1934.

THE MICA MYTH IN DARJEELING WATER

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—There is an impression amongst the visitors to Darjeeling that the water supplies contain mica, and it is sometimes suggested that mica in the drinking water causes irritation of the intestinal mucosa, with resultant diarrhoea. The water supply of Darjeeling is obtained from a number of perennial springs on the western slope of the Senchal range. The springs connect with a closed concrete conduit and deliver into

a reservoir known as 'Senchal Lake'. A glance at a geological map of the Darjeeling Hill Territory shows that the western portion of the Darjeeling District, including the Senchal range, is constituted by gneiss. 'The gneiss of the Darjeeling District is of the foliated type, apparently a true gneiss composed of translucent colourless quartz, opaque white felspar and dark brown and silvery mica, varying in texture from fine-grained to moderately coarse. The gneiss frequently passes into mica-schist or feldspathic mica-schist, bands of quartzite are rare, while hornblendic rocks are extremely uncommon'. It may be noted that quartz is pure silica. Felspar consists of the silicates of aluminium with either sodium, potassium or calcium and rarely barium. The micas are silicates, and in most cases orthosilicates, of aluminium with potassium and hydrogen, also often magnesium, iron, sodium and lithium, and they have the characteristic micaceous structure; muscovite, the most common of the micas, is an essential constituent of mica-schist and related rocks and is a prominent component of certain common varieties of granite and gneiss. As the water passes through these materials, it does not, as a rule, carry them in solution or suspension. The 'mica theory' in Darjeeling water seems to have been based only on surmise—as the water passes through micaceous soil, it must take up mica particles'. It is not known if anybody has ever detected mica in the water. In fact, the water from the lake or springs is clear and sparkling. There is practically no suspended matter or irritating substance. The total solids (that is, the total substances of every kind which are left behind when the water is evaporated to dryness), total hardness and chlorine, respectively, amount to 3-4, 1.0 and 0.4 parts per 100,000 parts of water. The water is of a high degree of purity, both chemically and bacteriologically. Thus, the presence of mica is not suspected from the general characteristics of the water supplies. Nevertheless, with a view to finding out if there was any truth in the 'mica theory' in Darjeeling water supplies, the writer of this article carried out the examination of the water in all possible ways while he was employed as chemist to the Darjeeling Municipality, but mica could not be detected. At last the matter was referred to Sir E. H. Pascoe, the then Director of the Geological Survey of India, and two samples of residues, obtained in one case by the evaporation of 1,000 c.cm. of the lake water and in the other by the evaporation of 1,000 c.cm. of the mixed spring water before its entrance into the lake, were sent to him for examination. In his letter No. 1569/23 of the 29th March, 1926, he stated as follows:—

'The residues are extremely fine, but even under a high power nothing could be detected which appear to be mica..... I know of no better test for mica in water than a microscopical examination of the residues on evaporation'.

Yours, etc.,

NISHI KANTA RAY, B.A.,
Bacteriologist.

VACCINE LABORATORY,
PUBLIC HEALTH DEPARTMENT,
BENGAL, CALCUTTA.

[Note.—The letter is of special interest in view of the fact that an investigation into the cause of 'hill diarrhoea' in Darjeeling is at present in progress. The question of mica in the water is of course being considered.

Our correspondent does not state at what time of the year he carried out his investigation but from the date of Sir E. H. Pascoe's letter we gather that the residues he examined were from water he collected during the cold weather, a time of the year when diarrhoea is not epidemic.

Our correspondent's observations are in keeping with the findings in the present investigation on 'hill diarrhoea', but they cannot be considered as closing the discussion on the subject.—Editor, I.M.G.]

THERAPEUTIC PROPERTY OF COCONUT OIL

To the Editor, THE INDIAN MEDICAL GAZETTE

Sir,—Coconut is known in India as having a high nutritional value. Hindus use it in culinary preparation in the form of coconut milk or coconut oil.

One of us noted it having been given in the form of coconut milk in Indian homes for aphthous patches.

This suggested to us that it might contain one or more vitamins, and we used pure neutral coconut oil in the form of injections in the following conditions: cachexia, beri-beri, burning of feet, sprue, dermatosis, xerophthalmia, hemianopia. All these patients have tolerated perfectly and shown signs of improvement.

We give intramuscular or hypodermic injections, 5 c.cm. every day, or every alternate day; or intravenous injections, 1 to 2 c.cm. every alternate day up to 15 injections.

We are continuing the trials on a big scale and hope to give the result later, but we send this preliminary note to have it registered.

Yours, etc.,
E. GAFFIERO.
Z. ANDRE.

PONDICHERY.

[Note.—The intravenous injection of oil is a very unusual procedure and one that is likely to be followed by oil embolism. This statement should therefore be accepted with reserve.—Editor, I.M.G.]

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL H. R. NUTT, V.H.S., is appointed Honorary Surgeon to the King, 28th February, 1934, vice Major-General Sir J. D. Graham, Kt., C.B., C.I.E., retired.

The services of Major M. Taylor, Officiating Superintendent, Central Mental Hospital, Yeravda, are replaced at the disposal of the Government of Bihar and Orissa, with effect from the afternoon of the 20th June, 1934.

The services of Major G. D. Malhoutra are placed at the disposal of the Government of Bihar and Orissa for employment in the Jail Department, with effect from the 22nd June, 1934.

The services of Major D. R. Thomas, O.B.E., Officiating Imperial Serologist, Calcutta, are replaced at the disposal of the Government of the Punjab, with effect from the date on which he relinquishes charge of his duties.

Major S. D. S. Greval, an Officer of the Medical Research Department, is appointed to officiate as Imperial Serologist, Calcutta, with effect from the date on which he assumes charge of his duties.

Major W. E. R. Dimond, Assistant Director, Public Health, North-West Frontier Province, is appointed to officiate as Inspector-General of Civil Hospitals, North-West Frontier Province, during the absence on leave of Colonel C. I. Brierley, C.I.E.

The services of Major J. R. Katariya are placed at the disposal of the Government of Bengal for employment in the Bengal Jail Department, with effect from the date of his assuming charge of his duties.

Major S. R. Prall is appointed to be Superintendent, St. George's Hospital, Bombay.

Major T. A. Doran is appointed to officiate as Resident Medical Officer, St. George's Hospital, Bombay, with effect from the 11th June, 1934.

The services of Captain G. J. Joyce are placed temporarily at the disposal of the Government of the Punjab, with effect from the 18th June, 1934.

The services of Captain E. A. O'Connor are placed temporarily at the disposal of the Government of Bihar and Orissa, with effect from the 2nd July, 1934.

The services of Captain P. J. Kelly are placed temporarily at the disposal of the Government of Madras, with effect from the 8th July, 1934.

Subject to His Majesty's approval, the under-mentioned officers, whose appointment on probation was notified in February 1932 and March 1933, are confirmed on completion of one year's satisfactory service:—

Major

B. R. Tandon.

Captains

P. V. Karamechandani.

D. P. Mitra.

R. K. Misra.

T. D. Ahmad.

K. R. Sahgal.

M. Jafar.

M. S. Gupta.

A. M. Chaudhuri.

A. N. Chopra.

P. V. Bamford.

D. N. Chakravarti.

H. D. R. Zscherpel.

S. Annaswami.

K. Jilani.

T. B. Pahlajani.

J. R. Dogra.

Asa Singh.

S. Narain.

R. R. Bakshi.

F. M. Khan.

B. D. Khurana.

D. Datt.

D. C. Chopra.

M. G. Saincher.

Jaswant Singh.

B. L. Taneja.

Saugham Lal.

S. W. H. Askari.

A. K. Gupta.

Hoe Min Sein.

V. Srinivasan.

D. P. Nath.

H. H. Mahmood.

Subject to His Majesty's approval, the under-mentioned officers, whose appointment on probation was notified in June 1933 and September 1933, are confirmed on completion of one year's satisfactory service:—

Captains

B. M. Rao.

C. H. Dhala.

A. N. Duggal.

M. Ata-Ullah.

B. S. Sandhu.

S. Ahmad.

B. N. Khan.

C. C. Kapila.

I. Baksh.

V. M. Albuquerque.

LEAVE

Colonel C. I. Brierley, C.I.E., Inspector-General of Civil Hospitals, North-West Frontier Province, is granted leave for 1 month and 29 days, with effect from the 24th July, 1934.

PROMOTIONS

Majors to be Lieutenant-Colonels

P. C. Banerjee. Dated 2nd June, 1934.

B. Prasad. Dated 2nd June, 1934.

A. N. Bose, M.B.E. Dated 8th June, 1934.

J. M. Mitchell, O.B.E. Dated 13th June, 1934.

M. G. Bhandari. Dated 14th June, 1934.

N. J. Gai. Dated 20th June, 1934.

M. M. Cruickshank. Dated 28th June, 1934.

Previous notification of June 1934 in so far as it relates to the promotion of Lieutenant (on probation) W. M. E. Anderson to the rank of Captain (on probation) is cancelled.

RETIREMENTS

Lieutenant-Colonel K. S. Singh. Dated 21st June, 1934.

Lieutenant-Colonel V. N. Whitmore, O.B.E. Dated 7th June, 1934.

DISTINGUISHED SERVICE

The names of the undermentioned have been brought to notice by His Excellency Field-Marshal Sir Philip W. Chetwode, Bt., G.C.B., K.C.M.G., D.S.O., Commander-in-Chief in India, for distinguished services rendered in connection with the military operations against the Upper Mohmands, period 28th July to 3rd October, 1933:—

Colonel E. W. C. Bradfield, C.I.E., O.B.E. (Edin.), V.H.S., Assistant Director of Medical Services, Peshawar District.

Major D. V. O'Malley, O.B.E.

Captain S. D. Dalal.

Lieutenant J. O'Neill.

Notes

A NEW INTRA-UTERINE CANNULA

ANYONE who has injected mercurochrome-glycerine into the uterus for septic conditions must have experienced certain difficulties in keeping the medicament in the cavity for any length of time. Injecting the solution with an ordinary rubber catheter or long metal tube and removing it immediately afterwards allows the liquid to drain away, especially when the cervix is not closed. This cannula, which is made in three different sizes to suit individual cases, has a small trap-door, which opens one way only. A long intra-uterine metal tube fixed to an ordinary 20 c.cm.

Cannula.

Trap-door closed.

Trap-door open.

Long metal pipe.

'Record' syringe is passed through this cannula into the uterine cavity, the solution is injected, and the tube removed allowing the trap-door to close. The cannula with the trap-door closed prevents fluid escaping from the cervix and can be allowed to remain as long as necessary. Messrs. N. Powell and Company have made this instrument for Dr. J. R. Parakh, Bombay.

FRACTURE BEDS AND FRACTURE TABLES

MESSRS. MALGHAM BROTHERS of 26, Custom House, Fort, Bombay, have asked us to announce that they can supply both Hawley-Scanlan fracture x-ray and orthopaedic tables, and also Lawson Tait fracture beds, to which reference was made in an article on fracture equipment that appeared in our January and March numbers.

They have also asked us to say that they are prepared to supply to a few surgeons a detailed booklet describing the Hawley-Scanlan table.

AN IDEAL INFANT FOOD

THE amazing strides that have been made in recent years in the production of infant foods is exemplified by the one well-known in practically every household in India—namely Glaxo. The proprietors of this food, in every step they have taken in reaching the magnificent reputation that Glaxo to-day enjoys have shown extraordinary scientific foresight and initiative.

This commenced when they chose New Zealand as the venue of their milk supply, for in that country the dairy herds are of the Jersey and Guernsey strains, so famous for the quality of the milk they provide. In addition, New Zealand is the only milk-producing country in the world where the cattle graze in pasture land the whole of the year round and stall feeding, which affects adversely the quality of the milk, is unknown.

Moreover, the Government of New Zealand has tackled the problem of bovine tuberculosis in a manner that sets an example to most of even the European countries.

It was the Ministry of Food in England that were the first 'official' users of Glaxo, and during the War their first order for it, to be used for the feeding of infants in England, was for 600 tons.

Then came the intense work of vitamin research which still proceeds, but which commenced in real earnest and on an international scale just after the War. In this work, the scientists of the staff of 'Glaxo' have played an important part, and in that important publication 'Vitamins—A Review of present Day Knowledge', published by the Medical Research Council not long ago, four of the contributors were members of the Glaxo staff. But one of the many

independent research workers—namely, Katherine Coward—had shown that raw cow's milk contains practically no vitamin D, and the findings of her work, which resulted in this conclusion, were published or quoted in a number of reputable scientific journals.

It is a corollary, therefore, that a food made from milk can be no more rich in vitamin D than the milk itself if the latter is deficient in such an important constituent.

Moreover, the Ministry of Health some 18 months ago drew the attention of the infant-welfare bodies under their jurisdiction to a great improvement that could be made to the diet of infants for the prevention of infantile anaemia, and recommended a method of modification.

In the commencement of this article, the remark has been made that the proprietors of Glaxo had shown remarkable scientific foresight and initiative, and in support of this, it is interesting to observe that long before either the findings of Katherine Coward were published, or the statement of the Ministry of Health was made, the manufacturers of Glaxo had made the addition of vitamin D, and the modification for the prevention of infantile anaemia that had been recommended.

Furthermore, insofar as the supply of Glaxo destined for the Indian market is concerned, the packing of it is carried out in air-conditioned surroundings—that means to say, the air which enters the packing room is washed and purified before it enters. In addition, all Glaxo coming to this country, which it does direct from New Zealand, is placed in cold storage immediately on arrival, and users of this food have probably observed upon opening a tin, a degree of freshness which, if they were able to compare the contents with powder immediately after manufacture, they would find identical.

The rigidity of bacteriological and scientific control, throughout the stages of its manufacture, the skill employed in the perfecting of it, the scrupulous care that is being taken to retain its freshness, make Glaxo

the ideal infant food for India, and especially does this apply during the hot weather and monsoon months when infantile diarrhoea plays such havoc with the health of infants.

THE VELOX SPUTUM MUG AND FLASK STERILIZER

For many years it has been the practice in sanatoria and hospitals in dealing with sputum mugs and flasks to pour the contents down the drain and then boil the vessel. The method was crude and is certainly open to certain objections, but it was the only method available and was therefore accepted.

It is now no longer necessary to take up this defeatist attitude as an appliance has been placed on the market that makes it easier to carry out the proper disinfection of these receptacles than it was to go through the old performance that was often little better than 'eye-wash'.

The mugs or flasks with their contents are brought along in a wire tray supplied with the Velox sterilizer; the mugs are then placed inside the machine in an inverted position, and the sputum falls into the water in the water space; the tray is then placed over these mugs, the cover screwed down, and steam turned on. The steam causes the water to scour the mugs inside and outside and while doing so the steam pressure rises to 15 pounds per square inch and sterilizes the mugs, tray and sputum. Some air is present in the sterilizer at the commencement of the operation; this air is expelled through a special air filter attached to the machine. The sputum, lying in the lower portion of the sterilizer, is now sterile and disintegrated. The cock below the machine is now opened and this disintegrated sputum is ejected into the drain under pressure.

The sterilizer is opened, mugs or flasks are found to be clean and sterilized, and the operation is repeated on the next set of mugs or flasks.

Simple in design, active and effective in result, this sterilizer should have its place in all sanatoria.

Upon the same principle this company have designed a bedpan sterilizer which is just as effective.

Messrs. Balmer Lawrie and Company, Limited, of 103, Clive Street, Calcutta, and 5, Graham Road, Ballard Estate, Bombay, are the sole Indian agents for the Grampian Engineering Company, Limited, Stirling, Scotland, the manufacturers of Velox plant.

Further particulars on page lx.

GONEAL

This preparation is a silver and calcium caseinate which is said to give excellent results in the treatment of the complications of gonorrhoea, such as arthritis, epididymitis and prostatitis. The action is mainly one of protein shock—or protein therapy as it is now more euphemistically called, but the presence of silver adds a specific element to the compound.

In the complications we have mentioned, the intramuscular injection of Goneal exercises the same resolving action which is produced by specific vaccines. A hyperæmic and inflammatory reaction is produced in the diseased tissues, and this, without doubt, is one of the principal elements in the therapeutic effect of both protein and vaccine treatment. But Goneal, for its special constitution and composition, has the advantage of being more exactly dosable, of being very well tolerated, as it does not cause the violent reaction which follow vaccine treatment, and finally its therapeutic action is more rapid and more complete.

Dosage.—Goneal should be administered by deep injection in the gluteal muscles. Injections are generally given on alternate days. Usually one box is more than sufficient for one course of treatment. Injections do not produce general reaction worth

mentioning, so that Goneal treatment may be carried out with the greatest confidence.

It is a product of the National Opothropic Institute of Pisa and has been tested in the medical clinic of the Royal University of Turin from where very satisfactory results are reported.

RHEUMATISM

INFLAMMATORY conditions are by no means confined to the winter months, and rheumatism does not govern itself by the calendar. So Antiphlogistine is an all-year therapeutic agent, indicated for and often affording the most grateful relief in the treatment of articular and non-articular rheumatism.

The moist heat which it maintains for more than 12 hours, reinforced by the osmotic and phagocytic actions of its chemical constituents, tends to improve the local metabolism, promote absorption of the swellings in and around the muscular fibres, helps to restore movement in stiffened joints and muscles and to bring relief from the pain.

Antiphlogistine is indicated for the majority of inflammatory lesions, whether deep-seated or local and those physicians who are not conversant with its uses, or who may wish to give it further clinical trial, are invited to write for samples and literature. The Denver Chemical Mfg. Co., 163, Varick Street, New York, U. S. A.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors *ask for them at the time of submitting their manuscripts*.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

LATENT MALARIA INFECTION IN MONKEYS

By R. KNOWLES

LIEUTENANT-COLONEL, I.M.S.

Professor of Protozoology
and

ASSISTANT SURGEON B. M. DAS GUPTA, L.M.P.

Assistant Professor of Protozoology, Calcutta School of
Tropical Medicine

Introduction

It may be recalled that Napier and Campbell (1932) discovered a *Plasmodium* infection in a 'Singapore' monkey—at first wrongly identified (by zoological authorities) as *Cercopithecus pygerythrus*, but subsequently shown to be *Silenus (Macacus) irus*—which produced severe and fatal malaria, often accompanied by hæmoglobinuria, on passage into *Silenus (Macacus) rhesus*, the common monkey of Bengal. This parasite was intensively studied by Knowles and Das Gupta (1932), who passaged the strain into *Silenus rhesus*, *Silenus radiatus*, *Semnopithecus entellus*, *Hylobates hoolock*, and also into three human volunteers, who contracted monkey malaria, the infection being a very severe one in one of these volunteers. These workers were extremely puzzled by the great variations in morphology, associated with varying grades of severity of symptoms, in the different hosts used; thus, typically, the infection in *S. irus* morphologically and clinically resembled one with *Plasmodium vivax* in man, whilst the infection in *S. rhesus* clinically resembled one with malignant tertian malaria in man, and the parasites morphologically resembled *P. falciparum* (except that the gametocytes were spherical and not crescentic in shape and that the hæmozoin was in loose granules and not jet black).

Subsequently to this the strain was sent to Lieut.-Colonel J. A. Sinton, v.c., I.M.S., Director, Malaria Survey of India, and, in a series of papers covering and reviewing the whole subject of monkey malaria, and including a tremendous amount of original investigation, Sinton and Mulligan (1932, 1933) established the fact that the original strain seen in *Silenus irus* at the Calcutta School of Tropical Medicine, must have been a mixed one with two species of monkey plasmodium. At first we were incredulous of this finding, since the naturally-infected monkey first discovered had shown only an extremely scanty infection, but a thorough study of Sinton and Mulligan's papers, a study of a pure-line strain of *Plasmodium inui* var. *cynomolgi* which Colonel Sinton was kind enough to send us, and subsequent work at the School has convinced us that these authors are right and that we were, in actual fact, dealing with a mixed strain.

As the subject of monkey malaria is now being studied so widely, we may perhaps here give a brief synopsis of the two species of parasite concerned, taken from Sinton and Mulligan (1933), and our own work:—

Plasmodium inui var. *cynomolgi* Mayer, 1907.

Natural host, *Silenus irus*. Reported from Malaya and Java. The young rings are from one-fifth to one-third of the diameter of the infected red corpuscles; are usually thin and hair-like. An accessory chromatin dot is frequently present in the ring stage. Slightly older forms are often very irregular.

The growing trophozoite forms lie in corpuscles which are enlarged, often pale, and which show Schüffner's dots in abundance. These appear early and are constant in appearance. The trophozoites are very amoeboid; the vacuole is at first well developed, but is usually not seen in the segmenting forms. Pigment appears relatively late, is golden brown in colour, and the granules are fine.

The mature schizont-rosettes lie in enlarged red corpuscles which show Schüffner's dots. The merozoites number about 16. The duration of the schizogony cycle is 48 hours.

The gametocytes resemble those of *P. vivax*, and lie in enlarged red corpuscles showing Schüffner's dots. The pigment is not very abundant.

The infection is readily transmissible to mosquitoes. The infection in *S. irus* is benign and chronic in character, with little accompaniment of illness; it may persist for months. When passaged into *S. rhesus* the infection takes readily, but is mild in character, often however prolonged; the infected monkeys all recover spontaneously.

In splenectomized *S. irus* the infection is mild, with recovery.

Plasmodium knowlesi Sinton and Mulligan, 1932.

Natural host, *Silenus irus*. Reported from Malaya.

The young rings are from one-third to one-half the diameter of the infected red corpuscles; the chromatin in the ring is generally dot-like or blob-like and well in evidence; it often occurs as a small curved bar resembling the similar appearance in *P. falciparum*. An accessory chromatin dot is often present. Early division of the chromatin and multiple infection of the red corpuscles are very marked features at this stage (in *S. rhesus*). Slightly older forms occur as rings with a more solid appearance.

The growing trophozoite forms lie in red corpuscles which show no trace of enlargement, which are not pale, and which show no stippling (with the usual stains). The infected corpuscles are frequently distorted—oval, fimbriated, crenated or polyhedral in appearance. The growing trophozoite forms are rounded, non-amoeboid, or only very slightly amoeboid. Pigment appears early, is relatively abundant, the granules are fairly coarse, and the colour varies from greenish brown to almost black.

The mature schizont-rosettes recall those of *P. falciparum*, but the number of merozoites is much less—from 8 to 11, usually 10. They lie in red corpuscles which are not enlarged, and may or may not quite fill the infected cell. The merozoites are arranged in a grape-like cluster. The duration of the schizogony cycle is 24 hours.

The gametocytes resemble those of *P. malariae*; they lie in red corpuscles which are neither enlarged nor stippled. Their pigment is coarse and dark.

The infection has not yet been transmitted by mosquitoes (in India).*

The infection in *S. irus* is mild, and parasites very scanty in films of the peripheral blood. When passaged

* In a recent private communication, the senior author has been informed that mosquito transmission of this species has been obtained at Horton in England

into *S. rhesus* the infection flares up, with the blood swarming with parasites; the infection in this species is invariably fatal (unless treated with quinine or atabrin), and often associated with a terminal hæmoglobinuria.

In splenectomized *S. irus* the infection proves fatal, but quinine or atabrin treatment may save life.

Thanks to Colonel Sinton's assistance we now have pure-line strains of both *P. inui* var. *cynomolgi* and *P. knowlesi* maintained in our department, and during the past two years have carried out much experimental work with them. The *P. knowlesi* strain has proved valuable in experimentally testing new synthetic remedies against malaria in monkeys.

* * * * *

During the year 1933 six *S. irus* monkeys were inoculated with massive doses of *P. knowlesi* from infected *S. rhesus* monkeys. These all took the infection, but showed only scanty parasites in the blood films, and recovered spontaneously after varying periods.

Now, Kikuth (1933) and Regendanz, working on *Trypanosoma lewisi* infection in rats, have shown that if the spleen be extirpated at the commencement of the infection, one can often observe that the increase in the number of trypanosomes is extended over a much longer period, and the non-pathogenic *T. lewisi* in many cases takes on a pathogenic character. This they attribute to the fact that the spleen produces a substance—ablastin—which inhibits multiplication of the trypanosomes. Accordingly, we decided to test whether splenectomy would reduce the resistance of *S. irus* to infection with *P. knowlesi*, to which it is usually rather tolerant.

A splenectomized Silenus irus

A young *S. irus* monkey, weighing 1 kilo, 190 grammes, was taken, and thin and thick blood films from it examined daily for five days. No parasites were detected.

With some difficulty 2 c.cm. of blood was withdrawn from its great saphenous vein and inoculated into a young *S. rhesus* monkey—an animal exquisitely susceptible to monkey malaria. We had previously found in the case of a human volunteer infected with monkey malaria that when parasites were extremely scanty in the blood and could easily be missed in blood films the inoculation of 5 c.cm. of blood from the patient into a *S. rhesus* resulted in a fatal infection in that animal. We regarded this test as the most crucial one applicable to ensure that the donor was not infected with monkey malaria naturally acquired.

The inoculated *S. rhesus* remained quite well and free from infection. We concluded therefore that the *S. irus* was free from natural malaria infection. The monkey was now splenectomized. For 24 hours it was given water only and no solid food. On the third day

after operation it appeared to be in good health and took its usual diet.

Nine days after the splenectomy the monkey appeared to be in good health and to have completely recovered from the effects of the operation. (Unfortunately blood films were not examined from it during this period.)

It was now inoculated intraperitoneally with one c.cm. of blood from a *S. rhesus* infected with *P. knowlesi*—a dose of approximately 94 million parasites. This strain of *P. knowlesi* had been serially passaged through 62 *S. rhesus* monkeys, was a pure-line strain with constant morphology, and, as far as we knew, quite unmixed.

The incubation period in *S. irus* monkeys inoculated with monkey malaria in our previous series (Knowles and Das Gupta, 1932) had been from 7 to 11 days, and during the first five days after inoculation blood films were unfortunately not taken from this animal. The monkey appeared to be in good health.

On the fifth day after inoculation the monkey suddenly became acutely ill and died. An immediate post-mortem examination was held, and revealed an almost incredibly heavy infection in the heart blood. No less than 78.5 per cent of the erythrocytes were infected, some cells even containing as many as three parasites. Fig. 1 is

Fig. 1.—Photomicrograph of a smear of the heart blood, showing the intensity of the infection, and that some of the infected red corpuscles are definitely enlarged and stippled ($\times 700$).

a photomicrograph from a stained film of the heart blood. Fig. 2 is a composite drawing from different fields of the same. Fig. 3 is a drawing from a section of the liver. The extreme intensity of the infection will be realized from these figures. It recalls that seen in a *S. rhesus* dying from a fatal infection with *P. knowlesi*, and is utterly unlike the scanty and benign infections in non-splenectomized *S. irus* with this species of monkey malaria.

The amazing feature of the infection, however, was that a dual infection with both

P. knowlesi and *P. inui* var. *cynomolgi* was present. The cytoplasm of the growing trophozoites was not amœboid, but many of the infected red corpuscles were markedly enlarged and showed Schüffner's dots.

Fig. 2.—Photograph of a coloured drawing from a stained film of the heart blood, showing the presence of both *P. inui* var. *cynomolgi* and *P. knowlesi*.

Fig. 3.—Section of the liver, showing the venous sinuses distended with infected red corpuscles and pigmented Küpffer cells.

Two questions immediately arise :—

(i) Was the blood of the donor infected with both malaria species? This, we believe, may be ruled out at once. The strain of *P. knowlesi* used was a pure-line strain; it had been passaged in series through 62 *S. rhesus* monkeys, and had never shown any variation from its normal morphology and virulence.

(ii) Did the *S. irus* have a latent infection with *P. inui* var. *cynomolgi* which was not detected by blood examination, or even by inoculating its blood into a *S. rhesus*—an

extremely susceptible animal? This infection flared up as the result of the splenectomy.

Latent infections in Silenus irus

We believe the second to be the real explanation of the presence of both species of malaria parasites. In order to test this question further, five young *S. irus* monkeys were purchased in the market, separately caged, and thin and thick blood films examined daily from each for ten days. Results were as follows :—

Monkey A showed scanty or very scanty parasites on the 3rd, 4th, 5th, 6th, 8th, 9th and 10th days of examination, i.e., the films were positive on seven out of ten examinations. The species present was *P. inui* var. *cynomolgi*, and all phases—rings, growing trophozoites, schizonts and gametocytes—were seen.

Monkeys B, C and D gave negative results throughout.

Monkey E showed extremely scanty parasites on the 1st, 3rd, 6th, 7th and 10th days of examination, i.e., five out of ten examinations were positive. On four of these occasions only very scanty rings were detected in the thick films. On the 7th day extremely scanty gametocytes were seen. The infection was so scanty that it was impossible to determine the species of parasite present.

Thus, prolonged blood examinations showed two out of the five monkeys to be naturally infected with monkey malaria. Three appeared to be absolutely free from infection.

Having failed to detect parasites in three out of the five monkeys, we decided to induce protein shock, and gave to each of all five monkeys an injection of 2 c.cm. of normal horse serum, as suggested by Sinton and Mulligan (1933) to re-awaken any latent infection. Four hours after the injection thin and thick blood films were taken from each monkey and, after fixation and staining, were very carefully searched. Monkeys A and E showed a definite increase in the number of parasites present. No parasites could, however, be detected in the films from monkeys B, C and D, despite prolonged search. Thus, after protein shock, three out of the five monkeys still remained 'negative'.

We next tried the method we have always used for the diagnosis of latent infections; Sinton and Mulligan (1933) have suggested the name 'isodiagnosis' for this method. From each of the three monkeys B, C and D, two c.cm. of blood was withdrawn and injected into a *S. rhesus* monkey—three of the latter being used. The *S. rhesus* inoculated from *S. irus* B showed a severe infection with *P. knowlesi*, thus showing that *S. irus* monkey B was infected with this parasite. The *S. rhesus* monkeys inoculated from monkeys C and D remained in good health, showed no parasites at any time, and at the time of writing—33 days after the inoculation—show no trace of infection. Thus,

by isodiagnosis, a third monkey—B—was found to be infected.

Finally, we splenectomized *S. irus* monkeys B, C and D. Thin and thick blood films from all three monkeys were examined daily, after the splenectomy, with the following results:—

Monkey B showed an infection with *P. inui* var. *cynomolgi* from the fourth day onwards. Some of the forms encountered were suspicious of a mixed infection with *P. knowlesi* as well. This monkey still remains in good health and still shows parasites on the 33rd day after inoculation. The infection is a low grade one.

Monkey C showed a mixed infection with *P. inui* var. *cynomolgi* and *P. knowlesi* on the fourth day after inoculation. This flared up with great rapidity and the monkey died on the seventh day after inoculation with its blood swarming with parasites.

Monkey D showed an infection with *P. inui* var. *cynomolgi* on the fifth day; this infection is a scanty one; the animal is in good health, but is still infected on the 33rd day after inoculation.

Discussion

To summarize, we may put the case as follows:—

(i) By prolonged blood examinations over ten days two monkeys—A and E—were found to be infected. By ordinary laboratory standards the other three monkeys—B, C and D—would be regarded as 'clean' (i.e., non-infected) animals.

(ii) Protein shock did not improve these findings; the parasites in monkeys A and E became more numerous, but monkeys B, C and D were still 'negative'.

(iii) 'Isodiagnosis' (i.e., inoculation of the blood into the very susceptible *S. rhesus*) showed that monkey B was also infected. This procedure showed that a third out of the five monkeys was infected.

(iv) Blood examinations after splenectomy showed that monkeys B, C and D were all infected. In other words, all five *S. irus* monkeys, taken at random, showed malaria infection but this fact was only detected after splenectomy.

With regard to species, the infections were as follows:—

Monkey A was infected with *P. inui* var. *cynomolgi* only.

Monkey B was infected with *P. inui* var. *cynomolgi*, possibly with a scanty infection with *P. knowlesi* as well.

Monkey C was infected with both *P. inui* var. *cynomolgi* and *P. knowlesi*; this infection proved fatal after splenectomy.

Monkey D was infected with *P. inui* var. *cynomolgi* only.

Monkey E showed infection, but the parasites were so scanty throughout that the species could not be determined.

Sinton and Mulligan (1933) comment on the following methods for detecting latent malaria infection in monkeys:

(i) Blood examinations (thick films) searched at weekly intervals over a period of some months. This is admittedly a tedious procedure, and would probably have to be supplemented by even more prolonged search of thin films for the species diagnosis.

(ii) Cultural methods, by the Thomson's modification of Bass and John's technique. Here the diagnosis of species may be impossible, as the predominant strain may overgrow a scanty infection with another species. Also other methods are more easily carried out, and possibly more reliable.

(iii) Protein shock. Sinton and Mulligan consider this a valuable aid to the diagnosis of latent infections, and give records of other workers who have also found it useful. It certainly increases the number of parasites in the peripheral blood, and may possibly be of value in the diagnosis of latent malaria in man. On the other hand, as our experience with the five monkeys shows, it often fails to reveal a latent infection.

(iv) 'Isodiagnosis', i.e., the inoculation of the blood into a susceptible animal of the same genus. This gave us a third positive out of the five monkeys concerned in the experiments recorded above. It is not applicable to man, since no animal susceptible to inoculation with human malaria has so far been discovered. Sinton and Mulligan consider that with methods (iii) and (iv) combined, extremely few, if any, latent infections would escape detection.

(v) Splenectomy, followed by daily examinations of thin and thick blood films. Sinton and Mulligan consider this a most valuable procedure; on the other hand 'animals which have proved to be uninfected by this method cannot afterwards be used to study the usual pathogenic effects of any species of *Plasmodium* in the normal animal. This is a distinct disadvantage'. In our hands, however, in the above series of five monkeys, the method revealed two latent infections which had defied diagnosis by all other methods. To find out whether a monkey has a latent infection or not, it seems the most reliable of all methods. Unfortunately, it may result in the infection flaring up and proving fatal, e.g., monkey C.

Sinton and Mulligan (1933) recommend the following routine procedure in the detection of latent malaria infections in monkeys:—

(i) Examination of thick blood films daily for some weeks. If no infection is detected, then—

(ii) Protein shock. If no parasites are detected within 24 hours, then—

(iii) Isodiagnosis. If no parasites have been detected by all three methods, they regard the animal as not infected, and state that in their

hands splenectomy has not improved the diagnosis if these three methods fail. Our experience with the five monkeys whose history has been detailed above has been different.

It would seem that in Nature *Silenus rhesus* monkeys are never or hardly ever infected with malaria parasites. The matter is fully discussed by Sinton and Mulligan (1933). They give all the records available from the literature. Only two reliable records of natural infection of this species with monkey malaria are on record: one by Chimisso (1922), the species having been identified as *Plasmodium scimipitheci* by Sinton and Mulligan (1932), and the other a record of infection with *P. inui* in *S. rhesus* in Tonkin by Mathis and Leger (1911). Thousands of specimens of *S. rhesus* must have been subjected to the most careful scrutiny in connection with the investigation of other diseases, yet there is no other record of natural plasmodial infections in this species of monkey. From 1912 to 1914 Colonel Acton, I.M.S., and the senior author of the present paper examined the blood of every *S. rhesus* used at the Pasteur Institute of India, Kasauli, in any experimental work in the hope of obtaining a natural strain of monkey malaria, but never found any infected. Since the Calcutta School of Tropical Medicine was opened in 1921, the authors of the present paper have year by year searched blood films of monkeys of this species used for other experimental work, amounting to some hundreds in all, and have never detected any infection. Sinton and Mulligan (1933) record having examined the blood of more than 300 monkeys of this species, without detecting any infection.

On the other hand, it would be interesting to carry out splenectomy in this species, and see whether by this procedure the existence of any latent infections can be brought to light. Also *S. rhesus* is readily susceptible to infection with *P. inui* var. *cynomolgi*, and—one may say—exquisitely susceptible to infection with *P. knowlesi*, the latter infection invariably proving fatal, if treatment is not instituted.

Matters are quite different with *Silenus irus*. As will be seen from the results recorded in this paper, six specimens of this species, bought at random in the Calcutta market, all showed infection with monkey malaria, the infection being revealed by blood examination in two, and being latent in the other four. Young specimens of *S. irus* appear to be infected with monkey malaria almost without exception. Further, as has been shown by Knowles and Das Gupta (1932), this infection is transmissible to man, and may provoke quite a severe attack of malaria in this subject.

Summary

1. A description is given of the two parasites concerned in monkey malaria in Malaya, viz *P. inui* var. *cynomolgi* Mayer, 1907, and *P. knowlesi* Sinton and Mulligan, 1932.

2. A splenectomized *Silenus irus* monkey inoculated with *P. knowlesi* from an infected *Silenus rhesus* died with an overwhelming malaria infection. Examination of the heart blood after death showed both *P. inui* var. *cynomolgi* and *P. knowlesi* to be present. Presumably the *S. irus* had a latent infection with the former species, which was re-awakened into activity by the splenectomy.

3. In order to test this point further, five fresh *S. irus* monkeys were purchased. Repeated blood examination showed that two of these were infected. The induction of protein shock did not improve the findings. By 'isodiagnosis'—i.e., inoculation of the blood into a susceptible host of the same genus—a third monkey was found to be infected. Finally, by blood examination after splenectomy, all five monkeys were found to be infected. In one monkey (C) splenectomy caused a latent infection to flare up and become fatal.

4. Monkeys of species *Silenus (Macacus) rhesus* appear to be almost entirely free from naturally-acquired monkey malaria; on the other hand monkeys of species *Silenus irus (Macacus cynomolgus)* appear to be very heavily parasitized with both *P. inui* var. *cynomolgi* and *P. knowlesi*, young monkeys of this species being almost always infected.

5. Methods of detecting latent malaria infection in monkeys are discussed. The most certain method appears to be blood examination after splenectomy.

Acknowledgments

We are indebted to Dr. J. C. Gupta, M.B., and Dr. N. De, M.B., of the Pharmacology Department of the Calcutta School of Tropical Medicine, for carrying out splenectomy in the monkeys used in these experiments.

A CLINICAL STUDY OF CLIMATIC BUBO AND ALLIED CONDITIONS

By R. V. RAJAM, M.B., B.S. (Mad.), M.R.C.P. (Edin.)
Venereal Specialist, General Hospital, Madras

AN increasing volume of literature on this subject, both clinical and experimental, has been appearing in foreign medical journals for the past decade. Though this disease is fairly common in this country, there has been little reference to it in medical journals in India; this state of affairs seems to justify this article. The writer has attempted a clinical review of climatic bubo and allied conditions, examined and treated during the year 1933 in the venereal clinic of the Madras General Hospital.

It is now generally recognized that the disease belongs to the venereal group and is caused in the vast majority of cases by sexual contact. Stannus (1933) called it 'the sixth venereal disease'. The experimental researches of continental workers, such as Hellestrom and Levaditi, have proved that the disease is caused by a filterable virus, and that what is known as lymphogranuloma inguinale in the West is identical with climatic bubo in the East. The outstanding pathological feature of the disease is the predilection of the virus for the lymphatic system where it induces characteristic changes.

The introduction of Frei's intradermal test with an antigen prepared from the pus of climatic bubo has not only been of immense value in diagnosing this condition from other forms of lymphadenitis but has also helped to include other clinical manifestations of the disease, such as elephantiasis of the genital regions in both sexes, ulceration of the vulva, perianal elephantiasis, and ulceration and inflammatory stricture of the rectum, under the same aetiological group.

The number of cases investigated and treated is as follows :—

TABLE I
Climatic bubo

TOTAL ..	168	15

Frei's reaction

As far as possible the diagnosis of these conditions was confirmed by the Frei's intradermal test. As can be seen from the figures given below, the specificity of the test is very high. The antigen was prepared for us by Dr. Goyle, Professor of Pathology, Medical College, Madras, from the pus of infected glands removed by operation in the clinic. The value of each batch of antigen was tested by controls on normal patients or patients suffering from other venereal diseases. All the batches of antigen supplied except one were found to be quite reliable. 0.1 c.cm. of the antigen was injected intradermally on the flexor aspect of the forearm and at the same time a saline control was also carried out. The reaction was examined 48 hours later. A well-marked reddish infiltrative dome-shaped papule was taken as a standard reaction for the positive result (figure 1). In the majority of positive cases the reaction was fairly well marked after 48 hours.

Fig. 1.—A case of climatic bubo (a) with positive Frei's reaction (b). The lighter area on the forearm represents the papule. The print with the arrow is the saline control.

In three cases the reaction was delayed as long as 96 hours after the test. In nine cases the reaction showed a tendency to central necrosis (figure 2). In 19 cases the infiltrated papule was more than 1 cm. in diameter with œdema all round and in a few cases the lymphatic gland at the bend of the elbow was enlarged and slightly tender. In all the positive cases the reaction took on an average eight to ten days to subside completely, leaving a pigmented

mark over the site of injection. In a few cases of climatic bubo of less than one week's duration, the Frei's test was at first negative but when the test was repeated at intervals of a

Fig. 2.—A case of climatic bubo with a pustular Frei's reaction. (Note the central pustulation with the infiltration of the papule; the arrow marks the control.)

week the positive reaction began to appear (*vide* case II).

The test was not performed in all the cases under review as during the first three months of the year the antigen was not available. Altogether it was done 281 times in 269 persons; it was positive in 124 cases, negative in 103, and 42 patients did not attend again so that their result was not read. The results are analysed in tables II and III.

TABLE II

Analysis of positive Frei's test

TABLE III

Analysis of negative Frei's tests

	Males	Females
Climatic bubo	3	1
Genito-anorectal syndrome	2	0
Chancroid	4	3
Chancroid and bubo	16	0
Active syphilis	33	4
Latent syphilis	2	1
Syphilis and gonorrhoea	0	1
Gonorrhoea	8	0
Infective granuloma	6	3
Warts on penis	1	0
Non-venereal cases	11	4
TOTAL	86	17

Table II includes six cases of positive Frei's reaction but with no *active* climatic bubo; there was a history of past bubo with evidence of scars in the groins in these cases. The positive reactions in these cases show that the person may retain the allergic sensitivity long after the disease is cured.

EPIDEMIOLOGY

Sex incidence.—The marked disproportion of 50 to 1 in the sex incidence of climatic bubo is a striking feature and in our series is much more marked than the figures quoted by other workers. Two explanations may be adduced for the rarity of the condition in women. It is quite possible that the women may harbour the virus as a saprophyte in their genitals without suffering any disability though being infective to male contacts. The second possible explanation is the peculiarity of the lymphatic drainage of genitals in women. Only the upper half of the vulva and clitoris have lymphatic connections with the groin glands; the lymphatics of the lower part of the vulva, vagina and cervix drain into the pelvic and perirectal lymphatic glands.

Age incidence.—The ages of the patients varied from 15 to 60 years, the majority being between 20 and 30.

Racial incidence.—Among the males 130 were Hindus, 13 were Mohammedans, 3 were Indian Christians, 3 were Anglo-Indians and 1 European. The females were all Hindus. In the case of males a history of extra-marital coitus was elicited in 145 cases; the three females were all prostitutes.

The primary lesion.—As is well known, the primary lesion through which the virus enters the lymphatic system is so small, painless and evanescent that the patients do not notice it. In our series in the males, there was no history or evidence of penile lesion in 104 cases. In 17 cases the lesion was single, small, superficial, painless, herpetiform and disappeared in a few days. In six cases the sore was single, sloughy, painful with irregular undermined edges. Dmelcos' test was positive in all the cases. In seven cases the sores were multiple; of these two were positive to Dmelcos' test. In three cases

the sore was single, slightly indurated, and nodular and *Spirochæta pallida* was found in one of these. In 13 cases there was a mucopurulent urethral discharge. Examination of smears showed that seven were cases of gonorrhœa and in the remaining six the smears showed only pus cells without any organisms. It is surmised that, in these six cases, the initial lesion was inside the urethra setting up a urethritis. The common situation for the typical primary lesion of climatic bubo was the frenal site or inner aspect of the prepuce. In the three cases in women, no primary lesion could be seen.

Incubation period.—The interval between the infecting coitus and the appearance of the bubo varied from a few days to three months, the average being seven to 10 days. The duration of the bubo varied from five days to eight years.

Site of bubo.—In 120 cases the bubo was unilateral. Sixty-four were in the right and 56 in the left. In 27 cases the condition was bilateral. In six cases there were only multiple scars in the groins or a single operation scar of past bubo. In 38 of the total number of cases the glands were broken down resulting in multiple fistulæ. The glands affected were those of the inguinal group. In a few of the long-standing cases the femoral group was also involved. The enlargement of the iliac glands was noted in 45 of the cases.

Onset and course.—The onset of the disease is usually insidious. The evolution is slow and the condition is subacute from the beginning. The glands of the groin get enlarged with india-rubber consistency and are slightly tender in the early stages. At this stage the glands are very like those of syphilis. In the course of one or two weeks they become matted together by peradenitis and tend to adhere to the overlying skin which becomes thickened, rugose and assumes a peculiar violaceous tint in fair-skinned individuals. Multiple points of fluctuation next appear and may break down, discharging a small quantity of thick creamy pus, and in a neglected case the groins may be riddled with these fistulæ. Secondary infection may supervene and the discharge become more profuse. Changes may occur in the skin of the areas drained by the affected lymphatic glands. A subacute lymphangitis with œdema may affect the skin of the penis, scrotum, groin and upper part of the thigh. Infection may spread to the femoral set of glands and occasionally a phlebitis of the saphenous vein may supervene. In long-standing cases, multiple chronic indolent fistulous ulcers occur on the skin of the penis, scrotum, pubic region and thighs. It is not known whether these ulcers are directly due to the activity of the virus or secondary to lymphatic obstruction and invasion of the area by other organisms. The iliac set of glands rarely undergo suppuration. In a few of the cases, the involvement of the inguinal glands was

minimal, the chief brunt of the infection falling on the iliac group which formed a large tender mass. The tendency of inguinal adenitis is not always to suppurate and burst through the skin; in some cases, the enlargement unaccountably disappears even without any treatment, to reappear after varying intervals. Such recurrent adenitis without abscess formation was observed in half a dozen of our cases.

Constitutional symptoms.—A low fever was fairly common during the first week or two of the disease. Lassitude, headache, and arthralgias are constant features. Blood examination showed a moderate leucocytosis in the early stages. Blood changes of secondary anæmia were observed in a few of the long-standing cases. The only skin affection observed in our cases was a pustular impetiginous eruption on the extremities and buttocks. In none of the cases was any general lymphadenitis or enlargement of the spleen noticed. In one case (case II) the onset of the disease was very acute with bilateral tender inguinal adenitis, severe constitutional symptoms of high fever, profound toxæmia, delirium, etc. Blood examination showed a polymorphonuclear leucocytosis (22,000 per c.mm.). The patient was in a toxic condition for nearly a week and then gradually recovered. Such an onset and course is very unusual in climatic bubo.

Association with other venereal diseases.—As may be seen from table I, climatic bubo may coexist with other venereal diseases, but its course and evolution was not in any way modified by them.

The behaviour of the Wassermann reaction in climatic bubo.—There were 24 cases of clinically undoubted climatic bubo in which the Wassermann reaction of the blood was either strongly positive or weakly positive. In 19 of these cases, Frei's test was positive. In none of these cases there was either a history or clinical evidence of syphilis. We were not able to follow the subsequent behaviour of the Wassermann reaction in these cases but in a few the test became negative after a few weeks though the patients did not get any antisyphilitic treatment. This positive Wassermann reaction has been observed in the early stages by American workers. This peculiarity in the behaviour of the Wassermann reaction requires further investigation before any definite opinion can be given regarding the specificity or otherwise of the reaction.

Diagnosis.—Diagnosis is usually a simple matter in uncomplicated cases. The points for diagnosis to remember are the presence of a tiny superficial painless evanescent primary penile lesion, more often the absence of any such lesion, the subacute inguinal adenitis, the slow course of the disease with a tendency to multiple foci of suppuration, the iliac adenopathy, the positive Frei's reaction when the test is performed with a reliable antigen and the

negative Wassermann and Dmeloos' tests in uncomplicated cases.

Prognosis.—As regards life, this is good, but the chronic morbidity associated with the disease, the absence of any specific treatment and the occurrence of anorectal ulceration and stricture in an unknown proportion of cases, make it rather a serious condition to contend with.

TREATMENT

It should be remembered at the outset that the condition may spontaneously subside and care should be taken in evaluating the efficacy of any particular therapeutic measure. The following are some of the methods advocated in the treatment of the disease :

1. Total or partial enucleation of the glands by operation.
2. The injection of antimony salts, *e.g.*, tartar emetic, neo-stibosan, urea stibamine and Fouadin.
3. The intramuscular injection of Solganol B (watery solution).
4. Injection of glycerine into the infected lymph nodes.
5. Intravenous injection of Frei's antigen filtered through gauze.
6. Injection of sera of patients convalescent from climatic bubo.
7. Protein shock and pyrexial treatment, *e.g.*, milk, T. A. B., and Dmeloos' vaccines.
8. Injection of iodine and its compounds.
9. X-rays.

We have tried complete enucleation in a number of cases with immediate satisfactory results, but in a large proportion of these a troublesome recurrent lymphangitis of the skin of the penis, scrotum, groin and thigh with bouts of fever and joint pains occurs. Further, from the records of the history of anorectal syndrome we have collected so far, a large percentage of these complications has occurred in males who had previously sustained a total enucleation. If this is true, there is a real danger in indiscriminate removal of the glands. In these cases it is quite possible that the first line of defence against the infection having been suppressed by total removal, the virus is enabled to disseminate unchecked into the lymphatics of the pelvis and perirectal regions resulting in perirectal infiltration, rectal stricture, ulceration, etc. Hence complete removal of the glands is not advocated and partial removal is recommended.

In our experience the following procedure has given the best results. In cases of unbroken climatic bubo the patient is given a course of Dmeloos' vaccine or milk injection on alternate days for four to six injections. In the majority of cases the glands subside remarkably. This is followed by a course of Fouadin injections on alternate days till the patient has received at least 50 to 60 c.cm. of the solution. Should any fluctuation be noticed in the glands, aspiration is performed and repeated if necessary. When the glands have almost subsided and

there is no pain or tenderness, the patients are discharged and advised to report as soon as there is any recurrence of the trouble, and the same treatment is repeated. Examination of the anus and rectum should be a routine practice in all cases of apparently-cured climatic buboes.

Our experience with solganol B was limited to a few cases and no definite opinion could be given about its therapeutic efficacy. Injection of neutral iodine or sodium iodide was extensively tried in previous years and was given up. We have no experience of methods 4, 5, 6 and 9 of the above list.

In a few of the cases on which we operated, after the groin wound was completely healed, the patients used to report with recurrent attacks of fever, joint pains, and painful oedema of the lymphatic area around the scar and sometimes of the penis, scrotum and thighs. The condition lasted for a week to 10 days and spontaneously subsided without any treatment. This periodicity in the constitutional symptoms bears a close resemblance to that observed in Hodgkin's disease. Two explanations may be offered for this clinical phenomenon; it may be due to the activation of the virus at the local site or it may mean that each invasion of the virus into the deeper lymphatic fields of the pelvis causes this train of symptoms.

Illustrative cases

I. Indian Christian male, aged 17 years. Denied any previous venereal history. Active agent in sodomy 45 days before he came to the clinic.

Physical examination.—No penile sore or urethral discharge. Long prepuce, with a dirty sub-preputial sac. Bilateral subacute inguinal adenitis of one month's duration. The glands were hard, matted together and adherent to the skin. The glands on the left side were bigger than those on the right. The masses were tender to palpation. Both iliac glands were enlarged, hard and tender. Frei's test was positive. Blood Wassermann was strongly positive. Patient had a few milk injections and one course of neosalvarsan and bismuth. It took five months for the glands to subside. Frei's test was positive again four months after the bubo had completely subsided. Wassermann was weekly positive then. He developed herpes zoster a month after the last neosalvarsan injection.

The points to note in this case are:—(a) the absence of a primary lesion, (b) the clinical condition of the bubo with iliac adenopathy, (c) the positive Frei's reaction, (d) the strongly positive Wassermann reaction in the absence of any clinical evidence of syphilis, (e) the slow response of the glands to antisymphilitic treatment, (f) the persistent positive Frei's reaction nine months after the appearance of the bubo, (g) the mode of infection.

II. Hindu male, aged 20. Exposure to infection three weeks before admission. No history of previous venereal disease.

Condition on examination.—A tiny superficial painless herpetiform sore at the frenal site. Bilateral inguinal adenitis, painful and tender, four days duration. Iliac glands—negative. No skin or mucous membrane lesion. Frei's test was negative at the time of admission. Blood Wassermann—positive. The patient was kept as an in-patient. He ran a high remittent temperature ranging from 102°F. to 104°F. for nearly a week. He was very toxic, slightly delirious, complained of pains in the joints and nape of the neck.

The temperature came down after a week with expectant treatment, but the groin condition became worse with increase in the size of the gland masses with adhesion of the skin. Iliac glands were enlarged, hard and tender at this stage. Frei's test was repeated and was strongly positive with a pustular reaction. Blood Wassermann reaction became strongly positive. No clinical evidence of syphilis. He had a course of Dmeleos' injections without much benefit. Multiple points of fluctuation appeared in both groins. At this time, nearly six weeks after the appearance of the bubo, he developed lymphatic oedema of the skin of the penis and scrotum. The Frei's test was repeated for the third time and was strongly positive, but the blood Wassermann reaction was negative. The patient defaulted and no further observation could be made.

The points worthy of note in this case are:—(1) The acute onset with severe constitutional symptoms of toxæmia; (2) the initial negative Frei's test which became positive after two weeks, and (3) the positive Wassermann reaction in the early stages of the disease which became negative in two months in the absence of any history or clinical evidence of syphilis.

III. Hindu male, aged 20. Denies any previous venereal disease. Exposure to infection two weeks before admission.

Condition on admission.—25th September, 1933. A soft undermined painful sloughing sore at the frenal site. No urethral discharge. Groin glands, skin and mucous membrane—negative. Dark ground examination of the sore for *Spirochaeta pallida*—negative. Wassermann reaction—negative. Local treatment with calomel and sulphur was given. The sore did not heal but was stationary. On 22nd October Dmeleos' intradermal test was positive. A course of Dmeleos' injections were given on alternate days, and the sore showed signs of rapid healing. On 9th November the patient developed enlarged tender glands in the left groin. Within a week the glands became considerably enlarged, matted and tender. The left iliac glands were also enlarged. The frenal sore had healed by this time. On 15th November Frei's test was doubtful-positive. A course of Fournier injections were given without any benefit. On 24th November Frei's test was strongly positive with a tendency to pustulation. Wassermann reaction was negative. On 5th December complete enucleation of the glands was performed under spinal anaesthesia. The wound healed in two weeks and the iliac glands disappeared.

Note.—This is a case of chaneroid with climatic bubo in which the virus of climatic bubo was incubating while the chaneroid was healing.

IV. Hindu male, aged 26. Attended the clinic in 1922 with bilateral buboes. Enucleation of the left groin glands was then performed. The glands in the right side subsided. Frei's test was not then performed. Blood Wassermann was negative. He came to the clinic 12 months afterwards with a history of repeated attacks of fever, pains all over the body, and painful swelling in both groins.

Condition on admission.—No penile sore, or scar or urethral discharge. Scar of operation in the left groin. Right groin glands enlarged, hard and painless. Lymphatic oedema of the skin of the upper part of the thigh and gluteal regions on the left side. Temperature 101.4°F. Complained of severe pains all over the body. Frei's test was positive and Wassermann-negative. The condition subsided with rest in the hospital and calcium chloride injections. The patient has since been coming to the clinic at intervals of six to eight weeks with the same recurrent attacks of fever, pains, etc. The oedema of the skin round about the old operation scar was becoming more marked and permanent with each attack. Repeated blood examination for filaria was negative. Frei's test was positive every time. Rectal examination revealed nothing abnormal.

This case illustrates the fact that the virus of climatic bubo may show periods of activity with intervals of

comparative quiescence. We have had three more such cases, and, whether it is a coincidence or not, all the cases have sustained enucleation of the glands at the time of the first attack.

V. European male, aged 25. A Swedish sailor who contracted the infection outside India. History of exposure to infection at Mauritius with a native woman 18 days before he was seen by us. Noticed a penile sore two days, and the swelling in the groins eight days after exposure. Small painless erosive sore at the frenal site. No urethral discharge. Bilateral inguinal adenitis of the size of a closed fist. The glands were hard, matted together and tender. The skin over the glands was slightly oedematous and purplish in colour. Both iliac glands were enlarged, hard and tender. Dark-ground examination of the sore was negative. Frei's test was strongly positive. Blood Wassermann was a single plus. Had a temperature of 100.2°F. on admission. Patient left Madras after three days as his boat sailed.

GENITO-ANORECTAL SYNDROME

This grave clinical condition has, thanks to the specific diagnostic value of Frei's test, been recognized as lymphogranulomatous in origin. It was for years thought to be a syphilitic manifestation, the so-called anorectal syphiloma of Fournier, though the condition was found resistant to antisyphilitic treatment and the Wassermann reaction was frequently negative. Koch's infection was also suspected in these cases on account of the close similarity in the histological appearance of the lesions. In our own experience the disease was mistaken for infective granuloma of the anus and rectum. In women it was considered to be gonorrhœal in origin. Many of these patients had fallen into the hands of surgeons who variously diagnosed the condition as fissure of the anus, fistulo-in-ano, inflamed piles, and malignant disease. It is only within the last few years that its ætiological relationship to climatic bubo has been recognized. The chain of evidence is almost complete, but Frei is still in doubt whether these anorectal complications are the direct results of the activity of the virus of climatic bubo, or the reaction of sensitized tissues to non-specific antigen and secondary infection. The localization of the disease in the perirectal and perianal lymphatics is stated to be more common in women on account of the peculiarity of the lymph drainage of the genitals, but in our series the males predominated over the females in the proportion of 2 to 1.

The cases

Eighteen were males whose ages varied from 16 years to 55 years, and eight were females aged from 15 to 32 years.

Among the males, six patients were professional passive agents in sodomy. Among the females five were prostitutes and three married women. There was a history of antecedent bubo in 11 males and in 1 female. In 10 of the male patients there was a scar indicating previous operation. The duration of the

disease varied from one month to 10 years. The average was three and half years.
 Frei's reaction.—

	Males		Females
Positive reaction ..	13	Positive reaction ..	7
Negative reaction ..	2	Test not performed	1
Doubtful reaction	1		
Test not performed	2		
TOTAL ..	18	TOTAL ..	8

Blood Wassermann reaction.—

	Males	Females
Strongly positive ..	1 case	3 cases
Positive ..	3 cases	1 case

In none of these Wassermann-positive cases was there any active clinical evidence of syphilis, and in the series among females the Wassermann-positive cases were all prostitutes.

The clinical conditions found on examination either alone or in combination are tabulated below :—

	Males	Females
Perianal ulceration ..	13 cases	5 cases
Elephantoid condition of the anal margin ..	8 "	3 "
Elephantiasis of the scrotum and penis, or labia ..	3 "	5 "
Perianal fistulæ ..	4 "	1 case
A rigid rugose, ulcerated condition of the anal canal and lower part of the rectum ..	16 "	4 cases
Stricture of rectum ..	10 "	6 "
Ulceration of labia and fourchette	2 "

Perianal ulceration.—This was found in the majority of cases. The ulcer, single or multiple, was irregular in outline, granulomatous with thickened nodular polypoid edges, usually situated in the anterior and lateral aspects of the anus and sometimes extending on to the perineum. The ulcers stop short of the anal margin.

Elephantoid condition of the anus.—Though not so common as ulceration this condition was found always associated with it. The anus is surrounded by multiple elephantoid masses of tissue covered by skin and ulcerated or scarred on their inner aspects. Often the elephantoid masses were separated by deep fissures extending on into the anus. These masses were often mistaken for piles and operations performed for their removal.

Elephantiasis of scrotum or labia.—The latter was more common and formed an important part of the genito-anorectal syndrome in women. The condition may be unilateral or bilateral, involving part or whole of the labia.

Perianal fistulæ.—These fistulæ, single or multiple, were found communicating with the perirectal space.

A rigid rugose condition of the mucous membrane of the anal canal and rectum.—This is the most characteristic lesion of the syndrome.

This lesion results from a progressive infiltration of the perirectal and anorectal lymphatics. In the early stages of the condition the mucous membrane of the rectum and anal canal is intact and non-ulcerated except the rugosity and rigidity of the wall. The perirectal inflammatory infiltration may go on to organization, resulting either in a cylindrical narrowing of the lumen or a ring-like stricture depending upon the location and extent of the lesions. Later, as a result of either trauma of hardened faeces, or secondary infection of the wall, the mucous membrane may become ulcerated. In all the cases the mucous membrane over the site of stricture was usually smooth and non-ulcerated. The ulceration was found only below the stricture. This hyperplastic inflammatory infiltration was confined to the lower 2½ to 3 inches of the bowel.

Inflammatory stricture of the rectum.—In all these cases the stricture was situated within reach of the examining finger. The distance of the stricture from the anal margin was 2 cm. in 5 cases, 4 cm. in 5 cases, 5 cm. in 4 cases, 6 cm. in 1 case and 8 cm. in 1 case, thus the majority of the strictures were situated between 2 and 6 cm. from the anus.

Character of the stricture.—In 13 cases the stricture was ring-like and in three cases it was cylindrical; the latter were all in males. In all cases but three, the tip of the index finger could be passed with a little difficulty. The mucous membrane over the stricture in all the cases was intact and non-ulcerated. The mucous membrane of the bowel proximal to the stricture was felt to be normal, soft and supple, in all cases except one.

Symptoms of anorectal syndrome.—A history of passing blood and pus from the rectum was the commonest complaint. An increasing difficulty in defæcation was observed in cases with stricture. Rectal tenesmus alternating constipation and diarrhoea, a sensation of imperfect emptying of the bowel were some of the other symptoms. It is remarkable how in some of the cases of almost impassable strictures the patients have been going on for years without symptoms of intestinal obstruction. The general health of the patients was satisfactory. There was no cachexia or emaciation.

Diagnosis.—The following points are helpful in the diagnosis of this condition :—

1. History of antecedent bubo.
2. Frei's positive reaction.
3. The long duration of the disease.
4. The clinical peculiarity of the syndrome as regards the site and extent of lesions.
5. A negative Wassermann reaction (in many cases) and the absence of any response to anti-syphilitic treatment.

Treatment.—The patients could not be kept under observation for a length of time sufficient to determine definitely the results of treatment.

In early cases of the syndrome with commencing stricture the injection of Fouadin combined with a regular passage of rectal bougies have produced encouraging results in our hands. Solganol B (watery) was tried in a few of the cases with satisfactory results, but the patients were lost sight of after they got a little better. In long-standing cases of stricture complicated by perirectal fibrosis, fistulae, etc., nothing short of surgical ablation of the diseased part of the bowel preceded by a colostomy would seem to be of any avail.

Illustrative cases

VI. Hindu male, aged 16, of a feminine type. Confessed to having been a victim to sodomy (passive agent). Complained of ulcer in anus of one month's duration. Developed small painful bubo on both groins fifteen days after the ulcer appeared in the anus.

Condition on admission (26th October, 1933).—No penile sore or scar. No urethral discharge. A small fluctuant bubo at the extreme outer end of both groins. Other glands in the groins were not palpable. An irregularly oval ulcer with thickened edges and granulomatous base situated in the right anal margin. Right iliac glands were palpable and hard. Rectal examination revealed nothing abnormal either in the anal canal or rectum. Frei's test was strongly positive. Wassermann and Dmelcos' tests were both negative. He had a course of solganol B injections. The ulcer did not show any sign of healing. Then he was given 10 injections of Fouadin on alternate days. The buboes in the groin subsided and the ulcer in the anus showed signs of healing. The patient defaulted at this stage. He came again three months later, complaining of passing blood and pus in the stools.

Condition after three months.—The buboes in the groins have completely healed, though the glands both inguinal and iliac were palpable and painless. A thickened recently-healed scar was visible at the site of the old ulcer near the anal margin. Digital examination of the rectum was very painful and revealed a rigid, polypoid condition of the mucous membrane with a commencing ring-like stricture 5 cm. from the anal margin. Frei's test was repeated and found strongly positive. Wassermann—negative.

This is an interesting case of anorectal syndrome from several aspects.

1. The primary lesion in this case was at the anus and represented by the ulcer.

2. The lymphatic gland at the outer end of the inguinal group on both sides was secondarily infected from the anal ulcer.

3. The absence of any lesion of the rectum during the early stages (four to six weeks) of the disease.

4. The insidious development of the anorectal syndrome within a space of three months.

5. The uselessness of either solganol or Fouadin in preventing the onset of this complication though the latter might have helped to heal the primary lesion.

6. The persistent positive Frei's reaction and the repeated negative Wassermann reaction.

VII. Male, aged 27.

Previous history.—Attended the clinic in January 1932 with typical secondary syphilis and a strongly positive Wassermann. He had two courses of anti-syphilitic treatment amounting to 6 grammes of

neosalvarsan and 4 grammes of metallic bismuth during 1932. He developed jaundice during the middle of the first course and the treatment had to be interrupted for a period of nearly six weeks. He was very irregular in attendance during the second course. In January 1933, the third course of injections was started and again he was irregular in attendance and, in spite of this, his blood Wassermann was repeatedly negative after the first course of injections and still remain so. (The blood was tested six times in two years.) In July 1933, he complained of passing blood and pus in his stools. Duration two months. Examination revealed a raised indolent ulcer all round the anal margin and slightly extending into the anal canal. Rectal examination was painful and showed a rough raw condition of the mucous membrane of the rectum with no stricture or narrowing of the canal. Denied any fresh exposure to infection either natural or unnatural. Groin glands slightly palpable. No penile lesion. Frei's test was positive and Wassermann negative. In spite of the repeatedly negative Wassermann he was given the fourth course of injections (3.6 grammes of neosalvarsan and 2 grammes of bismuth), on the supposition that the rectal condition may be luetic. At the end of the fourth course the condition was distinctly worse.

Proctoscopic examination in March 1934.—A scarred area, a third of an inch proximal to the anocutaneous margin with superficial ulceration of the anus above this covering the anterior third of the rectal wall and extending from 1 inch to 1½ inches in width. Definite narrowing of the anal canal. Ulceration and scarring of lymphogranuloma inguinale. Frei's test was repeated and was still positive. Wassermann—negative. The patient is attending the clinic and receiving Fouadin injections and dilations with rectal bougies.

VIII. Hindu male, aged 34 years, married.

Previous history.—Had gonorrhoea in 1921 and bubo in 1922. Underwent an operation for the latter in one of the city hospitals in Madras. In 1923 he noticed he was passing blood in the stools. The condition was diagnosed as anal fissure and was operated on at Bangalore. Since then the anal ulcer has not healed. In June 1933 he had another operation for fistula-in-ano in this hospital.

Condition on admission (November 1933).—A linear deep scar in the left groin. No penile sore or scar. No urethral discharge. Glands of the groin were not palpable. An irregular indolent granulomatous ulceration involving the perianal region and extending for nearly 1½ inches along the perineum. The edges of the ulcer were thickened and nodular. Digital examination of the rectum revealed a very tight almost impassable stricture 5 cm. from the anal margin. The mucous membrane below the stricture was rugose, rigid, and ulcerated. Frei's test was strongly positive and Wassermann negative. Pathological examination of a section from the rectum was reported as chronic, inflammatory and characteristic of lymphogranuloma.

IX. Hindu male, aged 25. Victim of sodomy 4½ years ago. Ulcer in anus. Passing of blood in stools and difficulty in defaecation of four years' duration. His condition was thought to be infective granuloma and he had received in previous years a lot of antimony injections without any benefit.

Condition on admission.—Old circumcision scar. Groin glands on both sides, palpable. Elephantoid condition of the scrotum. Extensive nodular ulceration of the perianal region, perineum and natal folds and extending into the anus and rectum. Elephantoid condition of the external parts of the anus (*vide figure 3*).

Digital examination.—A hard nodular ulcerated condition of the mucous membrane with a very tight stricture 6 cm. from the anal margin. The finger could not be passed through the stricture. Frei's test was negative

twice with an antigen of one-in-ten dilution. Wassermann was negative. The patient absconded before any further investigation could be made. The peculiarity in this case is the negative Frei's test in spite of the extensive long-standing clinically-typical condition of the anorectal syndrome.

X. Female, aged 25, a prostitute. Complained passing of blood and pus in stools. Duration 2½ years.

Condition on admission.—Scars of healed ulceration on the lower third of the labia and fourchette. Painless

the stricture was rugose and rigid. The examining finger was stained with pus and blood. Frei's test was strongly positive. Wassermann—negative. Examinations of smears from methua, cervix and rectum were negative to gonorrhoea. In this case the pathological condition was the stricture with infiltration of the wall of the rectum above the stricture which is rather unusual. She had no other manifestation of the syndrome. No information is available regarding the husband.

XII. Female, aged 25, a clandestine prostitute.

Complaint.—Ulceration of genitals and external piles. Duration 9 months.

Condition on admission.—Groin glands on both sides palpable, discrete and painless. A scar on the right groin. (History of bubo three years ago) Extensive indolent looking ulcerations on both lips of the vulva. An indurated healed scar on the fourchette. No speculum examination was done. Anal outlet surrounded by folds of skin with ulcerations in between the folds. Digital examination revealed a commencing ring stricture 4 cm. from the anal margin. The mucous membrane below the stricture felt nodular and rigid. Frei's test was strongly positive. Wassermann—negative. Tests for gonorrhoea negative. The ulcerations healed with Foudin injections and the stricture was dilated with bougies.

Elephantiasis of the vulva with or without ulceration.—There were four cases of elephantiasis of the labia with ulceration of the fourchette and vaginal wall. There was no inguinal adenitis or anorectal lesion in these cases. Both the Frei's test and the Wassermann reaction were strongly positive. The ulceration healed with antisyphilitic treatment, but the elephantoid condition remained uninfluenced. The question in these cases is whether the labial condition was due to the virus of climatic bubo or of syphilis or of both. Vulvar elephantiasis has been known to be caused by diseases other than the virus of climatic bubo. We have seen a good number of cases of elephantiasis of the vulva, secondary to infective granuloma, syphilis and filaria. In some of the cases where Frei's test was performed the result was found negative. Therefore, it is very likely that elephantiasis of the vulva in women may have a varied aetiology and should not be considered as pathognomonic of lymphogranuloma in the absence of other lesions of the genito-anorectal syndrome. A positive Frei's test in the absence of other venereal diseases is highly suggestive, but in our cases they showed a strongly positive Wassermann reaction also.

Summary and conclusions

1. This report is based on the investigation of 183 cases of climatic bubo and allied conditions during the year 1933.

2. The results of Frei's test carried out in these cases and others are given. Attention is drawn to the fact that a positive reaction may be obtained long after the entire disease has subsided.

3. The clinical features are dealt with in detail.

Fig. 3—A case of genito-anorectal syndrome (vide case IX).

discharge from the vagina and groin glands not palpable. An irregular granulomatous ulcer about 1½ inches in diameter on the left anal margin with thickened edges. Elephantoid masses surrounding the anal margin. Digital examination of the rectum revealed a rigid polypoidal and ulcerated condition of the mucous membrane with a ring-like stricture 2½ cm. from the anal margin. The stricture admitted the index finger with some difficulty. The mucous membrane on the proximal side of the stricture was normal. Frei's test was strongly positive with a diffused infiltrative erythema all round for nearly 1½ inches. Blood Wassermann positive-strong even after repetition but the patient had no clinical evidence of syphilis. Urethral and cervical smears were negative to gonococci. As the patient is a prostitute, it is quite likely that the case is one of latent syphilis with lymphogranuloma of the rectum.

XI. Female, aged 32, married.

Complaint.—Passing of blood and pus in stools 1½ years' duration. No previous history of bubo or ulcers in the genitals.

Condition on admission.—No urethral discharge. Mucoid discharge from the cervix. No ulceration nor scarring of the labia. Groin glands not palpable. External parts of the anus nothing abnormal. Digital examination of the rectum revealed a ring-like stricture 4 cm. from the anal margin. The mucous membrane below the stricture was slightly granular to the feel but was otherwise soft and supple. Stricture admitted the index finger. The mucous membrane proximal to

4. The association of climatic bubo with other venereal diseases is pointed out but it has no effect on the course of climatic bubo.

5. The question of the behaviour of Wassermann reaction in climatic bubo is discussed. In a certain proportion of cases of climatic bubo, diagnosed clinically, as well as on the basis of the Frei's test, yield a positive Wassermann reaction though there is no clinical evidence of an associated syphilitic infection. The Wassermann reaction may become negative without any antisyphilitic treatment.

6. Some points in the diagnosis of this condition are stressed.

7. Various methods of treatment employed by different workers, have been mentioned and those methods which have been carried out in this hospital have been described. Both a course of Dmeleos' vaccine and milk injection followed by Fouadin injections have proved of great value in many cases of unbroken climatic bubo. Surgical treatment is confined to aspiration wherever there is fluctuation. Partial removal of the gland is a safer method than complete enucleation as there is less risk of the occurrence of complications.

8. Various clinical manifestations of genito-anorectal syndrome have been described and its special incidence in persons addicted to sodomy is pointed out. The anorectal syndrome was found to be commoner in men than women. This finding is in contrast to that of other workers. Perianal ulceration was found to be the commonest condition. The rectal stricture which may be ring-like or cylindrical is usually situated 2 to 6 cm. from the anus. These conditions are important as their relationship with the climatic bubo virus is a recent observation, and it is believed that a great many cases of rectal stricture, elephantoid condition of scrotum and labia, etc., of erstwhile doubtful ætiology are really of this nature.

9. Five cases of climatic bubo and seven cases of genito-anorectal syndrome have been described with a view to illustrating some of the clinical features of these conditions.

My thanks are due to the staff of the pathological department of the Medical College, Madras, particularly to Dr. Goyle and Dr. Krishnaswamy for the preparation and supply of Frei's antigen and for various suggestions in the preparation of this article. My thanks are also due to the staff of the X-ray Institute for the clinical photographs. Lastly, I must express my indebtedness to my clerk T. K. Ramathan, for the valuable help he rendered in preparing the statistical portion of the article from the records of the department.

FILARIAL AFFECTIONS OF THE MALE GENITAL TRACTS

By P. N. RAY, B.A., M.B., F.R.C.S. (Eng.)

Honorary Junior Visiting Surgeon, Medical College Hospitals, Calcutta

DURING the past few years very important advances have been made in our knowledge of the pathology of filariasis and its complications. In the present review, attention is drawn to some of the more recent advances, regarding the affections of the male genital tracts.

The filarial worm (*Wuchereria bancrofti*) in its adult or mature stage is an inhabitant of the lymphatic system of man. O'Connor (1932) and his colleagues have recently brought forward convincing evidence that the filarial worm itself is the essential factor in the syndrome associated with *W. bancrofti* infection. Lymphatic filarial obstruction has been explained in terms of damage done to the main lymphatic trunks or to the corresponding lymphatic glands by the immature larvæ or adult worms. But evidence has gradually accumulated that adults may live in numbers in the smaller lymphatics of the limbs and on the distal side of lymphatic nodes. The conditions then are such that so long as the lymph circulation remains reasonably normal every microfilaria from these adults must pass through the nodes concerned and the passage will induce a considerable cellular reaction in them. Persistent passage of embryos is then likely to be followed by fibrosis and lymphatic obstruction (Lane, 1931). If the length of the testicular lymphatics and their termination in the juxta-aortic lymph glands are kept in mind, it would not be difficult to understand the pathological changes that occur. In the following pages an attempt will also be made to consider the factors that determine the differences in the type of genital lesions.

Lymphatic varix of the cord or lymphatic varicocele

This is very frequently the earliest, or the only manifestation of the filarial infection of the male genital tract. The condition deserves careful attention because of its liability to lead to more serious complications and for its being mistaken for a bubonocoele.

Clinically, the patient may complain of a thickening of the cord but usually it is characterized by the absence of any symptoms. If an early diagnosis is made, it is usually during a routine examination of a patient. It resembles a varicocele in its fullness of the cord and in imparting the sensation of a 'bag of worms' but it is differentiated by the fact that it does not readily disappear when the patient lies down. The maximum fullness of the cord is noticed towards the evening and it almost disappears in the morning after a night's rest.

Although an impulse may be present on coughing, little difficulty will be found in differentiating the condition from an inguinal hernia or bubonocoele, if the characteristic features are recognized. It is, however, necessary to point out that, in about 5 per cent of cases, a lymphatic varix is associated with a bubonocoele. It may also be mistaken for a diffuse hydrocele or lymphangioma of the cord. In case of doubt, examination of the aspirated fluid may reveal microfilariæ or chyle. The parent worm and microfilariæ are usually present in these varicose lymphatics or in close proximity to them.

Excision of the lymphatic varix is not justified as the risk of cellulitis or the persistence of a chyloous fistula is very real. In this connection, it is of interest to mention that a case of lymphatic varix of the groin was successfully treated by the writer with local injections of sodium morrhuate solution (B. D. H.). The semi-fluctuating swelling was converted into a firm solid mass, without giving rise to any lymphatic edema of the lower extremity.

Endemic funiculitis

This condition may be acute, subacute, and chronic or recurrent. The acute type usually ends in a septicæmia and, clinically, it is so well known that no further description is needed. On culture of pus, streptococci, *B. coli*, etc., are commonly obtained. The condition starts as a lymphangitis of the cord, the severity of which is due to a secondary bacterial infection. Thrombosis of the pampiniform plexus is usual. This condition is associated with a high rate of mortality (50 to 75 per cent).

With regard to the subacute, chronic or recurrent types, the prognosis is better. It is commonly associated with a nodular epididymo-orchitis. Owing to the presence of a painful inguino-scrotal swelling, absence of an impulse on coughing, vomiting, abdominal pain and constipation, it is not always easy to differentiate the condition from a strangulated inguinal hernia. In case of doubt it is best to operate. With regard to termination, the condition either subsides or ends in suppuration.

In a recent case, suppuration was noticed within the inguinal canal and along the spermatic cord in association with thrombosis of the lymphatics and pampiniform plexus. The testicle was found to be hard in consistency and much enlarged, but the associated hydrocele was not infected. No microfilariæ were present in the peripheral blood. The blood count was also interesting, the total white cell count being 10,600 per c.mm. and the percentage of eosinophil cells nil. On culture of the pus, *B. coli* and *B. proteus* were obtained. The complement-fixation test was positive. The patient made an excellent recovery.

Hydrocele

It is well known that a hydrocele of the tunica vaginalis may be secondary to some disease of the testis or epididymis, e.g., gonococcal epididymo-orchitis. An effusion into the tunica vaginalis may also be due to obstruction to venous or lymphatic flow, or may be the result of irritation of the lining membrane itself. In the majority of cases in this country the so-called idiopathic or primary hydrocele is filarial in origin. This statement is based on the following facts:—

1. In nearly 10 per cent of cases, the hydrocele fluid contains microfilariæ (Rao, 1931).

2. Adult filariæ have been found in the tunica vaginalis in a large number of cases.

3. Lymph varix of the cord and endemic funiculitis are usually followed by a hydrocele.

4. The presence of bilateral hydroceles in case of scrotal elephantiasis is rather the rule than the exception.

5. In cases of long standing, nodular epididymo-orchitis is present, and mature filariæ, dead or living, have been found mostly in the epididymis. Sections of small nodules show eosinophil granulation tissue.

6. Hydroceles are found to be very common in filarial areas and rarer in non-endemic areas.

Observations by Brug (1931) in the Dutch East Indies confirm Korke's statement (1929) that the 'typical forms' of microfilaria seem to be more associated with affections of the genitalia and the 'atypical forms' more with elephantiasis of the limb. The atypical form of the microfilaria of *W. bancrofti* of Korke appears to be identical with those of *W. malayi* of Brug. From the morphology of the embryo filaria and its development in a particular mosquito, this latter is undoubtedly a distinct species. The adult filaria, however, has not yet been discovered. It is necessary to point out that Acton and Rao (1930) have not mentioned any such morphological differences. According to them, in hyperendemic region the first glands through which the larvæ pass are subjected to repeated trauma and are severely damaged; this results in elephantiasis, usually of the leg; while, in regions of low endemicity, the larvæ pass through the glands in the limbs and reach the juxta-aortic group of lymph glands which they damage and the result is lymph varix of the cord, hydrocele and chylocele.

The operation for radical cure of hydrocele is regarded as an item of minor surgery. Of the late complications that may occur, the following are of importance from our point of view, e.g., scrotal or penile elephantiasis, lymph scrotum and chronic epididymo-orchitis.

Chronic epididymo-orchitis or fibrosis of the testis

In the literature on genital filarial affections, little attention appears to have been paid to this condition. It is obvious that the investigation

of the pathological relationship of the filarial worm to chronic enlargement of the testicle is beset with many difficulties. A case recently described by the writer is unique in several respects (Ray, 1934), and throws some light on this obscure condition.

Clinically, the condition is seen—

- (i) with or without scrotal elephantiasis,
- (ii) in association with a hydrocele of the tunica vaginalis,
- (iii) with partial or complete occlusion of the vaginal sac, or
- (iv) with a lymphatic varix of the cord,

or the condition may persist for years after an operation for the radical cure of hydrocele or scrotal elephantiasis.

These facts and the pathological findings clearly demonstrate the filarial origin of this condition. A summary of the pathological appearances of the case, described by me, is given here:

The epididymis was comparatively more enlarged than the body of the testis, and, on section, the former presented a homogeneous necrotic mass in its centre. Microscopically, sections of adult female worms and numerous embryos contained within the uterus were seen within the dilated lymphatics under the tunica albuginea (plate XI, figs. 1 and 2). The sections, through the body of the testis, showed scattered areas of round-cell infiltration with a varying number of plasma cells and fibroblasts in the interstitial tissues and in the neighbourhood of the seminiferous tubules (plate XI, fig. 6). Atrophy of the tubular epithelium and fibrosis were noted in certain areas. No endarteritis obliterans was noticed: contrast this with plate XI, fig. 7. The epididymis presented an interesting picture. It contained a mass of necrotic material which had undergone hyaline degeneration (plate XI, fig. 3). Sections of degenerating adult filaria could be identified. This area was surrounded by a zone of round-cell infiltration with some admixture of plasma and eosinophil cells and foreign-body giant cells (plate XI, fig. 5). This picture resembled that of a caseating tubercle, but no tubercle bacilli could be demonstrated. Blood vessels did not show any endarteritis obliterans or perivascular infiltration. As no evidence of secondary pyogenic infection could be discovered, the conclusion was reached that the adult filaria was the real or essential cause of the pathological changes in the testicle. They vary at different levels (plate XI, figs. 1, 2 and 5). The presence of eosinophil cells is most marked near the vulval end of the worm, because of the discharges of the embryos and uterine fluid which act as irritants (plate XI, fig. 2).

It is of interest to note that if the test tube containing a specimen of blood is left undisturbed for a few hours, the microfilariae appear

to huddle together into a bunch, and, if they are nearly dead, leucocytes are found adhering to them. This phenomenon appears to take place also *in vivo*. According to O'Connor (1932), the remains of the dead parasite are shut off like a foreign body from the neighbouring tissues in a 'cocoon-like case' of hyaline material. Eventually, the whole area becomes fibrosed. Such is probably the ultimate fate of the testicle, if it escapes suppuration.

With regard to diagnosis, this condition has to be differentiated from (1) a new growth of the testicle, (2) syphilitic orchitis or gumma, (3) haematocoele and especially at an early stage from (4) tuberculous or *B. coli* epididymo-orchitis. The most important diagnostic signs are the comparatively greater enlargement of the epididymis, the presence of testicular sensation, lymph varix of the cord and the history of recurrent attacks of testicular pain with successive increase in size or lymphangitis of the scrotum. Microfilariae or chyle may be present in the aspirated fluid from the sac of the tunica vaginalis. During the later stages, especially after suppuration has occurred, it is likely to be mistaken for a breaking down gumma. Gonococcal infection may be excluded by negative prostatic smears. Clinically, it is very difficult to differentiate the early case from tuberculous epididymo-orchitis, and many testicles have been removed in error. But two clinical features may be helpful in the diagnosis. If the testicle is examined towards the evening, a lymphatic varix of the cord will be seldom missed, and, secondly, if the patient is interrogated with tact and sympathy, the history of the occurrence of post-coital testicular pain will usually be forthcoming. When in doubt, rest in bed for a few days and the use of a suspensory bandage are advisable. In case of filarial disease, the epididymis suffers more than the testis, and occlusion of the ductuli efferentes or the duct of the epididymis causes retention of the contents of the seminiferous tubules. This type of pain is probably due to increased tension and congestion of the testicles which will ultimately induce chronic inflammation and fibrosis. Unfortunately, this condition is frequently bilateral and in consequence sterility appears to be a common sequela.

Complete obstruction of the ductus deferens does not, as one might suppose, cause atrophy or diminution in the size of the testis, and in this condition the testicle may actually increase to an enormous size. In the light of the pathological findings, described above, it appears reasonable to conclude that the inflammatory reactions are mainly due to the presence of the adult filariae and their embryos. The fate of such a testicle may be suppuration, degeneration or fibrosis. The latter change appears to occur after organization of the remains of the dead filaria. The diagnosis of a fibrotic testicle (plate XI, fig. 8) of this type is very difficult.

Fig. 1.—(Upper). Note the scanty cellular reaction, around the dilated lymphatic, containing sections of adult worm. (1/6 by 2 Zeiss).

Fig. 2.—(Lower). Showing oblique sections of an adult female filaria, containing numerous microfilariae within the uterus. Note the cluster of eosinophil cells. (1/6 by 2 Zeiss).

Fig. 5.—Section of adult worm within a dilated lymphatic of the testis. Note the ovary contained within the uterus. (1/12 by 2 Zeiss).

Fig. 3.—(Upper). Showing hyaline degeneration of epididymis. (1/6 by 2 Zeiss).

Fig. 4.—(Lower). Section of epididymis. Note the giant cells. (2/3 by 2 Zeiss).

Fig. 6.—(Upper). Showing cellular reactions in chronic epididymo-orchitis (filarial). (2/3 by 2 Zeiss).

Fig. 7.—(Middle). Syphilitic orchitis, showing characteristic changes. Note endarteritis obliterans. (6L by 12X Leitz).

Fig. 8.—(Lower). Fibrosis of testicle (filarial). (2/3 by 2 Zeiss).

Microscopically it is differentiated from a new growth by the signs of chronic inflammation and fibrosis, particularly around the seminiferous by the absence of endarteritis obliterans (plate XI, fig. 7). A negative Wassermann reaction will not exclude the possibility of syphilitic orchitis. The therapeutic test may be given a trial to see its response to treatment.

With regard to the laboratory tests, a few words are necessary. When positive, these are of value, but the examination of the peripheral blood for the presence of microfilariae is a test on which much reliance cannot be placed. During an attack of lymphangitis, microfilariae tend to disappear from the blood. Similarly in an early case, when there is no lymphatic obstruction, there is a constant high eosinophilia indicating a leakage of toxin into the peripheral blood. When lymphatic obstruction is complete, as in elephantiasis, the eosinophil count is practically normal.

Elephantiasis of the scrotum and penis

The pathological changes associated with lymphatic stasis, oedema and elephantiasis have been considerably elucidated; it is, however, not quite clear why the adult filariae should be present in the spermatic cord and epididymis in such large numbers. It appears that as a result of lymphatic blockage at a higher level, e.g., pre-aortic group of glands and cysterna chyli, aberrant migration of the adult worms takes place into these organs. It has also been suggested that the use of the lymphatic or the blood 'escalator' by the infective larvae (Lane, 1932), and the local suitability of the tissues are two important factors on which the distribution of the disease is dependent. According to Romiti (1933), the cord is the habitat of the fertile adult in most cases. It has also been suggested that the genital tracts are attacked by a different species of filaria. An important fact which is very often overlooked is that the filarial affections of the male genital tract occur after puberty during a period of increased vascularity of the parts associated with sexual maturity and activity. It is in favour of the 'theory of blood escalator'. The youngest patient that I have seen suffering from serotal elephantiasis was between 14 and 15 years of age. According to Iyengar (1933), the earliest age for the presence of microfilaria in the peripheral blood is 2½ years, for occurrence of lymphangitis 8 years, and for elephantiasis of the leg 11 years.

What are then the causes of the comparative immunity of children from elephantiasis? No proof is available in support of natural immunity. It is more likely that the immature larva in its passage along the lymphatics or the lymph gland is held up and is either imprisoned or destroyed by an active cellular reaction. The absence, or certainly the extreme rarity, of genital elephantiasis in childhood is possibly due

to the absence of vascularity of the parts and their non-development before puberty.

It is now generally recognized that the tropical elephantiasis is frequently not caused by filaria. The reason for the greater frequency of elephantiasis nostra in the tropics is the greater exposure of the skin to infection. Kuntzen, who writes from Payer's clinic, believes that lymphatic obstruction plays the major rôle, the crsipeloid streptococcal infection being secondary and acting only to intensify the course of the disease (Muller and Jordan, 1933).

Lymph serotum

Clinically, lymph serotum is differentiated from serotal elephantiasis by its reddish-brown colour, thick and velvet-like integument, and by the presence of vesicles or small cysts, either discharging or encrusted. The discharging fluid may be clear or chylous and may amount to several ounces in 24 hours. It may continue for several days causing great prostration and locally giving rise to an eczematous condition of the skin.

With regard to the mechanism of lymph serotum, Aeton and Rao (1930a) have pointed out that it usually occurs after an operation for radical cure of hydrocele. I have also seen cases in which lymph serotum has appeared after operation for serotal elephantiasis, after radical operation for inguinal hernia, and after excision of lymphatic varix of the cord, respectively. The treatment is unsatisfactory. With rest in bed and local applications, the discharge of fluid usually ceases for a time. In one case, local x-ray therapy during the quiescent period proved very beneficial.

Causes of inflammatory reactions

Authoritative opinion is still divided on this subject. There is no doubt that inflammation or suppuration is common in genital filarial affections because of the liability of the parts to chafing, intertrigo or scabies. Recent investigations tend to show that inflammatory reactions are probably due to the liberation or production of toxic substances during the process of disintegration and absorption of the dead worm. The part played by the microfilarial periodicity regarding passage and destruction of the embryos is yet to be clearly defined. In my personal experiences, in many cases no evidence of secondary infection could be obtained. Giglioli (1933) states that he has never obtained a positive culture from serum drawn by puncture from the inflamed tissues of uncomplicated typical filarial lymphangitis and lymphadenitis, when these have not progressed to suppuration. In some cases even the smear proved negative and the culture remained sterile.

STREPTOCOCCAL SEPTICÆMIA AND FILARIAL ORCHITIS

By M. N. DE, M.B., M.R.C.P. (London)

Professor of Pathology

and

K. D. CHATTERJEE, M.B.

*(From the Department of Pathology,
Medical College, Calcutta)*

STREPTOCOCCAL SEPTICÆMIA is usually due to the hæmolytic strain. The organisms of this group give rise to lesions which are less localized, tend to spread and are more often fatal than those caused by other pyogenic bacteria. It was Rosenbach who, in 1894, first pointed out the above characters of the streptococcal lesions. The severity of a streptococcal infection depends on two factors, viz. (i) the invasiveness of the microbial strain, i.e., its virulence and toxigenic properties, and (ii) the local and general resistance of the individual host. The remarkable property of spreading and invasiveness can be

(Continued from previous page)

Summary

In this paper, the recent advances in our knowledge regarding filarial affections of the male genital tracts have been discussed and reviewed. In particular, attention has been drawn to a condition, which has been described as chronic epididymo-orchitis, or fibrosis of the testicle of filarial origin. Clinically, and pathologically, its filarial origin has been demonstrated. The ultimate result is suppuration, degeneration, or fibrosis. The diagnosis of a fibrosed testicle of this type is very difficult, if other manifestations of filarial infection are not present.

My best thanks are due to Lieut.-Colonel R. N. Chopra, I.M.S., the officiating director, and to Dr. Sundar Rao, the filariasis research worker, of the Calcutta School of Tropical Medicine, for their kindness in giving me every facility for my work.

explained by the fact that there is hardly any satisfactory mobilization of the phagocytes in this infection. Moreover, leucocidin produced by the organisms kills the phagocytes that may have aggregated at the site of the infection, particularly in its earlier stages. Finding no barrier, the micro-organisms invade the tissue spaces and the lymphatic channels with great rapidity resulting ultimately in septicæmia. It is for this reason also that the exudate from a fatal streptococcal lesion appears to be serous rather than purulent and when examined it is found to contain few polymuclear cells. When, however, definite pus has formed, the prognosis becomes better as it signifies the mobilization of the phagocytes and the formation of a protective barrier. It may be remembered that a virulent strain of hæmolytic streptococci may gain entrance through a minute skin abrasion, such as a prick or a scratch, and produce a fulminant septicæmia with hardly any inflammatory reactions at the site of entry.

This condition is known to develop from wound infections, either in the dissecting room, in the operating theatre or during an accidental injury. It may also arise from erysipelas and puerperal infection in females. In our country, a fairly common occurrence is found in acute orchitis and funiculitis in males. The last-named condition appears to be a very important cause, and, though it has been recognized for a long time, its seriousness does not seem to have been appreciated by the profession in general. It may be interesting to note that out of a series of 75 consecutive cases in the Calcutta Medical College necropsy examinations from 5th April, 1933, to 20th August, 1934, three cases have been found to be due to this condition. A short note of these cases with the important post-mortem findings may be of interest.

Case 1.—Clinical diagnosis: meningitis.

Hindu, male, aged 27, was admitted on the 10th May, 1933.

Condition on admission.—Unconscious and very toxic with cerebral symptoms; temperature—104°F.; respiration—32 per minute; pulse—very rapid and almost imperceptible. Left scrotum was acutely inflamed and contained fluid. Hydrocele on the right side. Crepitant râles were present in both the lungs. Spleen just palpable. Blood examination showed leucocytosis. *Streptococcus hæmolyticus* was isolated on blood culture. Patient died 16 hours after admission. Duration of illness—2 days.

Post-mortem findings.—Acute orchitis on the left side with fibrino-purulent fluid inside the tunica vaginalis. Small foci of suppuration were present along the structures of the spermatic cord, extending up to the abdominal cavity. Posterior abdominal vessels intensely congested and lymph glands enlarged. Hemorrhagic turbid fluid in all the serous cavities. Cerebral vessels injected. A pair of adult filariæ were found in one of the dilated lymphatic vessels along the spermatic cord.

Bacteriological examination.—Materials taken from the serotal fluid and splenic pulp showed chained cocci. Cultures from the above and from the heart's blood showed *Streptococcus hæmolyticus* (β type of Smith and Brown) which grew well both under aerobic and anaerobic conditions.

PLATE II

Fig. 1.—Infection with *Streptococcus hemolyticus* in filarial orchitis. The testis, which is situated in the centre, is cut open and exposed. The cavity of tunica vaginalis contains masses of fibrin. Microfilariae and *Streptococcus hemolyticus* were found in the exudate.

Fig. 2.—An early acute bacterial endocarditis of the pulmonary semilunar valves. Vegetations are small and nodular and situated at the line of apposition. They have not yet shown any signs of breaking down or ulceration.

Fig. 3.—Photomicrograph of a section of a lymph gland, showing a pair of adult filariae in a lymphatic space. There is a mass of inflammatory cells along with the parasite.

Case 2.—Clinical diagnosis—septic pneumonia.

Hindu, male, aged 17, was admitted on the 22nd May, 1934, complaining of pain and swelling of the right testis for the last 8 days and high fever for the last 5 or 6 days.

Condition on admission.—Very toxic, jaundiced and cyanosed; temperature—103°F.; pulse—120 per minute; respiration—30 per minute. The right testis was swollen to about four times the normal size. The left testis was normal with tenderness and fluctuation. Tongue—dry and coated. Liver and spleen—not palpable. Heart—nothing abnormal detected clinically. Lungs—rhonchi and crepitations in the right lung and crepitant râles in the left.

Blood culture showed *Streptococcus hæmolyticus*.

Blood examination on the 23rd May, 1934. Total white cells—10,500, polymorphs 82 per cent, small mononuclears 16 per cent, large mononuclears 1 per cent, eosinophils 1 per cent.

Culture from hydrocele fluid showed pure growth of *Streptococcus hæmolyticus*.

Patient died 4 days after admission, i.e., after 12 days of illness.

Post-mortem findings.—Right testis was swollen with fluid inside; no external wound was present; skin not adherent; inguinal glands were not grossly enlarged.

The cavity of the tunica vaginalis was filled with greenish, tough, masses of fibrin (plate XII, fig. 1) with a small amount of slightly cloudy fluid. The surface of the testis was covered with a bright-red hæmorrhagic exudate and the substance of the gland looked congested. The inflammatory features were found to extend upwards along the structures of the cord which was swollen, congested and covered with fibrin.

In the peritoneal cavity, all the posterior abdominal blood vessels were standing out very prominently and were of a dark crimson colour. This condition was present up to the attachment of the diaphragm. The inguinal and para-aortic lymph glands were swollen, enlarged and markedly congested.

Lungs.—In the right lung there was a small abscess at the base of the upper lobe and patches of consolidation over the base of the lower lobe. There was about 9 ounces of fibrino-purulent hæmorrhagic fluid in the right pleural cavity. The left lung was congested and œdematous but there was no consolidation.

Heart.—Small vegetations were found on each of the pulmonary semilunar valves (plate XII, fig. 2) at their lines of apposition. Other valves were normal.

Spleen.—The organ was enlarged (500 grammes). It was congested, soft and diffuent, resembling a typical septicemic spleen.

Liver and kidneys—congested.

Bacteriological investigations.—Smears from the hydrocele fluid and splenic pulp showed chained cocci (streptococci). Cultures from heart's blood, pleural exudate, splenic pulp and hydrocele fluid showed typical colonies of *Streptococcus hæmolyticus*, both under aerobic and anaerobic conditions.

An interesting feature of the finding from the hydrocele fluid was the presence of microfilariae.

Histological examination.—Microsection of the inguinal lymph gland showed a pair of adult filariæ (plate XII, fig. 3).

Case 3.—Clinical diagnosis—acute general peritonitis.

Hindu, male, aged 18 years, was admitted on 9th August, 1934.

Condition on admission.—Restless; condition low; jaundice present; pulse—very low, rate—123 per minute; respiration—40 per minute; temperature—101°F.; left scrotum was acutely inflamed. Abdomen distended and tender.

Culture of hydrocele fluid obtained by puncture showed pure growth of *Streptococcus hæmolyticus* (β type of Smith and Brown). The latter organism was also isolated from the blood.

Patient died two days after admission.

Post-mortem findings.—Suppurative orchitis on the left side, purulent peritonitis, bilateral plastic pleurisy;

purulent on the left side. Lungs—œdematous and congested.

Bacteriological investigations.—Hæmolytic streptococci found in smears, as well as in cultures from scrotal pus, heart's blood, spleen pulp, peritoneal and pleural fluids. The growth of the organism was luxuriant, both under aerobic and anaerobic conditions.

Microfilariae were also found in the hydrocele fluid.

Comments.—Streptococcal infection of the testis and the epididymis is very common in our country and is often fatal. In most of the cases, filarial infection is also present, with or without any active manifestations of the disease. The condition is ushered in by an acute attack of lymphangitis or an inflammation of the testis and epididymis, associated with a sharp rise of temperature, with chill and rigor. The parts become intensely painful and tender. A very marked degree of toxæmia is commonly present. Within 3 or 4 days, all the features of a grave septicæmia supervene and the patient succumbs. In such a case, if a blood culture is done, hæmolytic streptococci will always be isolated. When the resistance of the individual is very strong, the acute process passes into a subacute stage with localization of the infection and formation of an abscess inside the tunica vaginalis.

The gross appearance (*vide* plate XII, fig. 1) of such a fulminant streptococcal infection is very constant and characteristic. The cavity of the tunica vaginalis is filled by a fibrinous mass, with varying amounts of slightly cloudy fluid in the dependent part, the surfaces of the tunica showing hæmorrhages. The epididymis and the cord are equally involved and are considerably thickened, being infiltrated with a similar type of exudation. The process is not limited to the scrotum, but is found to extend along the structures of the cord into the abdominal cavity and the acute congestion, hæmorrhage and fibrino-purulent exudate may be traced along the retro-peritoneal lymphatics and blood vessels, on either side of the vertebral column up to the pillars of the diaphragm. All the lymphatic glands in the inguinal and para-aortic regions are enlarged, swollen and intensely congested.

In the acute stage, the fluid withdrawn from the tunica vaginalis by puncture with a syringe and needle shows a very high albumen content with little or no cellular exudate. As the process becomes subacute or chronic, large numbers of pus cells appear in it. Microfilariae are often found in such a fluid. The writers have frequently demonstrated microfilariae in the hydrocele fluid and adult filariæ in the dilated lymphatic varices, as well as in the lymph nodes (*vide* plate XII, fig. 3) of such cases. The streptococci which have been isolated from such cases are always of the hæmolytic type and grow well, both under aerobic and anaerobic conditions. As the organisms do not usually inhabit the human body, one would surmise that the source of infection must usually be exogenous, but in some cases it is undoubtedly

endogenous. In the present series of cases, so far as we have been able to gather, there is no history to suggest any exogenous infection. The source of the organism thus becomes a debatable subject and requires further investigation.

Secondary localization.—Usually very few localized lesions are found in association with acute streptococcal septicaemia. In our present series of cases there were foci in the lung and heart. Case 2 is of particular interest because of the localization of the lesion in the pulmonary valves. Acute bacterial endocarditis arising in the course of a streptococcal septicaemia usually develops in the left side of the heart (mitral or aortic). It is the usual belief that all the diseases acquired during extra-uterine life involve the cardiac valves of the left side of the heart because they bear the greatest strain, whereas those acquired in the intra-uterine life involve those in the right side. This present case, though an extremely rare condition, shows that acquired lesion may develop on any of the cardiac valves, but the factor that decides the choice requires to be investigated. Furthermore, it is known that in acute bacterial endocarditis the organism settles particularly on damaged valves; but the pulmonary valves in this case did not show any evidence of previous damage.

Such a generalized infection with *Streptococcus haemolyticus* following upon acute orchitis and funiculitis is very common in our country.

The finding of the microfilariae in the hydrocele fluid brings up the question of the relationship of this streptococcal infection to the presence of filariae. This aetiological connection is not yet clearly understood. It is now accepted as an established fact that filarial infection in males usually remains localized in the scrotum, testis and epididymis as well as in the structures of the cord. It is curious that the streptococcal lesion also develops in the same places where the filariae have already localized.* It

(Continued at foot of next column)

[* Acton and Sundar Rao (1929), after studying a number of cases of filarial lymphangitis, were able to show that secondary infection may be either endogenous or exogenous; in the former case the infection comes from the gums, teeth, tonsils, or gut. In a case reported separately these writers (1929a) recovered the same organism, a haemolytic streptococcus, from the abscess and from an infected tooth of the patient.

Acton and Rao (1929b) have also pointed out that in every case the worm produces a 'kataphylactic' condition of the tissue, which then becomes infected with some secondary organism, either a staphylococcus, in which case the infection will be localized, or a streptococcus, when a generalized infection is more likely to follow.

EDITOR, I.M.G.J

ON THE CONCENTRATION OF QUININE IN THE BLOOD AFTER INTRAVENOUS AND INTRAMUSCULAR INJECTIONS

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.,

A. C. ROY, M.Sc.

and

ASSISTANT SURGEON B. M. DAS GUPTA, L.M.P.

(School of Tropical Medicine, Calcutta)

THE object of this investigation is not to establish the superiority of any of the routes of administration of quinine over the others, but to determine whether or not there is any difference in the concentration of quinine attained in the blood when the two more commonly used parenteral routes are employed, and incidentally

(Continued from previous column)

may be reasonably inferred that the association of the two infections must be very intimate. What is the exact scientific basis of this mutual relationship has not yet been fully worked out. It may be that under normal conditions both the organisms remain in the area in a condition of symbiosis and it is the sudden disturbance of this mutual control which may be responsible for the acute attack. Or it may be that the filarial worms only make the soil suitable for the growth of streptococci, either by their irritant action as foreign bodies, their toxin or by producing some alteration in the tissue environments by an as-yet-undetermined factor.

Summary

(1) The peculiar nature of the pathogenesis of haemolytic streptococci renders the organisms prone to get into the general circulation and cause septicaemia.

(2) In our country, such a septicaemic condition is often found to arise from an acute orchitis and epididymitis and is intimately associated with a previous filarial infection.

(3) The haemolytic streptococci isolated from such cases either from the blood or from the infected tissues grow luxuriantly both under aerobic and anaerobic conditions.

(4) The morbid anatomy of three such cases obtained recently from the Calcutta Medical College Hospitals has been described.

(5) A very unusual localization of the organisms with acute bacterial endocarditis of the pulmonary valves has been described.

(6) The rôle of the filarial infection in the causation of fulminant streptococcal septicaemia, though very definite, is not yet fully understood.

For clinical notes of the cases we are indebted to Lieut.-Col. J. C. De, I.M.S., Capt. P. Ganguly, and Dr. U. N. Roy Choudhury, the physicians and surgeon of the Medical College Hospitals, Calcutta.

to compare these concentrations with that obtained by the oral method.

Without entering into any discussion regarding the possible production of tissue necrosis or other ill effects attending the administration of quinine by the parenteral routes, one is confronted with widely divergent views in the literature regarding the rate of absorption and the comparative clinical value of the administration of quinine by these different methods. For instance, statements such as 'no doubt the intramuscular method of giving quinine is far and away the best' (Kelly, 1907), and 'half a grain of quinine by hypodermic injections gives more certain results than 30 to 40 grains by the mouth' (Smith, 1911) are contrasted with others such as 'the temperature of the malarial patients takes about 12 hours longer in coming to normal when treated with hypodermic method than when quinine is given by the mouth' (Megaw, 1907), 'the absorption is slower from the subcutaneous tissue than from the mucous membrane of the gastric tract' (Scott, 1907), 'intramuscular injections are actually more slowly absorbed' (Fletcher, 1923), and 'intravenous injections can at best save only a short time in the attainment of maximum concentration in the blood' (Vedder and Masen, 1931).

Again the tardier elimination of quinine in the urine when administered by the parenteral routes, than when given orally, as reported by several authors (Kliene, 1901; Giemsa and Schaumann, 1907), is taken as an indication of the slower absorption by the former methods. MacGilchrist (1911) states that according to Mariani the total elimination of quinine in the urine during four days after its administration is intravenous 27.94 per cent, intramuscular 35.43 per cent, and oral (fasting) 40.80 per cent. In this connection the following remarks of Clark (1934) may be fittingly quoted: 'quinine sulphate which is insoluble and quinine bihydrochloride which is soluble are excreted in the same quantities and about the same rates. The amount of quinine excreted and the rate of its excretion are nearly the same whether the drug is given by the mouth, intramuscularly or intravenously'.

As regards the concentration of quinine attained in the blood when administered by these different routes, there is also no unanimity of opinion. Morgenroth (1918) for instance found that the quinine content of the blood was 1 in 20,000 a few minutes after intravenous injections and 1 in 150,000 after oral administration of therapeutic doses. Disappearance of the drug from the blood was found to be very rapid. Hatcher and Gold (1927) on the other hand could not detect its presence in specimens of blood drawn after a few minutes of oral, intravenous or intramuscular administrations.

The literature on this subject has been ably reviewed and summarized by Karamchandani (1933).

Methods of quinine estimation

Formerly the concentration of quinine in the blood was determined by the method described by Ramsden and Lipkin (1918). In this method the blood was extracted several times with hot saturated acid ammonium sulphate solution and the quinine was extracted from this solution by means of ether after alkalization with concentrated ammonia. The quinine left as residue on evaporation of the ether extracts was dissolved with saturated ammonium sulphate solution in a boiling brine bath, cooled and the turbidity produced on the addition of Tauret's reagent compared against several sets of standard quinine solutions similarly treated. Acton and King (1921) followed mainly the procedure described by Ramsden and Lipkin with some important modifications. They suggested that the concentrated ammonia used for alkalization must be specially purified to get rid of the pyridine bases, almost invariably found in ammonia, as these bases also produce a turbidity with Tauret's reagent and their presence will lead to incorrect results. Ramsden and Lipkin's method was laborious and time-consuming and even with the improvement effected by Acton and King there was an average error of 25 per cent.

Vedder and Masen (1931) dispensed with the use of ammonia altogether and made a very important observation that the blood itself was sufficiently alkaline to render the quinine soluble in ether and that quinine could be recovered quantitatively from the laked blood without adding ammonia or other alkali.

This simplified the procedure and eliminated the sources of error considerably. The method adopted by us, which consisted essentially of that described by Vedder and Masen with some minor modifications, is given below.

The inner tube A of Vedder and Masen's extraction apparatus is packed vertically with narrow strips of

Whatman's filter paper, no. 1, neither too loose nor too tight, some smaller pieces being placed at the bottom. What led us to replace the asbestos fibres by filter

paper was that we found that the latter soaked the blood better than asbestos. With asbestos it was somewhat difficult to ensure uniform packing, and, if in any particular place the packing was too tight, the blood was held up there unabsorbed, resulting in incomplete extraction by ether. Two cubic centimetres of the blood accurately measured was slowly and more or less uniformly distributed amongst the vertically placed paper strips. Any blood that might escape absorption in the upper strips would get absorbed in the smaller pieces of filter paper at the bottom. The tube was then left for about 10 minutes to allow the blood to get completely soaked into the strips of filter paper. Then, with a clean platinum loop, the strips that had come together were detached and reshuffled so that ether might freely circulate and maximum surface be exposed to its solvent action. A small pledget of cotton was placed in the mouth of the tube, which was then inserted in the tube B. The construction of the tube B was similar to that used by Vedder and Masen, excepting that there were three small projections just above the constriction, somewhat like Buchner's tubes used for anaerobic cultures, to allow the ether to pass freely. Constructing the tubes in the manner described by the above authors we found that ether would often accumulate round the inner tube above the area where it had come in contact with the outer one and did not freely percolate to the bottom of the outer tube.

Ether was poured through the top of the tube A, so that after filling it up, it was allowed to overflow and fill nearly half of the bulb portion of the tube B. This was then connected to a reflux condenser through which cold water was allowed to circulate and was immersed in a warm water bath up to the level of the ether in tube B. After the extraction had been allowed to proceed for 2 hours, the inner tube was removed and the ether extract contained in the outer tube was put in a hot water bath to evaporate away the ether. It was then put inside a steam oven for a few minutes. Five cubic centimetres of $2N.H_2SO_4$ saturated with zinc sulphate were then added and the tube was immersed in a boiling brine bath for 3 minutes in order to bring the quinine into solution. The solution while still hot was filtered through a small Whatman filter. From the filtrate cooled down to the room temperature 3 cubic centimetres were then accurately measured into one of a set of small test tubes of uniform bore and constituted from same kind of colourless glass tubings, and to the others varying amounts of standard quinine solution in $2N.H_2SO_4$ saturated with $ZnSO_4$ were added. The standard quinine solution used contained 0.01 milligramme of quinine per 1 cubic centimetre of the solution. The total volume in each tube was then made up to 5 cubic centimetres by the addition of varying amounts of the acid zinc sulphate solution. The whole set of tubes was then brought to a uniform temperature by putting them in a beaker containing some tap water for a few minutes. 0.1 cubic centimetre of Roy's reagent was then added, mixed and the unknown compared with the standards against a white background.

Vedder and Masen recommend the use of potassium bismuth iodide reagent; but as it appeared to offer no advantage over the reagent recommended by Roy (1926) we used the latter. No gum arabic solution was added to stabilize the colour formed as it was found that even after 15 minutes the variation in the shades of colour were quite distinct without the addition of gum and could be easily read. We preferred to take readings with the naked eye instead of with the colorimeter as the former could be more readily taken and two or three unknowns could be compared against the same set of standards. Some of our readings obtained with the naked eye were also checked by means of the colorimeter. As we did most of our experiments on monkeys, we had to use 2 cubic centimetres and sometimes even smaller amounts of blood for our experiments.

To test the accuracy of this method, known amounts of quinine were added to monkey blood, well mixed and aliquot parts of this were treated in the manner described above.

The results were quite satisfactory as will be seen from the following table:

TABLE I

	Quinine added in milligrammes	Quinine recovered in milligrammes
1	0.020	0.020
2	0.020	0.018
3	0.015	0.015
4	0.015	0.018
5	0.010	0.008
6	0.010	0.010

Having satisfied ourselves with the accuracy of the method we proceeded to make our experiments on monkeys. The results are given in table II.

The monkeys were given the doses mentioned against each, of quinine acid hydrobromide dissolved in 2 cubic centimetres of distilled water.

We carried on our experiments mostly on monkeys, but in order to determine the concentration actually occurring in man, observations were also carried out on human patients in the Carmichael Hospital for Tropical Diseases. The results are given in table III.

With regard to the results obtained with the monkeys it appears that there is not any marked difference in the concentration of quinine attained in the blood at different intervals of time when the effect of its administration by the two routes, i.e., intravenous and intramuscular, is compared. In the former case the maximum concentration was found in the 15 minutes specimen which varied from 1.75 to 1.00 milligramme per 100 cubic centimetres of blood (average 1.37 milligramme per cent) as was to be expected. In the case of intramuscular injections also the average maximum was attained at almost the same time (variations between 1.7 to 1.05 milligramme per 100 cubic centimetres, average 1.37 milligramme per cent), although in individual cases there were deviations from this. After half an hour the concentration varied from 1.80 to 0.75 milligramme per 100 cubic centimetres (average 1.27 milligramme per cent) in the case of intravenous injections, while in the case of intramuscular injections it varied from 1.80 to 0.70 milligramme per 100 cubic centimetres (average 1.36 milligramme per cent). After two hours interval the intravenous results varied from 0.80 to 0.55 milligramme per 100 cubic centimetres (average 0.63 milligramme per cent), while with the intramuscular route the variations were from 1.3 to 0.4 milligramme per 100 cubic centimetres (average 0.83 milligramme per cent). After 5 hours, when the intravenous route was employed it was found that the

N.B.—With human beings in the case of intramuscular and intravenous injections 5 and 20 cubic centimetres of distilled water were respectively used to dissolve 0.5 gramme of quinine acid hydrobromide.

quinine concentration had come down considerably (variations between 0.40 to 0.25 milligramme per 100 cubic centimetres, average 0.36 milligramme per cent) but in the case of the intramuscular route the concentration was maintained at a somewhat higher level (variations from 0.90 to 0.25 milligramme per 100 cubic centimetres, average 0.64 milligramme per cent). No appreciable amount of quinine was found in the blood after 24 hours of intravenous injections, but after intramuscular injections, some of the specimens drawn after 24 hours showed the presence of small but appreciable amounts of quinine.

A perusal of these results will show that quinine is retained in the blood for a somewhat longer time when given intramuscularly than when administered by the intravenous route. Unfortunately similar experiments with the oral route could not be performed with these animals, as monkeys will not swallow quinine even when carefully concealed in such food as bananas. If attempts are made to give it forcibly by the stomach tube they struggle, and generally get pneumonia and die. We therefore carried out a series of comparative experiments by all these routes in human beings.

Table III gives the results of such experiments. It will be observed that here also the same want of regularity which characterized the results with individual monkeys is apparent. For instance, in cases 1 and 3, the quinine concentration was found to be greater and maintained for a somewhat longer time in the case of intramuscular than with the intravenous route, but this does not apply to cases 2 and 4, where the concentration is nearly the same with both these routes except that attained after 15 minutes, which is definitely higher in the case of the intravenous method. Again with the same individual the results of intravenous injections of the same dose of quinine at different times (*vide* table III, case 1) do not run exactly parallel.

We also gave these individuals 0.5 gramme of quinine hydrobromide orally, with a view to see how the quinine concentrations in the blood at different intervals of time compared with those obtained by the two parenteral routes. In case 1 the results closely follow those obtained by the parenteral routes, but in cases 2, 3 and 4 the concentration obtained within the first few hours is definitely smaller. After that the concentration rises practically to the level of parenteral routes.

Taking these results as a whole, it appears that there is a good deal of individual variation as regards the concentration attained in the blood at different intervals of time, other initial conditions remaining almost the same, and even with the same individual when the same dose and route are employed the results of two

different experiments do not exactly run parallel. The concentration of quinine obtained in the case of monkeys, though on the average somewhat higher than with human beings, follow almost the same course.

Absorption after intramuscular injection

Our next object was to see if any appreciable amount of the quinine injected intramuscularly was left unabsorbed at the site of injection. The views expressed by the different workers on this subject are rather conflicting. Mariani for instance found that when quinine bihydrochloride (1 in 5) was injected into the leg muscle of a rabbit, 66.5 per cent of the injected quinine could be recovered from the site of injection 15 hours later. Dudgeon (1919) however could recover only traces of quinine from the muscle injected with concentrated solutions of quinine. Karamchandani (1933) repeated this experiment with a view to checking the results of the previous workers using Vedder and Masen's technique for blood with some modifications to suit the extraction of quinine from the minced muscles. He injected 0.5 gramme of quinine acid hydrobromide in a 1 in 3 solution into the gluteal muscle of a rabbit. After 17 hours the rabbit was killed and a portion of the injected muscle weighing 8.3 grammes was removed and the quinine content was estimated. This result shows that 80 per cent of the injected quinine was recovered from the muscles round the site of injection. We repeated this experiment using the technique used by Karamchandani but with much smaller amounts of quinine. We could see no justification for giving $7\frac{1}{2}$ grains or about 0.5 gramme of quinine hydrobromide, which is the dose for a human adult, to a rabbit weighing only about 2 kilogrammes. It would not be fair to draw any conclusions from experiments done under such abnormal conditions.

We therefore injected 0.02 gramme of quinine acid hydrobromide, which is the amount calculated on the basis of the body weight, dissolved in 1.0 cubic centimetre of distilled water into the gluteal muscle of a rabbit weighing 1.8 kilogramme. After 20 hours blood was withdrawn by heart puncture and the animal was killed. No quinine was found in the blood. A portion of the muscle from the injected area was then removed and another similar portion from the other leg was also cut off. These pieces of muscles were separately weighed, minced in a mortar with glass powder and then mixed with thinly cut pieces of filter paper and extracted with ether in a Vedder and Masen's apparatus for four hours. Quinine was estimated in the manner described above. This experiment was repeated with another rabbit weighing 2.0 kilogrammes with the results mentioned below :

TABLE IV

		Weight of muscle in grammes	Milligramme of quinine recovered	Percentage of the quinine injected
1. Rabbit, weight 1.8 kilogrammes	Muscle from the injected area.	3.5	0.05	0.32
	Muscle from the other leg.	4.7	nil.	..
2. Rabbit, weight 2.0 kilogrammes	Muscle from the injected area.	6.8	0.06	0.38

From the figures given in table IV we are justified in concluding that, in the case of intramuscular injections, only small proportions of the quinine injected remain unabsorbed at the site of injection after 20 hours, if administered in the usual clinical doses. The failure of absorption in the case of Karamchandani's experiments is due to severe injury caused to the tissue by the presence of large doses of quinine in the form of an acid solution.

Discussion.—The laborious experiments, the results of which are given in this paper, show that, if allowance is made for small variations due to the constantly changing factors in the animal organism, the concentration of quinine in the blood after administration by the oral and parenteral routes runs almost parallel. In some cases the concentration obtained within the first few hours after oral administration was definitely smaller, but the concentration soon rose to practically the level of the parenteral routes. It will be seen therefore that in ordinary cases no very great advantage can be claimed for any particular method. The routes selected by the clinician should therefore be what suits the patient best. It should be emphasized here that the clinical condition of the patient is the best guide in deciding what route should be adopted. The oral route is undoubtedly the method of choice in the vast majority of patients. The condition of the tongue is an excellent indication of the state of the gastric mucosa; in ordinary attacks of malarial fever the tongue is moist and slightly furred, and under these circumstances quinine is absorbed very well from the gut. If the tongue is dry, red and cracked, quinine is absorbed badly, and in such cases other means should be adopted. Quinine is generally absorbed readily from the gut; even in cases of severe malaria complicated with dysentery quinine has been shown to be absorbed. In those cases however, in which there is nausea and vomiting, or when the bilious vomiting of malignant tertian infection is present, it is useless to give quinine by the mouth. In such cases the parenteral routes should be adopted, the intravenous or the intramuscular route to be selected according to the requirements of the individual patient. As soon as the condition of the gastro-intestinal tract improves, administration by the parenteral

routes should be stopped and the drug given by the oral route. In view of the possible injury to the blood vessels, muscles, nerves, etc., by parenteral injections, this method should not be used for routine treatment of malaria, but is specially indicated in acute cases of severe type for as long as the emergency lasts.

Summary and conclusions

1. Quinine acid hydrobromide was given to two animals, particularly to two monkeys, and the concentration of quinine attained in the blood at different intervals of time in these animals and in four human cases was estimated.

2. The average maximum concentration was found in the blood after 15 minutes in both the cases; the average figures for blood drawn after half an hour and one hour respectively are about the same in both, and the concentrations in specimens of blood drawn after two hours and onwards show a gradual fall in both, though the intramuscular figures are somewhat higher than the intravenous ones.

3. In the case of intravenous injections no appreciable amount of quinine could be detected in the specimen drawn after 24 hours of the injection, but when the intramuscular route was used some of the 24-hour specimens showed the presence of small but appreciable amounts of quinine.

4. With human beings the figures obtained are similar to those obtained in the case of monkeys, though the concentrations obtained in the latter case are higher. The results of the oral administration of quinine are similar to those obtained with the parenteral methods, but the concentration reached within the first few hours by the oral method is sometimes much smaller.

5. There is a good deal of individual variation regarding the concentration attained at different intervals of time, and, even with the same individual when the same dose and route are employed, the results of two different experiments do not run exactly parallel.

6. The clinical condition of the patient is the best guide in deciding what method of administration should be adopted, in acute cases. The oral route is undoubtedly the method of

QUININE IN THE THERAPEUTICS OF MALARIA

By R. A. MURPHY, L.R.C.S.I., L.R.C.P.I., L.M.

Medical Officer to Tea Estates, Luskempore, Sylhet

To most of us with tropical experience, the symptoms and treatment of malaria, as described of late from temperate zones, have been most bewildering, and in fact we have felt that, were all that has been published to be confirmed, we must in the past have been most unobservant and allowed our patients to suffer very unnecessarily. Conclusions have been stated dogmatically and it has appeared to be thought that what applied in Camberwell must also apply in Cathay. The latest *Report of the Malaria Commission of the League of Nations* has, however, cleared the air considerably by the statement that 'the therapeutics of malaria, like every other aspect of the disease, is much more a local and individual problem than has hitherto been thought'.

(Continued from previous page)

choice in the large majority of patients, but parenteral routes should be adopted when this is not practicable. In view of the injury likely to result to the blood vessels, muscles, nerves, etc., by parenteral injections there is no justification for the routine use of this method in the treatment of malaria.

For many years it has been obvious, from the literature and the contradictory descriptions of the disease, that neither the human host nor the parasite are fixed quantities. There are probably many factors concerned, race, environment, present and past treatment, and heredity, which may affect the relations of the human host to the parasite, and the latter may consist of various strains, or it may be influenced by the insect species or the length of the period elapsing between transmission from host to host. These complications make the problem and generalizations on it difficult, and it has to be realized that findings under certain conditions or in certain climates may not be applicable elsewhere.

It is, therefore, not so extraordinary that opinion regarding the treatment and cure of malaria with quinine even after so long a trial is still unsettled. Some pin their faith to treatment by large doses, such as forty grains daily, others are satisfied with twenty, and it has even been stated that a grain or two for a couple of days is sufficient. Statements affirming a cure require to be accepted very cautiously, for in the first place there is no certainty as to how long periods of latency may be, or for how long after infection relapses may be possible, and in this matter also observations made in England quite possibly do not apply to the tropics. A change to the hills or a more temperate zone is a powerful adjuvant to the body winning in the fight against the parasite, so that results of experiments in more salubrious climes may not help with the management of the disease locally. Then, if the environment is not changed, the possibility of re-infections cannot be excluded, and these cannot be differentiated from relapses.

The standard course given

In an effort to effect a cure I have for many years prescribed a three months' course of quinine, ten grains daily, to suitable patients, including all my few European patients. Only the latter are here considered, as, on account of the precautions they take, they are not so liable to re-infections, and also they can be kept better under observation. Cases which have been free of fever for at least one year are counted as cures; it is not likely that in the enervating climate of Sylhet latent periods would exceed a year. Those getting fever with parasites within the year count as relapses, with the exception of a few cases where on the second occasion a different species of parasite was found. Patients who left the district before the elapse of one year are classed as unknown.

The average period between attacks is probably between two and three years, e.g., one patient had attacks in April 1928, September 1929 and October 1933, the first and last being benign and the intermediate attack malignant tertian; another patient had attacks of benign tertian in 1923, 1925 and 1932, each time in

June; and the writer has had three attacks in 1920, in 1923, and in 1931, the second one malignant tertian and the others benign, complete freedom being enjoyed in the intervening periods.

With these criteria the results of treatment in 110 cases have been :—

Cured	80
Relapsed	20
Results unknown	10

It is doubtful if there were any genuine relapses, as some were possibly re-infections and some patients certainly did not carry out the full treatment; a number confessed to not having done so, but unfortunately no note of this fact was made.

Courses limited to about six weeks appear to fail. The impression is that children require bigger proportionate doses, or possibly they are more exposed to re-infections.

Although the number of cases is small I feel that they have a definite value in that the patients were followed up in a way that is not usually possible in practice. Quite short courses have been reported as giving a big proportion of cures, but such are certainly not effective here. It may be that, if, instead of returning to work when their temperature has been normal for forty-eight hours, as patients do here, they rest for two or three weeks, they would do better on short treatments.

A few days quinine followed by three days atabrin appears to be useless as a cure, but two weeks quinine followed by nine days atabrin, three tablets daily, is promising and worthy of further trial.

In the treatment of the attack of fever twenty grains of quinine daily appear to be quite as efficacious as the larger doses, which only aggravate the discomfort of the patient. When quinine cannot be taken orally, intramuscular injections are effective, and these, given into the gluteus muscles, appear to have no untoward consequences. I used to give these injections very freely, but since I have used adrenalin to control vomiting they are hardly ever called for. The bilious remittent type of fever with its severe vomiting is unusual here, or they might be more often required. My assistants still continue to give a large number of injections and have an unshakable belief in them. They generally give them when the patient has had fever for about three days with quinine orally. The temperature comes down shortly after, as would be expected in any case, and doctor and patient are quite satisfied.

Only a few out of the many can be given a three months' treatment, and some even of the few will fail to stay the course, but the individual who can and does will, I believe, not be disappointed.

Discussion

The Malaria Commission say 'During the primary attack it may not be safe to abstain

for a day or two from giving a specific drug, but it is quite safe to do so in the first and any subsequent relapse'. This is a very sweeping statement, and, in my opinion, questionable. My own observation is that relapses may on occasion be more severe than the primary attack. A common history in a coolie child is two or three days fever treated with quinine; after ten days to three weeks the child has more fever, for which he is not brought for treatment, and he dies with convulsions on the second to the fourth day of the presumed relapse. Neither is the infection necessarily malignant tertian for that to occur. It is true that in the case of malignant tertian to some extent the Commission's advice is qualified, but the doctrine is an exceedingly dangerous one to preach to the laity, for blackwater fever most frequently occurs in just those patients who have been unadvisedly taking quinine on the lines recommended by the Commission. Moreover, a permitted relapse may take the cerebral form with disastrous consequences.

The ideal of the Commission appears to be Lagos and similar places, where nearly all the children and half the adults harbour parasites, and yet appear healthy. But has the toll taken in the process of acquiring this clinical immunity been considered, or that the scales are weighted against the patient in the case of intercurrent disease, accident, or maternity?

Not at least to attempt, as far as drugs and circumstances permit, a thorough treatment and cure would appear to be a policy of retrogression, more especially with the newer synthetic preparations at our command. The much-sought specific has yet to appear, but will probably be not long delayed. Recently an advertisement of a proprietary preparation announced the cure of numerous cases with one powder. Let us hope this flight of fancy will soon really materialize.

[*Note.*—The writer of the paper has just retired after many years of practice in Assam; during these years he has acquired a reputation as an astute clinical observer; we therefore welcome this summary of certain aspects of his clinical experience in the treatment of malaria. The figures he gives are not large, but, as he says, they make up in quality what they lack in quantity for he has had exceptional opportunities of following up his cases.

We note that he gives, as one of the reasons for the occurrence of relapses, failure to take the full course, some of his patients admitting their delinquency. His observation that 'courses limited to about six weeks appear to fail', seems to be dependent on the admissions of these delinquents, but is he certain that all of his 'successes' completed the full course of treatment? It seems possible that he did not question these patients nearly so closely.

Whilst we heartily agree with the writer that experience gained in Epsom is not necessarily applicable in Luskerpore, we must point out that, though he has shown that his three months' course will effect a reasonably good cure rate, he has produced no evidence to show that a shorter one would not have been equally effective.—Ebrton, I.M.G.]

THE EARLY TREATMENT OF MALARIA

By H. WILLIAMSON, O.B.E., M.D., F.R.C.S.(Ed.)
MAJOR, I.M.S.

Civil Surgeon, Quetta

and

SHAMSHER SINGH, I.M.D.

Civil Hospital, Quetta

ONE of the commonest problems facing the doctor in India is the case of acute malaria which he is called to see for the first time, and on his answer to the question 'What is the best immediate treatment?' may depend both the health of the patient and the reputation of the doctor, so it is in the hope of answering this question that this paper is written.

There is a lamentable tendency, particularly among the younger members of our profession, to trust laboratory reports more than clinical observation, and we cannot help feeling that in the matter of intramuscular quinine some of us have been rather led astray by conclusions based on laboratory experiments which are not confirmed by clinical experience. We have, for instance, been shown sections of rabbits' muscles containing clots and necrotic tissue after injections of quinine, but, so far as we are aware, human muscles have not been similarly displayed, and it has been our experience, over a large number of cases, that when proper precautions are taken no disability whatever, apart from occasional soreness, follows intramuscular injections of quinine.

Perhaps we have been fortunate, but in our cases, both in and apart from the present series, neither abscess nor tetanus has occurred, and we submit that these rarities should no more discourage the use of a very valuable procedure than they do ordinary surgical operations. All surgeons have seen a 'clean' hernia go septic after operation, and tetanus has been reported after appendicectomy, but there seems to be no diminution in the zeal of either patients or surgeons for the performance of these operations. One authority has even described intramuscular quinine as a 'criminal procedure', but we feel that he was arguing from insufficient data based on laboratory experiments, and was not giving clinical facts their full value.

We have recently been carrying out a series of experiments in treating a series* of 600 cases of 'parasite positive' benign malaria. Our

cases have been treated in the following ways:—

A. Quinine by the mouth (300 cases)

On admission, a blood smear is taken, and calomel, grs. 5, and sodium bicarbonate, grs. 10, given.

Four hours later, this is followed by half an ounce of magnesium sulphate in two ounces of water.

After the bowels have moved well, Sinton's mixture, quinine sulphate, grs. 10, citric acid, grs. 15, water to oz. 1, is given three times a day, with intermediate doses of twenty grains of sodium bicarbonate in water.

In studying a large number of temperature charts we have found a rather striking fact emerge, namely that if the temperature does not exceed 101.5°F. during the first 24 hours the above treatment is nearly always successful within 48 hours, i.e., the temperature falls to normal and remains there. If the temperature is higher, either it will take longer to come down or quinine injections have to be used. For some reason quotidian infections reacted much better than tertian.

B. Quinine by intramuscular injection (150 cases)

This was given in three classes of case:

- (i) Those which had not reacted to oral quinine after 48 hours.
- (ii) Those with high fever.
- (iii) Those with vomiting.

In the last class of case the quinine was generally mixed with a quarter of a grain of morphia, with the result that the vomiting and distress ceased within an hour, the patient went to sleep, and woke up feeling much better and often with a normal temperature.

It may, perhaps, seem unnecessary to give details of our technique in giving intramuscular quinine, but so convinced are we of the importance of asepsis that we venture to give the procedure in detail.

Sterilization of the syringe and quinine solution.—A 2 c.cm. 'Record' syringe is used, and is sterilized in its box, about two drachms of water being poured into the box, which is then closed, and, supported on a stand (a couple of cigarette tins do very well), boiled for five minutes over a spirit lamp. With the small amount of water mentioned boiling occurs after about a minute. When the syringe has been sterilized for five minutes the lamp is removed and the syringe, still in its closed box, allowed to cool while the quinine solution is prepared. A dessertspoon is now half filled with water (preferably distilled, but this is not essential) which is boiled over the lamp until it is reduced by about half, when 15 grains of quinine bihydrochloride, in powder or 'Tabloids', are added. The boiling is continued until the quinine has dissolved and the solution has become reduced to about 2 c.cm. (about a quarter of the dessertspoonful). The syringe is now removed from its box and the hot solution drawn up into it, the needle is fitted and the filled syringe laid aside while the patient is prepared. Where a number of patients are to be injected a larger syringe is, of course, used, with a fresh needle for each.

* [Note.—It is not clear what the writers mean by a series of 600 cases; it seems improbable that exactly half required parenteral injections and that 25 per cent of a series of benign tertian infections were cases of cerebral malaria. If the numbers had not been mentioned, the paper would have appeared as a general summary of experience—the interpolation of the numbers might lead to erroneous deductions. For this reason we hesitated to publish this note for some time; we do so now as the subject seems to us to be due for discussion.—Editor, I.M.G.]

Preparation of the patient.—The patient is turned on his face or side and the upper and outer quadrant of one buttock scrubbed with an iodine swab. In women or shy people the deltoid may be used, but the buttock is better.

Injection of the quinine.—By the time the iodine on the skin is dry the syringe is generally comfortably warm. If it is hot one must wait for a minute or two until it feels about blood-heat. If it is too cold the quinine solution is apt to be too thick to go through the needle. The patient is now told to relax his muscles (one of us, from personal experience, can testify to the importance of this) and the needle of the syringe quickly thrust vertically into the gluteal muscle, the solution is injected, and the needle withdrawn. It is an advantage to have a minute bubble of air at the needle end of the syringe before injection, as this ensures that none of the solution enters the subcutaneous fat. After the injection the site is massaged for about a quarter of a minute.

Results.—As already mentioned, no untoward results have followed this treatment in our hands, either in the present or in other series of cases. Sometimes a certain amount of soreness has followed the injection, but this has never been severe or of more than a few days' duration, and it has never been so severe as that commonly felt after an anti-typhoid inoculation.

Therapeutically, the effect has almost invariably been that within 24 hours after the second, and often after the first injection, the temperature has come down to normal and remained there, after which quinine by the mouth has been given. The average number of intramuscular injections was two, and it was rarely necessary to give more than four, in fact one might say that if four daily injections of quinine do not control the fever, that fever is not due to malaria. We should like, therefore, to emphasize here that we do not advocate prolonged treatment of malaria by quinine injections, either intramuscular or intravenous, as once the temperature has remained normal for 48 hours, quinine by the mouth is quite capable of keeping it there. One great advantage of injected quinine is that the attendant knows that the patient is getting 'what the doctor ordered', and another is that it is rarely followed by tinnitus, nausea or vertigo. In chronic or 'quinine-resistant' cases it is a great advantage to add one grain of sodium cacodylate.

Children.—Children are given proportionate doses, and it is in them, especially those unable or unwilling to swallow quinine, that intramuscular quinine perhaps has its happiest results. When a child is feverish it is cross and 'negativistic', but when the temperature is normal again the child becomes more rational, and will usually swallow quinine, atabrin or plasmoguin.

C. Intravenous quinine (150 cases)

In cases of cerebral malaria it has been our experience that this is undoubtedly the method of choice.

In the present series we have used three different methods, but in all cases the vehicle

has been the same, namely 5 c.cm. of normal saline. The methods have been

- (i) Quinine bishydrochloride, grs. 5 (or in severe cases grs. 10).
- (ii) Ditto with 0.5 c.cm. pituitrin.
- (iii) Ditto with 1 c.cm. adrenalin solution.

The immediate therapeutic effect of intravenous quinine has been similar to that of intramuscular, but perhaps prompter and perhaps more transient, but very definite. It has, however, been marred by the occurrence of a 'reaction'. This reaction occurred in about thirty per cent of our cases, was most common and severe with quinine and pituitrin, less so with quinine alone, and least so with quinine and adrenalin, but was quite definite and troublesome enough even in this last method. It varied in severity from a passing rigor to severe vomiting, diarrhoea and collapse, which on occasion demanded vigorous treatment in the form of brandy and intravenous saline. In some cases the reaction occurred immediately, when it generally took the form of vomiting, and in others up to three hours after the injection. In one case, where the reaction came on three hours after an intravenous injection of quinine and pituitrin, the patient collapsed and died. In another, the patient developed severe purging and collapse two hours after an intravenous injection of quinine and adrenalin, but was revived by a hypertonic intravenous saline, and was quite well the next day. It seems fair to assume that these reactions are due to the method and not to the drug, as they were observed only after intravenous, and never after oral or intramuscular quinine.

It is the occurrence of these reactions which to our minds is the greatest drawback of the intravenous method. All our intravenous injections were given very slowly, about five minutes being taken over each, and all were given in five c.cm. of normal saline. A well-known Quetta practitioner put the case very well when he remarked, 'If I give intravenous quinine I often find another doctor in attendance next time I go to see the patient'. Another drawback is that for those not skilled in intravenous injections it is more difficult than intramuscular quinine, and more likely to be followed by an abscess. Even the expert finds it difficult in a patient with small veins or in a dark room.

Conclusions

(i) Quinine by the mouth controls cases of benign malaria without high fever, and is the method of choice in such cases, for early treatment.

(ii) The dangers of intramuscular quinine have been exaggerated, and it is the best treatment for severe cases of benign malaria, including those which have not reacted successfully to quinine by the mouth.

INTRAVENOUS QUININE THERAPY IN MALARIA

By S. SUBRAHMANYAM, L.M.P.

Government Headquarters Hospital, Ootacamund

In the treatment of malaria, intravenous quinine has been employed only very sparingly hitherto owing to the alleged risks attending it. However, since April 1932, in the treatment of about 300 cases of malaria of all types, this has been the method almost invariably employed in this hospital, and the following is the routine adopted throughout:—

Technique and dosage.—A stock sterilized solution of the acid hydrochloride in distilled water in the strength of a grain to each cubic centimetre is prepared and kept ready for use in a stoppered bottle, and is re-sterilized in a water bath twice a week. The adult dose that has been employed is 10 cubic centimetres of the solution, the injection being given once a day for six consecutive days. In every case the blood pressure is recorded both before and after the administration of the drug. The injection is given very slowly with the usual aseptic precautions into one of the veins at the bend of the elbow, and during the process of injection a careful watch is kept on the pulse, blood pressure and respiration. In cases of patients with low blood pressure—that is 100 mm. Hg. systolic—three to five drops of adrenalin solution 1 in 1,000 are added to the quinine prior to the injection. In those rare instances where during the administration of the injection, the blood pressure begins to fall considerably or there is respiratory embarrassment, the injection is stopped and no further attempt is made to give quinine intravenously.

The blood pressure variations before and after the injection.—The blood pressure variations have not been quite constant. There has generally been in the majority of cases treated a drop in the blood pressure, both systolic and diastolic, to an extent of 5 to 15 mm. Hg., rarely 20 to 30 mm.; occasionally the diastolic reading has remained more-or-less constant or has even risen higher. Very rarely—it was observed only once in the present series—both the systolic and diastolic pressures show an increase after the injection. Usually the blood pressure reading returns to its original level in about 10 to 15 minutes time.

Effects of the injection on the parasite.—Usually within 24 hours after the first injection,

the parasites have disappeared from the peripheral blood; in rare instances, however, the blood films have revealed their presence up to 48 hours after the first injection though in decreased numbers.

Complications

(1) Almost every patient has complained of some giddiness and slight burning sensation in the abdomen during the injection. These sensations are purely transient and need no special treatment.

(2) In a few instances, the blood pressure has dropped considerably. A hypodermic injection of 0.5 c.cm. of adrenalin solution, 1 in 1,000, is usually all that is necessary to restore the blood pressure to its normal.

(3) Cyanosis and respiratory embarrassment have not been observed in our series, but when they occur an injection of strychnine, 1/60 grain, supplemented by oxygen inhalations should be given.

(4) In one or two instances, phlebitis of a moderate degree has occurred; but this responded rapidly to treatment with two injections intramuscularly on successive days of 1 c.cm. of S. U. P. 36.

Contra-indications.—Excepting in the cases of very young children without good veins, and extremely debilitated persons, there does not seem to be any absolute contra-indication to the use of the drug intravenously. There were no bad effects in the case of a woman who was three months pregnant and who had the full course of the injections.

Results

Our experience shows that, provided the correct technique is followed, the risks are negligible. Every patient who had the full course was requested to report if there were any relapses, but so far only one patient has come forward; this patient was originally treated for malignant tertian infection and came back to the hospital after a few months with a blood picture showing benign tertian parasites.

The advantages of this method are:—

1. It cuts short the duration of the primary attack, the temperature ordinarily keeping down to normal after the first two injections.
2. The course of treatment does not extend beyond six days.
3. It is at once cheap and effective.

Out of the series treated the gross mortality was about 1.5 per cent, death occurring in three cases with cerebral malaria and in two with a malignant infection and severe toxæmia; these patients came under treatment too late.

My thanks are due to Lieutenant-Colonel A. S. Leslie, I.M.S., superintendent of this hospital, to whom I am very much indebted for his valuable advice and kindness in permitting me to make use of the hospital records.

(Continued from previous page)

(iii) Not more than four doses of intramuscular quinine need be given.

(iv) Intravenous quinine is the method of choice in cerebral malaria, but its dangers should be realized, it should not be used in other cases unless the patient can be watched for several hours after the injection, and even then intramuscular quinine is safer.

NOTES ON INTRAVENOUS VERSUS INTRAMUSCULAR QUININE

By D. MANSON, M.B., Ch.B., F.R.S., F.Z.S.

*Medical Officer, Jorchaut Tea Company, Limited
Cinnamara, Assam*

My earliest experiences of quinine by injection were in the Army in 1916. At that time, as far as my memory goes, quinine by the intramuscular route was not only regarded as bad practice, but was absolutely taboo, at least in the division in which I served.

I can still remember the trepidation with which I administered quinine intramuscularly in 1917; I hoped that the brand of Cain, which I was certain must have glowed on my forehead, was not too visible to those who saw these performances. I lived in fear of tetanus and abscess for days after each such case; my fear was never justified.

I have never abandoned the intravenous route, but I have used the intramuscular with ever-increasing confidence, a confidence which I have never found misplaced.

Most of my experience of quinine by injection came subsequently to 1920 when I took up tea-garden practice. My reasons for its adoption were several: firstly, there is less actual preparation in giving the injection and this appeals to the coolie. The puncture is made rapidly and the injection is all over in a minute or two. With intravenous quinine, more time is expended. It is often necessary in tea-garden practice to have an assistant to hold the arm and the time of injection is much longer depending on the dilution of the solution used which should never be less than 10 c.cms. The coolie enjoys the quicker route, and the absence of fuss and assistants makes for confidence. This is a very essential point in dealing with ignorant labourers.

Site.—I usually prefer the buttock in children as it is easiest to inject. In working adults also, I generally prefer the buttock, because, if there is any residual tenderness, the patient is not rendered unfit for his manual occupation.

In cases where there are no special indications, I prefer the deltoid site as absorption is quicker there on account of a better blood supply.

Indications.—I use intramuscular quinine in all cases of malaria with obstinate vomiting, hyperpyrexia and intense headache. In algid cases with heavy malignant tertian infections and in cerebral cases, I still prefer the intravenous route. Even in these cases, I am now in doubt about the advantages of intravenous quinine. I have seen collapse following intravenous injection in cerebral cases when quinine was given in doses of $7\frac{1}{2}$ grains in 20 c.cms. of normal saline plus adrenalin chloride (1 in 1,000) 5 to 10 minims. I am not certain that a larger intramuscular dose, even in cerebral cases, is not the better practice.

The main drawback to the intravenous route is shock following injection. However competently the injection is carried out, this does occur and in cases already in the stage of collapse, the onset of shock is very sudden and little can be done to check the inevitable sequel. In using intravenous quinine, I always give the quinine (bihydrochloride or bihydrobromate) in doses of 5 to 10 grains in 20 c.cms. and always with adrenalin chloride (1 in 1,000) in doses of 5 to 10 minims.

The sole advantages of intravenous quinine are the greater rapidity of action and the entire absence of local pain. Against those are to be put the risk of collapse, extreme sweating and, in some cases, complaint of dryness of the throat. In coolie practice also, the appearance of a drop of blood in the syringe, following the puncture of the vein, is often a cause of alarm to the patient.

The disadvantages of intramuscular quinine are that there is in 30 per cent of cases some residual tenderness. I have never seen tetanus follow injection. Abscess I have seen in a few cases in the last 15 years where assistants have been hasty or careless in administration. Given proper sterilization of the syringe, a decent needle, not rusty, and the sterilization of the site of injection with tincture of iodine, abscess occurs only in very few instances, if ever.

Generally the fault lies in the desire of the assistant to get the injection over and done with and he does not allow the tincture of iodine to remain long enough on the skin to ensure sterilization. I insist on a minimum of four minutes for this process.

The effects of intramuscular quinine are shown in a somewhat slower action, and are specially useful as excretion of quinine takes longer than in intravenous therapy. After-pain, in intramuscular injection, can usually be completely aborted by fomentations for a few hours.

In some parts of Assam there is a practice of using intramuscular quinine with adrenalin. I do not advocate this as it is evident that adrenalin must decrease the rate of absorption, and probably tends to induce after-pain. It is also evident that, if fomentation removes after-pain by inducing a local congestion, adrenalin must be, not advantageous, but actually deleterious.

I issued a questionnaire to my assistant medical officers and the result was that, out of fifteen, fourteen were in favour of the intramuscular route, in all cases when injection was called for except in extreme cerebral or algid cases. All used quinine bihydrochloride in doses of 5 to 10 grains and in dilutions of $1\frac{1}{2}$ to 3 c.cms., the majority favouring 10 grains in 2 c.cms. for adults.

For intravenous use, the usual dose was 5 to $7\frac{1}{2}$ to 10 grains in 20 c.cms. of normal saline plus, in all cases, adrenalin chloride (1 in 1,000)

(Continued at foot of next page)

SOME OBSERVATIONS ON THE COMBINED METHOD OF CLOT CULTURE AND WIDAL REACTION, AND ON THE PROGNOSTIC SIGNIFICANCE OF 'SMALL-FLAKING' OR 'O'-AGGLUTININS IN TYPHOID FEVER*

By D. W. SOMAN, M.B., B.S.

Bacteriology Department, Pathology School
Grant Medical College, Bombay

It is now generally recognized that the diagnosis of enteric infection by the agglutination test requires a degree of precision, the need for which has become more apparent only within recent years. It was strongly emphasized in a previous communication (Soman, 1932) that in order to minimize the chances of errors in the diagnosis by methods of agglutination alone, a clot culture should be made from the same sample of blood. The number of cases studied, and reported in this first paper being by no means large, it was decided to give a further trial to the method on the same lines, and to collect a larger series.

Thus the first part of this article deals with the method above mentioned and records the examination of 400 samples, sent for Widal reaction and clot culture during the last two years. The samples of blood were chiefly received from the J. J. and the allied group of

(Continued from previous page)

5 to 10 minims. All these men have had very considerable experience of both types of injection. I must make it clear that the technique does not influence their decisions because all use the intravenous route many times monthly in the treatment of other diseases, such as severe diarrhoeas and bacillary dysenteries, venereal diseases, anæmias, etc. Experience is the only factor and the general experience agrees with mine. In helping them to make their choice, I have never attempted to be dogmatic and have always allowed free scope to each man's clinical experience. Several reported early collapse in cerebral cases following injection and, whilst keeping an open mind, I am not certain that intravenous quinine may not have proved, in some cases, the last straw. On that point, I still have residual doubts.

I have personal experience of quinine by both routes and I now always ask for intramuscular. That queer catch in the throat and the feeling of faintness after intravenous quinine are really unpleasant. Personally I have never had pain or tenderness after properly-given intramuscular quinine.

I should not like to express my opinions as final or as representative of general opinion, but only as the personal result of a clinical experience of quinine extending over 17 years.

hospitals in Bombay. It is unnecessary to recapitulate all the advantages claimed for this method, since the results obtained from a larger series of cases confirm all the previous findings and the claims that were made.

The second part of this paper deals with 'O'-agglutinins and the actual technique employed in demonstrating them. A series of 150 samples of blood were tested by agglutination methods, with a special reference to the presence of O-agglutinins. Out of 150 samples only 50 of them turned out to be positive for typhoid infection, the rest being negative both by agglutination and culture test.

Clot culture and Widal

Of the 400 specimens examined, 288 were negative, both serologically and culturally, and 112 gave positive findings, 93—typhoid, and 19—paratyphoid A; in no case was paratyphoid B diagnosed.

The actual findings in these 112 specimens are shown below :

		Typhoid.	Para. A
Widal	+	27	1
Clot culture	+		
Widal	—	14	1
Clot culture	+		
Widal	+	52	17
Clot culture	—		

Note.—Widal tests were done by Dreyer's method and with formalized broth suspensions from the Standards Laboratory, School of Pathology, Oxford, and the test was taken as positive in the case of typhoid in a serum dilution of 1 in 50 or higher, and 1 in 25 or higher in the case of paratyphoid A infection. Clot cultures were done according to the technique previously described (Soman, 1932).

From the series tabulated above, the following facts emerge :

1. In Bombay *B. typhosus* plays a predominant rôle, compared with other enteric-group organisms, in causing enteric fevers. Paratyphoid B infection was not demonstrated and is thus apparently rare.

2. The clot cultures, although done at different periods during the course of disease, were positive in 45 per cent of typhoid infections, while the diagnostic H-agglutinins are always fluctuating and were absent in one-third of these culturally-diagnosed cases.

3. Clot culture is of special value in the case of children in which the late appearances of H-agglutinins in the blood is a noticeable feature necessitating repeated examination.

The large number of entirely negative findings may seem to call for an explanation. It is not possible to conclude that these were all non-enteric cases, as the specimens were not subjected to agglutination tests for paratyphoid C nor for the other *Salmonella* group of infections. Admittedly, the routine clot cultures gave negative results, but paratyphoid C or the

Salmonella organism rarely invade the blood stream, and, if they do, the bacteremia that follows is of the most transient character. The same is true of paratyphoids A and B organisms, the difference among them being only of one degree. The large number of negative clot cultures, 17 out of 19 cases for paratyphoid A infection, supports the above statement. Further, a number of so-called continued fevers are nothing but malignant tertian malarial infections.

O-agglutinins

It is now recognized that different components of the bacterial cell may give rise to separate and distinct agglutinins. As early as 1903, Smith and Reagh, from observations on motile and non-motile strains of the hog cholera bacillus, concluded that the somatic and flagellar constituents of a bacterium produced two corresponding agglutinins. This work has been much extended by Weil and Felix. They designated the two agglutinins as 'H' and 'O'. A motile bacterium, the 'H' variant, produces both 'H-' and 'O-' agglutinins, while the non-motile or 'O' variant produces only 'O'-agglutinins. These O-agglutinins are also variously described as somatic agglutinins, or small-flaking or granular agglutinins. The flagellar, or large-flaking agglutinins, resist a temperature of 70°C. for twenty minutes while the somatic agglutinins are damaged, though not quite destroyed, by this temperature. In a recent paper (Felix and Olitzki, 1928), it has been proved that, for *B. typhosus* and the Salmonella group, phenol and formaldehyde, in the concentrations usually employed in preserved bacterial suspensions, produce a transient or permanent inhibition of the O-agglutinins, while H-agglutinins remain unaffected. Hence it has become absolutely imperative to use separate alcoholic 'O' suspensions which are prepared from the most sensitive non-motile 'O' variant of *B. typhosus*. In the O-agglutination test the clumps are slowly formed and are small and dense, whereas in H-agglutination, or the customary Widal, the clumps appear more rapidly and are large, loose, and fluffy. O-agglutination is however a group reaction, common to typhoid, paratyphoids A and B and Gaertner infection, and for further differentiation within that group one may have to wait for the appearance of the H-agglutinins, which are specific.* Much depends

on the extreme sensitiveness of the strains of 'O' variants of *B. typhosus*.

A passing reference to this type of agglutinin and the part it plays in the course of typhoid infection has already been made in a previous paper, and since then it has been possible to put my suggestions into practice in a large number of cases and to verify them. It was suggested that during the course of typhoid infection some correlation exists between the presence of O-agglutinins in the serum and the presence of infective organisms circulating in the blood stream at the same time, which influences the prognosis of the case to a great extent. The present study of fifty cases of typhoid fever confirms the original suggestion and the findings, as will be immediately seen from reference to tables A and B.

While I was going through the literature on the subject of O-agglutinins I was investigating two cases of enterica, both in the second week of the disease. Clot cultures from both cases were positive for *B. typhosus*; the H-Widal was positive in both the cases in a serum dilution of 1 in 250; one of the patients died of toxæmia and the other one made an uneventful recovery. The suggestions of Felix regarding the prognostic value of the O-agglutination test encouraged me to test the serum of both these patients—which I had kept—for the presence of O-agglutinins; the tests demonstrated a complete absence of this type of agglutinin in the serum of the one that died, and its presence up to a dilution of 1 in 250 in that of the one that survived. It is interesting to note that the end titre of H, or large-flaking, agglutinins was also determined and was found to be almost 1 in 5,000 in both the cases.

This was the starting point of the investigation reported below. Since then, I have been able to verify this observation and by correlating my findings I am usually able to make a correct guess as to the chances of life of the patient, as far as possible independent of any clinical prognosis.

The following is the actual technique employed in performing the O-agglutination test:

A sample of blood five to ten cubic centimetres is received from the hospital in a sterile test-tube. The clear serum is tested in the usual way by the customary Widal for typhoid, and paratyphoids A and B, and a part of the serum is stocked aseptically for further use. The remaining clot is then cultured in a medium of sterile ox-bile. For the O-agglutination test, Dreyer's method of setting up the test, with only first series of dilutions, was used throughout (macroscopic). The titres were calculated from the readings obtained after four and a half hours incubation in the water bath at 53 to 55°C. and a further period of sixteen to twenty hours at room temperature. The last tube showing a definite trace of clumping was taken

*[Note.—The 'O' antigens of typhoid and enteritidis are similar but the 'O' antigens of both paratyphoid A and paratyphoid B are antigenically different from typhoid and from each other. The presence of O-agglutinins, therefore, is diagnostic in all cases except where there is suspicion of enteritidis infection; in these cases one has to wait for the appearance of H-agglutinins.

The author throughout used the term *OH*-agglutinins, instead of the more usual *H*-agglutinins. Further, he wrongly attributes this term to Felix (1929) in his quotation from that writer; we have corrected this quotation and in order not to confuse readers have used the now generally accepted term 'H-agglutinins'.—EDITOR, J.M.G.]

as the end point. Use of hand lens was made wherever required. Standard alcoholic suspensions, from the Standard Laboratory, Oxford, were used.

Thus, from one sample of blood three findings were noted each time, H-Widal, O-Widal, and the result of clot culture. Along with these triple findings, important details as regards the clinical history of the case were recorded. In every case thus observed, the previous history regarding inoculation with T. A. B. vaccine or any attack of typhoid fever within the last couple of years, or treatment with injections of 'sero-bacterin' (Mulfords) was ascertained with the utmost care.

When a series recorded in this fashion accumulated to fifty cases, of which the majority are controlled by positive clot cultures, it became possible to draw certain inferences which, in my opinion, fully substantiate the suggestions of Felix as regards the value of sero-prognosis. A critical analysis of tables A and B not only gives an indication of the value of O-agglutination in sero-prognosis and sero-diagnosis, but supplies valuable data regarding the appearance, period of maintenance and the disappearance from the serum of O-agglutinins.

Discussion on the tables

Fifty cases of typhoid fever are divided into two groups according as the case ended fatally or recovered. Table A shows twelve cases that ended fatally and table B thirty-eight cases of recovery. Fatal termination is the only criterion of severity here considered, although some of those that recovered were clinically of a severe type with a grave prognosis.

Table A.—The H-Widal, the O-Widal and clot culture were all done with the same sample of blood each time.

Firstly, it will be noted that O-agglutinins were absent in the first nine of twelve fatal cases; secondly, they were absent at a time when infective organisms were circulating in the blood; thirdly, the days of fever on which these findings were noted were very variable, extending from the eighth day to the twenty-eighth day of fever; fourthly, every patient died within two to three days of the last laboratory examination; and lastly, the titre of the H-agglutinins is a matter of no importance as regards the prognosis. This last is an important point in view of the old erroneous theory regarding the prognostic value of a rising H titre.

It is particularly interesting to study the clinical features of the last three cases from the table; O-agglutinins were definitely present in a serum dilution 1 in 250 (end titres not done). Whereas one would predict good chances of recovery under these conditions, death actually ensued.

It seems probable that even O-agglutinins are powerless in the presence of heavy secondary infections, such as those of pneumococci and

streptococci that were noted respectively in the first two of these cases.

Further it is possible that the critical point in the titre which determines death or recovery is higher than 1 in 250, which was the highest point to which the titre in any of these O-agglutination tests was carried.

Table B.—This records 38 cases of typhoid fever, the majority being controlled by positive clot culture, that recovered and were discharged from the hospital as cured. A few of these cases, namely, nos. 2, 3, 11, 18, 20 and 21, did not run a very smooth course during their illness, unlike the majority who made uneventful recoveries. Out of 38 cases clot cultures were positive in 22, while the rest were diagnosed clinically and serologically. Unlike the table of deaths, the table of recoveries demonstrates the presence of O-agglutinins at some stage of the infection, although the day on which they appear seems to be variable.

Usually the patient is admitted to hospital after six or more days of continued pyrexia at home, so that the earliest observation in this table is on the sixth day of fever, and the majority have been tested from the eighth day onwards. The last examination was usually done on the day the patient left hospital.

In connection with the tables, the following questions arise:—What is the earliest periods during typhoid infection at which O- and H-agglutinins, respectively, appear? Do both appear simultaneously, or one after the other? When O-agglutinins are once formed, are they liable to fluctuations or complete disappearance in the early part of the infection? What is the limit of their late appearance in the patient's serum, (a) when he is going to recover, and (b) when he is going to die? What is the earliest period at which they cease to be demonstrated in the convalescent patient's serum? And, lastly, what may be the longest period at which they can be demonstrated in the patient's serum during convalescence or after cure?

It may not be possible here to answer all these questions but certain generalizations can be made which do not seem to be in keeping with those of other observers.

O-agglutinins were absent in the four cases (table B) in which the first test was done on the sixth or seventh day, but of those done on the sixth or seventh day, but of those done in the second week, they were present in nine out of fifteen cases of table B and in only one out of six in table A. H-agglutinins were present in one of the cases tested on the seventh day, and in all but two of the fifteen tested during the second week.

In one case O-agglutinins were absent as late as the eighteenth day, but they appeared three days later and the patient's condition improved coincidentally.

In one case of table B the O-agglutinins had disappeared by the twenty-second day and in another on the twenty-eighth, but in five out of

six cases that were tested in the fifth, sixth and seventh weeks they were still present.

There are no consistent records by other observers regarding these particular points, but in the opinion of Felix and Olitzki (1928) both agglutinins are formed in the majority of typhoid cases though there may be great variations in the time of their appearance during the course of the disease. It is pointed out in the Medical Research Council's *A System of Bacteriology* (Vol. VI) that, compared with the H-agglutinins, the somatic or O-agglutinins seldom reach so high a titre during infection, usually disappear more rapidly after recovery, and are not known to be capable of resuscitation by non-specific stimuli.

O-agglutinins in sero-diagnosis

The diagnostic significance of the O-Widal is unchallenged and it is usually considered worth while performing this test as a diagnostic measure, but in this particular series, in which all were controlled by the H-agglutination test and 36 out of 50 by cultural methods, no single case of typhoid gave a positive O-agglutination test in the absence of H-agglutination. This is contrary to the experience of workers in Palestine (Felix, 1929) and South Africa (Pijper, 1930), and Gardner (1929) suggests that O-agglutinins are relatively more common in the typhoid encountered in the latter country than in Europe.

The quantity of O-agglutinins formed may be a variable factor, depending on season, country, or infective agent. In all the cases in this series, either the H-agglutination test is definitely diagnostic, or, in its absence, the culture

for *B. typhosus* is positive. Hence it appears that with the method of clot culture and the H-Widal test, there is little opportunity of missing the diagnosis of typhoid fever. Still it is advisable to follow Gardner's suggestions, who recommends that 'if inoculation be particularly excluded the estimation of O-agglutinins is only called for when the customary H-Widal is negative or doubtful'.

O-agglutinins in sero-prognosis.

The importance of the somatic agglutinins or O-agglutinins in the sero-prognosis has been stressed by Felix (1929), who observes, 'when the possibility of sero-prognosis in typhoid fever was recognized as being based on the regular and the close relationship between O-agglutination and the severity of the disease, but, independent of H-agglutination, the chief attention was directed to the O- rather than to the H-agglutination'. They are absent in the most severe cases and in a certain proportion of the slightest cases. Table A demonstrates clearly the truth of this statement. Stuart and Krikorian (1928) also record similar cases and observe that in view of the important rôle assigned by certain workers to the small-flaking or O-agglutinins in the production of immunity, it is of interest to record that such cases terminated fatally. The old method of sero-prognosis, by demonstrating the gradual rise in the H titre till it reaches a certain maximum, holds good no longer, as these agglutinins fluctuate over a wide range independently of the clinical course of the disease.

TABLE A

Deaths

Serial number	Day of fever	H-Widal	O-Widal	Clot culture	Day of death	Cause of death
1	8th	1 in 250	Negative	<i>B. typhosus</i>	12th	Toxæmia.
2	12th	Negative	Negative	<i>B. typhosus</i>	16th	Hæmorrhage.
3	12th	Negative	Negative	<i>B. typhosus</i>	..	Hæmorrhage.
4	22nd	Negative	Negative	<i>B. typhosus</i>	30th	Toxæmia.

TABLE B—concl'd.

Serial number	Day of fever	H-Widal	O-Widal	Clot culture
29	17th	1 in 250	1 in 125	Sterile.
30	?	1 in 125	Negative	Sterile.
31	?	1 in 50	1 in 50	Sterile.
32	?	1 in 250	Negative	Sterile.
33	11th	Negative	Negative	<i>B. typhosus.</i>
34	?	1 in 250	Negative	Sterile.
35	6th	Negative	Negative	<i>B. typhosus.</i>
36	9th	1 in 125	Negative	Contam.
37	?	1 in 50	1 in 125	Sterile.
38	10th	1 in 125	1 in 125	<i>B. typhosus.</i>

Note.—Nos. 2, 3, 11, 20 and 21 were all very severe cases and their condition became very low during the course of the disease.

No. 6:—*B. typhosus* was isolated from the urine on the 37th day.

No. 18:—This patient had fits and paresis of the extremities during the fever. Paratyphoid A 1 in 250 on the 8th day and 1 in 25 on the 13th day.

Summary and conclusions

1. Somatic agglutinins play a very important rôle in the immunology of enteric fevers, and particularly in typhoid fever. By estimation of the titre during the course of the infection, at very critical junctures in clinical prognosis it is possible to forecast with considerable accuracy the chances of life or otherwise for the patient. It is essential to consider the findings of O-Widal and the clot culture together from the same sample in interpreting the significance of the presence or absence of O-agglutinins. Their absence in the second week, combined with the presence of the causative organism in the blood, should arouse grave suspicion as regards the immunological response of the patient. Absence of O-agglutinins in the third week of typhoid fever with a negative clot culture may be looked upon as a natural termination of events.

2. Small-flaking or O-agglutinins play a very inconspicuous part in the sero-diagnostic of typhoid fever, especially in this part of the country (Bombay), and therefore it appears unnecessary to make use of the O-agglutination test as a routine measure, provided the combined method of clot culture and H-agglutination test from the same sample of blood is followed. Incidence of inoculated cases also being small, as compared with other advanced countries, there will be very few chances of discrepancies in the Dreyer's method of Widal test.

Even in inoculated persons suffering from typhoid fever, it is advisable to follow this combined method of clot culture and Widal reaction as then the clot culture will settle the diagnosis irrespective of O- and H-agglutinins.

Before concluding, I desire to express my gratitude to the Professor of Bacteriology and to the Professor of Pathology, Grant Medical

College, Bombay, for allowing me to carry on this work and helping me at every stage, and to the other members of the staff of the bacteriology department for the whole-hearted assistance they had given to me.

SOME OBSERVATIONS AFTER SPLENECTOMY IN RABBITS

By R. K. PAL, M.Sc., M.B. (Cal.), D.Sc., M.R.C.P. (Edin.)

S. PRASAD, B.Sc., M.B. (Cal.)

and

H. N. BANERJEE, B.Sc. (Pat.)

(From the Department of Physiology, Prince of Wales Medical College, Patna)

THE rôle of spleen on the cholesterol metabolism has not been fully ascertained as yet. Different results have been obtained by different workers regarding the cholesterol content of the blood after splenectomy. Combes (1928) found that splenectomy was followed by a temporary fall in the blood cholesterol. Frenczell and Nekludow (1928) found that splenectomy in dogs, cats and rabbits was followed by hypercholesterinaemia. According to Bugnard (1929) cholesterol in the blood is increased after splenectomy. In the face of these contradictory results, it seemed justifiable to carry out further experimental work to elucidate the relationship

of the spleen to lipid metabolism, and hence the present work was undertaken.

Splenectomy was done on eight rabbits (under chloroform anaesthesia) by an oblique incision along the left interior costal margin, about an inch and a half long. When the peritoneum was opened after cutting through the skin and muscle, the spleen lying on the gastric wall at once came into sight. The spleen was held up and all the branches of the splenic artery were tied separately. The spleen was finally removed and the muscles and skin were sutured, the former by catgut and the latter by silkworm gut. The wound, as a rule, healed by first intention and the sutures were removed on the tenth day after operation.

Blood was collected from an incision on the ear veins and the cholesterol content was estimated, by the Leiboff's method modified by Banerji (1933), once every week. Total counts for red blood and white blood corpuscles, haemoglobin content and reticulocyte count were also done and recorded at the same time.

The following table and graph show the average red blood cell count, haemoglobin content, colour index, white blood cell count, and the reticulocyte counts of the eight animals after splenectomy.

From this, it is obvious that splenectomy was followed by anaemia, both the red blood cell count and haemoglobin content being steadily diminished till one month, after which both of them went up again. There was a steady fall in the cholesterol content of the blood too, which ran parallel with the diminution of the red blood cell count and haemoglobin content. The colour index remained steady during the month following the splenectomy which showed that the haemoglobin content of each corpuscle remained constant. From the fourth week onwards, there was again a tendency for the red blood cell count and haemoglobin to rise, whereas the cholesterol content still continued to fall.

The white blood cell count at the same time steadily went up until the sixth week when it began to fall again. The reticulocytic count showed a sudden flaring up just after the splenectomy, but it came down gradually, reaching its normal level by the fourth week.

TABLE

Week	Red blood cell	Hæmoglobin	Colour index	White blood cell	Reticulo-cytes	Cholesterol
Before operation	6,342,142	101	0.8	7,186	2.15	67.4
First week	6,148,571	100.7	0.81	12,057	5.4	63.55
Second week	5,837,328	95.7	0.81	14,312	4.05	61.3
Third week	5,520,000	91	0.82	11,458	3.45	58.7
Fourth week	5,720,000	95.4	0.84	9,062	2.24	53.8

GRAPH

Red cells — unit	..	1,000,000 cells per c.mm.
Hæmoglobin "	..	20 per cent.
Colour index "	..	0.2.
Cholesterol "	..	20
White cells "	..	10,000 cells per c.mm.
Reticulocytes "	..	5 per cent.

Discussion

Many observers, *e.g.*, Pearce, Krumbhaar, and Frazier (1918), have observed temporary anæmia of the secondary type after splenectomy, but experimental results in our hands show that though there was a fall in the red blood cell count and diminution in the hæmoglobin content, the former remained about five and a half millions and the hæmoglobin content did not fall below 91 per cent, the colour index remaining almost the same. These facts clearly show that there was no true anæmia after splenectomy.

The fall in the cholesterol content was due to the diminution of the red blood cell count. As there was no rise in the cholesterol content, the slight diminution in the red blood cell count can not be explained as due to increased destruction of the red blood corpuscles. Increase in the white blood corpuscle and reticulocyte counts points towards an increased formation of these corpuscles. This is quite contrary to Krumbhaar's belief (1926) that probably the spleen gives rise to some substance which has a

stimulating influence on the red bone marrow cells. The increase in the white blood cell count was mainly due to increase in the number of polymorphonuclear cells, most of which belonged to the first and second groups of the Arneeth count, that is, they were recently-developed cells.

Curiously enough, in spite of the increase in the reticulocytic count the red blood cell count went down, a fact that has yet to be explained.

Summary

Splenectomy was performed on eight rabbits and certain hæmatological observations were made at weekly intervals; the results can be summarized, as follows:—

The cholesterol content fell slightly but steadily.

There is no anæmia though the red blood corpuscle count and the hæmoglobin content too showed slight diminution.

There was an increase in the white blood cell count and the reticulocytic count, showing a stimulation of the marrow activity after splenectomy.

A Mirror of Hospital Practice

TWO CASES OF PERIPHERAL NEURITIS TREATED BY INTRAVENOUS INJECTIONS OF SODIUM IODIDE

By A. B. SARDESHPANDE, M.C.P.S., B.M.S.
Medical Officer-in-Charge, Civil Hospital, Sadra,
Sabar Kantha

THESE cases were the result of influenza which prevailed in the towns and villages of Mahikantha in an epidemic form in the months of January, February and March of this year.

The object of reporting them is to show that, in cases which were quite helpless, the effect of intravenous injections was striking, the patients showing improvement within twenty-four hours after the first injection.

Clinical history

Case 1.—A Sikh youth, aged 22 years, was admitted to the civil hospital, Sadra, for an attack of fever and cough following a game of hockey. The temperature on admission was 101°F., the pharynx was congested and râles were heard over the base of the left lung. On the 25th January, 1934, the patient began to complain of tingling sensation in both the upper and lower extremities. On the 28th the lower extremities could not support the body-weight. On the 1st February the patient developed anaesthesia of both upper and lower extremities. The general reflexes were lost but the bladder and rectum were unaffected.

Condition of the patient before the treatment was started.—The patient was quite helpless, could not raise himself in bed without support, or stand even when supported; he was unable to grip an object with his hands. General reflexes were lost but the bladder and rectum were unaffected.

Treatment.—Intravenous injections of sodium iodide—15 grains in 10 cubic centimetres of distilled water—were started on the 15th February and were repeated on alternate days. Twenty-four hours after the first injection the patient began to feel stronger; the anaesthesia gradually disappeared, and his grip became firmer. The upper extremities improved earlier than the lower and he was up and moving about in a fortnight. He was given fourteen injections in all and was discharged cured.

Case 2.—An adult, 35 years of age, was admitted into the civil hospital, Sadra, on 2nd March, 1934, with a history of fever, cough and naso-pharyngeal catarrh of fifteen days' duration. On the fourth day of his illness, he began to notice numbness and tingling in both his upper and lower extremities.

Condition on admission.—The patient had a temperature of 100°F., the grip of both hands was weak; he could neither raise his arms nor raise himself in bed without help. He could not stand although he could move his limbs; knee jerks were somewhat exaggerated; ankle clonus and triceps reflex were absent.

Being encouraged by the result of the first case, intravenous injections of sodium iodide in fifteen-grain doses were started and were repeated every other day. The first injection was given on the 3rd March. On the 5th the upper extremity began to show signs of improvement. On the 7th he could raise his left arm fully and on the 9th he could sit in bed without help. He went on improving steadily, the right arm being the last to recover and he was discharged completely cured on the 22nd March, i.e., on the 19th day after the treatment was started. In all he had ten injections.

A CASE OF CEREBRAL MENINGEAL HÆMORRHAGE

By B. L. CHOPRA, L.R.C.P., L.M., D.P.H.,
D.T.M. (Liverpool)

District Medical Officer, North-Western Railway, Delhi

THE following case appears worthy of record as it illustrates the great diagnostic importance of lumbar puncture in cases of cerebral meningeal hæmorrhage, and shows also how such punctures may assist greatly in the treatment of meningeal hæmorrhage :

A man was admitted into the North-Western Railway hospital, Delhi, on the 4th February, 1934, in an unconscious state with a temperature of 101.4°F. The tongue was thickly furred and the pupils reacted to light. He was given a soap-and-water enema on admission but without satisfactory result. A blood film was prepared and examined for malarial parasites but was found to be negative. Next morning the temperature was 99.4°F. and his condition remained the same. At times he regained consciousness for short intervals

and was given nourishment. A soap-and-water enema was repeated but without any greater success than on the former occasion.

The temperature rose to 100.4°F. in the evening, the breathing became stertorous and his condition appeared grave at about midnight. There were signs of passive congestion of the right eyeball and paresis of some of the ocular muscles of the right eye; the pupil was dilated and proptosis was present.

The temperature was now 102.2°F. Twitching of the head and left arm was noticed. I suspected meningeal hæmorrhage and decided to do a lumbar puncture to confirm the diagnosis. About 50 cubic centimetres of cerebrospinal fluid were drawn off. The first 20 cubic centimetres of fluid came out under great pressure but it was quite clear in appearance. The remaining 30 cubic centimetres were blood-stained. The diagnosis of intradural cerebral hæmorrhage having been made it was decided to trephine the skull and remove any blood clot. A few hours later however, when I visited the hospital for this purpose, a great improvement in the patient's condition was noticed. The breathing was quiet. The passive congestion of the right eyeball had almost disappeared. The patient was quite conscious and no twitching of the fingers, etc., was noticed. The temperature had dropped to 99°F. It was considered advisable to postpone trephining the skull and to keep him under observation for a few days. Recovery was rapid and uneventful so that he was able to return to his work two weeks later.

My thanks are due to the Chief Medical and Health Officer, North Western Railway, Lahore, for his permission to publish this case.

LYMPHADENITIS OF THE RETROPERITONEAL GLANDS SIMULATING APPENDICITIS

By MONINDRANATH BOSE, L.M.F.

*Medical Officer, Amoragori Charitable Dispensary,
Howrah*

THE following cases are of interest not only on account of the comparative rarity of the condition, but also because of the difficulty experienced at an accurate clinical diagnosis :

Case 1.—An Ooriya boy, aged 16, was admitted as an in-patient to the Amoragori Charitable Dispensary suffering from pain in the right groin, thigh and knee. He had been unable to walk for two days. On admission his temperature was 100°F. His right hip was flexed to an angle of 45 degrees and extension was very limited and painful; tenderness in the right iliac fossa was very marked and a few enlarged inguinal glands were found. The abdomen moved well. The spine appeared normal. Rectal examination showed marked tenderness on the right side, but a mass was not felt. The bowels had been constipated and an action was secured on the day of admission by the use of castor oil.

Case 2.—A boy, aged 4 years, was brought to the out-door department when I was a medical officer of the Bargachia Thana Charitable Dispensary. He was limping and constipated and had previously complained of pain in the right hip. His temperature had fluctuated between 100 to 102°F. for at least a week. The extension of the right leg was limited and painful. There was slight rigidity in the right iliac fossa and above the pubis and tenderness over the abdomen which was very marked over McBurney's point. The right inguinal glands were slightly enlarged and painful. Rectal examination revealed tenderness high up on the right side, but no lump was detected. Nothing abnormal could be seen or felt in the spine or loin.

Differential diagnosis

In neither of the cases was a correct diagnosis made at first. The presence of lymphadenitis of the retroperitoneal glands was not recognized; they were diagnosed as an appendicitis. The insidious onset and absence of marked and progressive signs of peritonitis, in spite of continued temperature, distinguished it from appendicitis. As regards arthritis of the hip joint, a condition which is characterized by the immovability of the joint, a careful examination showed that all the movements could be made painless if the hip were held in flexion. Fibrositis of the loin muscles was a very common cause of pain in this region but no nodules of fibrous tissue could be palpated when the muscles were relaxed.

Case 2 was a type of mesenteric adenitis common in children, usually simulating appendicitis. The sudden rise of temperature as in this case along with relatively less signs of toxicity served to differentiate it from appendicitis.

The question of Pott's disease may possibly be considered but there was no loss of mobility of the spine, when the patient was sitting, consequently this was an argument for excluding the spine as the seat of the disease.

Psoas abscess, arising from tuberculous or pyogenic adenitis of the retroperitoneal glands, might suggest itself. The absence of swelling and fluctuation followed by a rapid recovery after rest and treatment with antiphlogistine excluded this possibility. The evidence in general pointed to a simple adenitis with abscess formation.

[Note.—Though the writer may be quite correct in his diagnosis, the evidence he adduces is not entirely convincing. No mention is made of the abdomen having been opened. It would of course not have been to the advantage of the patients had this been done, but it would have confirmed the diagnosis.—EDITOR, I.M.G.]

A CASE OF ENTERIC FEVER

By D. SUNDERARAJ, L.M.P.

Honorary Clinical Assistant, St. Bartholomew's Hospital, Ootacamund

BELOW is a record of a case of enteric fever beginning as an osteomyelitis, a phenomenon of great interest and of no less importance despite the fact that such a condition is rare:

The patient, a female child, aged 10 years, was admitted into our hospital on account of a high fever and painful swelling on the dorsal aspect of the left foot. On admission the temperature was 104°F., pulse—138 and respiration—40.

Surgical measures were adopted as treatment in scraping away the necrosed part of the metatarsal bone. The recovery of the local condition followed rapidly but the high temperature was singularly persistent and was accompanied by morning remissions.

In spite of the healthy post-operative wound, the temperature remained at the same level for a period of eight weeks, oscillating however between morning temperatures of 99° to 100°F., and evening temperatures of 104° to 105°F. It then gradually fell to normal by lysis.

Examinations of the blood at frequent intervals revealed an increase in the lymphocytic count, the maximum being 80 per cent during the third week of the febrile period.

Differential count of white blood cell—

	First week	Third week	Sixth week
	Per cent	Per cent	Per cent
Polymorphonuclears ..	64	12	59
Lymphocytes ..	24	80	36
Large mononuclears ..	10	5	3
Eosinophils ..	2	3	2
Basophils

Specimens of blood withdrawn from the vein, thrice during the course of the disease, were tested for the Widal reaction, the last two specimens proving positive.

Results of Widal reaction—

Third week	Fifth week	Seventh week
Negative	<i>B. typhosus</i> , positive 1 in 100.	<i>B. typhosus</i> , positive 1 in 200.
	<i>B. paratyphosus</i> , A, positive 1 in 25.	<i>B. paratyphosus</i> , positive 1 in 50.

The enlargement of the spleen was marked. The organ remained enlarged during the third week of illness to a breadth of two fingers below the costal margin.

The patient was treated as a case of enteric soon after her admission into the hospital after eliminating all possible causes of persistent pyrexia simulating enteric fever. This provisional diagnosis was confirmed later by an increased lymphocytic count, an enlarged tender spleen and positive Widal reaction.

In conclusion, I believe that it is possible for enteric fever to set in as osteomyelitis although such a bony lesion at the very onset of enteric fever is extremely rare.

I am indebted to our superintendent, Lieut.-Colonel A. S. Leslie, I.M.S., for having kindly permitted me to make use of the notes from the hospital.

AN UNUSUAL CASE OF STRANGULATED HERNIA

By S. V. SAHASRABUDHE, S.M.S.

Sub-charge, Civil Hospital, Satara

A WOMAN from a local village was admitted to the Satara civil hospital, on account of the strangulation of the lower abdominal wall. She had a brass pot sticking firmly on to the abdominal wall, with the protrusion projecting through the narrow neck of the pot. The condition of the strangled portion was blue and tense with blisters appearing on to the surface. On enquiry it was found that she had used the pot 'Tapeli' as a dry cup to relieve the pain in the abdomen.

When the hernia became strangled the villagers had cut open the base of the pot with the idea of relieving the patient but without effect. I chloroformed the woman and introduced castor oil over the projecting portion through the opened-up base to make it slippery and eventually succeeded in relieving the woman. The duration of the strangulation was five hours. She was discharged cured the next day.

This case illustrates how a narrow-necked pot is likely to be dangerous even although it is widely used as a country method of cupping.

Indian Medical Gazette

OCTOBER

INTRAVENOUS VERSUS INTRAMUSCULAR QUININE

For a number of years, certainly for the last twenty, there has been an official ban on intramuscular quinine. Textbooks, teachers and even regulations have been uncompromising in their condemnation of this method of administering quinine. Research workers have been called in evidence and have supported strongly this official attitude; they have shown that the injected quinine solution causes local necrosis so that the slightest sepsis will lead to abscess formation and possibly extensive tissue destruction; even in the absence of extraneous infection, endogenous infection may lead to the same result; and finally (the most terrifying bogey of all) enterogenous tetanus is held up, not as a theoretical possibility but as an experimental probability. Yet despite this unanimous teaching, despite these repeated warnings, despite even actual threats—the statement that giving of an intramuscular injection amounts almost to malpraxis—many of the most observant and careful practitioners throughout the length and breadth of this country, and probably of many other countries as well, continue to give intramuscular injections without the slightest hesitation when they consider that the special circumstances demand it.

Such a widespread exhibition of perversity in the medical profession should not, we feel, be overlooked. The pundits must assert themselves; they must either establish their case by scientific examination of the clinical experience of those who still persist in flouting their authority, or by repeating their experiments and providing even more convincing evidence in support of their contentions or, should they find that there had been any flaws in the interpretation of their experiments, withdraw from their present uncompromising position.

In other words, we consider that it is time that the question of intramuscular—that is, intramuscular *versus* intravenous—quinine was reopened. We stress 'intramuscular *versus* intravenous' because we do not believe that there is any need for the question of oral *versus* intramuscular quinine to be raised, nor that the routine administration of quinine by the intramuscular route can be too emphatically condemned. Oral administration is the method of choice and it is only in special circumstances that parenteral* administration is indicated;

there is certain to be some difference of opinion as to what constitute these special circumstances—some practitioners will produce their syringes on the slightest provocation, whereas others will adhere to the oral method until their patients are comatose. The parenteral route is indicated in case of emergency, that is to say cases in which one cannot afford to risk the possible delays of the oral route, *e.g.*, cases of heavy malignant tertian infection, and/or cases with hyperpyrexia or cerebral symptoms, in cases with persistent vomiting, and in other cases where one doubts the ability or the will of the patients to swallow, retain or absorb a suitable dose of cinchona alkaloids or other antimalarial drugs. In all other circumstances the drug should be given by the oral route; normally the absorption of the drug from the stomach is so rapid that little time is to be gained by giving it intravenously, and possibly less by giving it intramuscularly, but it is the risk of the possible rejection of the drug or of delay in its absorption that one cannot afford to take in certain cases.

The question of the danger of tetanus is a very difficult one; danger there undoubtedly is, as there is in any minor surgical procedure or in crossing a road. But we do not abandon minor surgery, nor remain always on one side of a road on this account. It is all a matter of the extent of the danger. Then the question arises. Can the danger be obviated by the exercise of care? The answer is that in none of our three examples can it be obviated entirely, but it can be reduced very considerably. With the exercise of scrupulous care the danger of introducing tetanus spores can be reduced to zero, but there is still the possibility of endogenous infection of the site. The case for this is largely dependent on theory; all experiments that are cited in support were conducted many years ago and some of them have been questioned. We then come to the clinical evidence; cases of tetanus following intramuscular injections have been reported—Semple collected ten such cases—but, in view of the vast number of injections that are given annually, this is not a very significant number. Semple, who was a great opponent of intramuscular quinine, brings human nature into his argument and says that clinicians hesitate to report deaths following their quinine injections. This is an argument that can be turned against him; we can imagine a clinician reporting a case of tetanus but we cannot imagine him admitting that it was probably due to his own carelessness. There is another point in this connection, though a clinician might hesitate to announce such a disaster from the house-tops, he would certainly discontinue to give intramuscular injections of quinine and would privately warn his friends of their dangers.

On the other hand it is not sufficient for a practitioner to say 'I have given so many

* We use this word as meaning 'in some other way than by the intestinal canal'.

Recently a writer on this subject made a distinction between intravenous and parenteral injections.

hundreds (or even thousands) of intramuscular injections of quinine and have never had a case of tetanus yet; therefore the practice is a safe one'. A man does not say 'I frequently cross roads; I am still alive; therefore it is quite safe to cross roads', and we know of no ethical law that allows each doctor one death for each procedure that he adopts before he discontinues it. The first part of the practitioner's statement is useful as evidence to be added to that of others, and it is only by the collection and statistical examination of such evidence that the case will be judged.

In the matter of less serious complications, such as abscess formation or extensive necrosis, we can give more weight to the evidence of the individual practitioner, and the experience of the majority seems to indicate that these accidents are rare if proper precautions are taken. Here, we feel, clinical experience should be allowed to override laboratory experiment. There is no doubt that quinine in the usual strengths injected into the muscles of animals—rabbits have usually been used—does cause necrosis, and it seems quite possible that some degree of necrosis follows these injections in man; the point to be settled, however, is whether this necrosis assumes any clinical importance, and this can be settled more satisfactorily in the field than in the laboratory.

A good deal of evidence has been produced to show that quinine injected into the muscles is absorbed very slowly—the fact has been claimed both as an advantage and as a disadvantage of this method of administration. We have not examined all the experimental evidence on this point but in most cases the argument depends on the injection of relatively huge doses into animals, after which it is shown that the majority of the quinine can still be recovered from the site of injection after varying intervals. A recent re-investigation of this point (reported on page 560 of this issue of the *Gazette*) has brought to light some very interesting facts. Therapeutic doses—in contradistinction to large experimental doses—were injected into monkeys by the intramuscular and by the intravenous route, and at intervals from fifteen minutes to twenty-four hours their blood was examined for quinine, quantitatively. At the end of fifteen minutes the amount of quinine in the blood was the same whether it had been injected intramuscularly or intravenously; at half an hour, at one hour and at two hours, the amounts were still the same in each group but at the end of five hours more quinine was present in the blood of the intramuscular group, and at the end of twenty-four hours it was only recovered in one case, and this one was in the intramuscular group. A few similar experiments on man indicated that the time of first appearance in and disappearance from the blood of quinine was much the same as in the monkey.

Given by the oral route, quinine was recoverable from the blood after fifteen minutes, but it was present in smaller quantities than when given by either of the other routes. These findings are far more in accord with clinical experience than were earlier experiments, and will help to narrow the gap between the laboratory and the field.

We will now examine the other side of the picture. Intravenous therapy generally is very popular in the medical profession; neosalvarsan and allied arsenicals are responsible for laying the foundation of this popularity, and in areas where kala-azar is endemic, the antimony preparations for establishing it, the list of medicaments that are given by this route increases daily. The pain associated with an intravenous injection is much less than that with an intramuscular injection, so that on this score they should be popular with patients, and as a general rule they are. This general rule does not however seem to apply in the case of quinine; intravenous quinine injections are popular with neither patient nor doctor, but it is very hard to find out the exact reason for this unpopularity. The fall of blood pressure that accompanies an intravenous injection causes a feeling of faintness in the patient and very often alarms the doctor, but there is seldom anything more definite than this to be said. Elsewhere in this number will be found a paper in which the writer uses intravenous quinine apparently as a routine measure; we do not consider that this is either necessary or justifiable, but we publish his results to show that it is possible to overcome this prejudice against intravenous quinine, and, even outside the Royal Army Medical Corps and research institutions, to become sufficiently enthusiastic to use it to the exclusion of all other methods.

During the last few months, without actually issuing a questionnaire, we have asked the opinion of a number of practitioners in different parts of the country regarding the respective merits of intramuscular and intravenous quinine. A few have replied that, though they seldom give either, they prefer the intravenous route, but the majority—the vast majority—give a reply definitely in favour of the intramuscular route. Many said that they gave intravenous injections in cases of extreme urgency, but others said that they had had, or had heard of, deaths following intravenous injections and that on no account would they give them. One reply took the form of a short note which we are publishing elsewhere in this issue; this is typical of the opinions expressed.

Let us once more make it quite clear that we are not raising the question of oral *versus* parenteral quinine. There can be no possible doubt that in ninety-nine occasions out of a hundred the oral is the route of choice and to give quinine intramuscularly as a routine is a

gross abuse. But we are not at all sure that the wholesale and indiscriminate condemnation

of intramuscular quinine has not helped to undermine authority and keep alive this abuse.

RAI SHAMBHU DAYAL SAHIB GOLD MEDAL

(1) A gold medal called the 'Rai Shambhu Dayal Sahib Gold Medal' will be presented for the best prize essay on a public health subject to be announced each year.

(2) The subject of the next essay is 'A scheme for the improvement of milk supplies in Indian towns'.

(3) The competition will be open to the general public including the medical, and the public health workers in the United Provinces.

(4) The essay is to be written in Hindi and should not exceed 3,000 words in length.

(5) Essays should reach the Medical Officer in charge, Provincial Hygiene Institute, United Provinces, Lucknow, by 15th November, 1934.

(6) The name and address of the competitor must be distinctly written on each essay submitted and the envelope should have the words 'Prize Essay' in the top left-hand corner.

(7) The Director of Public Health, United Provinces, shall judge the merit of the essay and his decision with regard to the award of the medal shall be final.

(8) No correspondence will be entered into on the subject of competition.

(9) No essay will be returned.

MANSON-ROSS RECEPTION

On 29th June, a reception was held at the London School of Tropical Medicine and Hygiene to celebrate the incorporation of the Ross Institute in the London School, and to do honour to two famous pioneers in tropical medicine, Patrick Manson and Ronald Ross.

An important function at this reception was the unveiling of a medallion and bust of these two great men which have been presented to the school. This ceremony was performed by the Right Hon. the Earl of Athlone, K.G., whose speech on this occasion we give below:—

'This evening we do honour at one and the same time to the memories of two of our greatest and most famous men, Patrick Manson and Ronald Ross.

We do honour to the memory of the one because, after his labours overseas alone and ill equipped, he had the vision and the courage to inspire and mould teaching and research in Tropical Medicine and to lay the foundations of a nobly-conceived centre of education.

The other to whom we do honour was in turn inspired by the Father of Modern Tropical Medicine, and, through toil and pain and strain, brought to mankind—and especially to the teeming millions of the tropics—a wonderful and priceless gift and we are reminded to-day that he, at the moment of his great discovery, when he wrote his inspired poem, turned at the same moment to write to the other great man to whom he owed so much: "My one wish is that you were here to share with me the pleasure which I have experienced yesterday and to-day in seeing your induction being verified step by step".

PATRICK MANSON, 1844-1922

Manson was a pioneer in the untrodden paths of medicine. He was a great doctor in every sense of the word and in every branch of his profession—although he styled himself "not so much a good surgeon as a good carpenter".

He left Scotland in 1865 at the age of 21 and went to Formosa, working there and in China for nearly a quarter of a century.

Few now can realize what such isolation meant, isolation in every sense; he had no books, no helpful companionship, no one but his own native intuition to consult. All these circumstances combined to make Manson the pioneer upon a vast uncharted field of medicine which lay at his feet, and there he taught himself to look down his primitive microscope and seek out the secrets for himself.

It came about that in the town of Amoy in 1877 he "stumbled upon an important fact with a distinct bearing on pathology"—a fact which was to unlock a new world—a fact which influenced the conception of the conveyance of disease, because he was able to discover by laborious experiment that a blood-sucking insect—the mosquito—acted as a nurse in propagating disease of man—the filaria worm.

Manson had no knowledge of the anatomy of insects and he had no instruments save a pen nib to carry out this fine work. He made great discoveries and described some half a dozen new parasites of man and several new diseases. No less ardent was he in seeking out new remedies—yet he was able to write "Men like myself are but poor and slow investigators crippled as we are with the necessity of making our daily bread".

About the year 1897 when Manson had been resident in London about seven years, he set himself to found and inspire the London School of Tropical Medicine, and on 1st October of that year he set out his scheme in an address at St. George's Hospital. In that address he gave the outlines of teaching and research in Tropical Medicine—in fact he laid down the lines upon which the instruction in the present school is based.

In due course he laid his scheme before Mr. Joseph Chamberlain, whose heart had been grieved with the great loss of useful lives on Government service on the West Coast of Africa. This great and far-seeing statesman at once appreciated the significance of these proposals with the result that within two years the original London School of Tropical Medicine was built and organized under the aegis of the Seamen's Hospital Society, with Manson as its presiding genius.

Here is a touch of self revelation, as contained in advice given by Sir Patrick Manson to his students:

"Never refuse to see what you do not want to see, or what might go against your own cherished hypotheses. These are just the clues to follow up, as is also, and emphatically so, the thing you have never seen before. The thing you cannot find a pigeon-hole for is the finger-point showing the way to discovery".

Manson was greatly distinguished in his career, absorbed in many fascinating scientific problems, honoured as an oracle in the school of his own creation. Some of his finest qualities were revealed in his handling of native races. He loved sport and good literature; he was fortunate in his home; his was a full and happy life, and his good deeds do follow him.

I unveil this tablet to the memory of Patrick Manson.

It is fitting that this memorial should find its permanent resting place in the central hall of this building, opposite the tablet which some little time ago I unveiled in honour of the memory of Andrew Balfour, that well-beloved man who was the first Director of this great school.

I have now the signal honour to receive this beautiful medallion and tablet from the widow and family of Sir Patrick Manson, and to ask Sir Herbert Read on

behalf of Sir Austen Chamberlain, the Governors, the Board of Management, and the Staff of the school, to hold it in safe keeping for all time.

RONALD ROSS, 1857-1932

Of the many debts which the Empire owes to Manson, not the least is that it was he who gave inspiration to Ronald Ross and pointed the road along which he travelled towards his great discovery.

In September, 1932, the whole Empire mourned the death of Ronald Ross. To-day, when we again recall his magnificent conquest of malaria, we do so on the occasion of the incorporation in this noble institution of the Institute which bore his name. The school is enriched by the addition of a great department of tropical hygiene which brings with it no substantial endowment in terms of money, but the priceless inheritance of the spirit of Ronald Ross and a zeal and courage to carry on that great warfare against Malaria which, after all, was the aim and the work of Ross throughout his life.

Ross had a fitting birthplace for one who was to tower above his fellow men in his genius, his patience, and his high moral courage. At Almora, in the Himalayas, where he was born, there were peace and pleasant coolness and everchanging views of the snows of the loftiest peaks of the world. In his school days he was, as he has told us, not interested in medicine—he wished to become an artist. Although he began the study of medicine at St. Bartholomew's Hospital, he was much more interested in philosophy, poetry, mathematics and in music than in medicine. When many years later he turned to the serious study of disease and to that branch of science in which he was to attain supreme distinction, he concentrated on the prevention of disease.

After entering the Indian Medical Service there began to sink into the mind of Ross the misery of life in India; the sad tale of poverty, of famine and of death. His reaction to this became more intense as the years passed.

Ross found the work of his life. He saw that many of the diseases of India were preventable, that disease was one of the chief causes of poverty and distress, that of all the diseases malaria was in many tracts a scourge far greater than either plague or cholera, and caused more sickness, misery, and death than any other disease.

Two strenuous years of work brought no result, but in that time Ross acquired a knowledge of the structure of the mosquito and worked out a technique for examining the insect. He toiled all through the hot weather—Indian hot weather, I would have you remember—but as failure followed failure he became exasperated and worked till he "could hardly see his way home". He tells us of his "dark, hot, little office"; and of the conditions under which he worked. "The screws of my microscope were rusted with sweat from my forehead and hands, and its last remaining eyepiece was cracked!"....."I was tired, and what was the use? I must have examined the stomachs of a thousand mosquitoes by this time. But the Angel of Fate fortunately laid his hand on my head", for under Ross's microscope at that moment was the very thing he sought. He looked—the problem is solved.

The discovery was important not only because it showed how malaria spread; it was hardly less important because it turned men to investigate insects as the carriers of other diseases, and within a few years the germs of yellow fever, relapsing fever, plague, typhus fever and sleeping sickness had all been shown to have insect hosts. Thus does a fundamental discovery open wide the flood-gates of knowledge.

Ross's triumph was more than that of the laboratory worker who after infinite patience and endurance has at last solved an interesting problem of pure science. It was the entry into a new and far more difficult territory which had to be conquered, and he was filled with a devotion to the cause of preventing disease.

King Edward's phrase: "If preventable, why not prevented?" was constantly on his lips and in his mind. He met with difficulties, misunderstandings, intolerable delays of which he was impatient. He did not spare his opponents and took no count of the bitterness which his attacks and challenges often aroused. Future generations will not hold him in less honour on this account.

The problem of antimalaria work is not a biological problem alone; it is also largely a sanitary and engineering problem. As such, it is one which must be dealt with not only by governments and municipalities, but by everybody, from the Director of Public Health to the person responsible for labour in any industry, and even to the chief of a village, all working in co-operation. The measures for stamping out this dreadful, wasteful disease must go forward everywhere with determination, with courage, and with high hope. That way lies the true path along which the workers in this school must go if they are to give Ross a real reward for his sacrifice and his labours, and do real honour to his memory.

I unveil this bust to the memory of Ronald Ross.

In memory of this great man, I accept this finely-executed bust at the hands of the sculptor, Lady Welby, and ask Sir Charles McLeod, the first Chairman of the Ross Institute, to receive it into the safe keeping of this institution; a worthy shrine for the noble memory of a noble man.

Historical note on the London School of Tropical Medicine, and on the Ross Institute

For several years after his return to England from China, Manson had urged that medical men, before proceeding to the tropics, should receive some instruction in the diagnosis, and treatment of tropical diseases, and in 1897 he formulated a scheme for a school of tropical medicine in London. In this year he became Medical Adviser to the Secretary of State for the Colonies, an office then held by Mr. Joseph Chamberlain.

The great mortality among Europeans in such climates as those of the West African colonies had from the first attracted Mr. Chamberlain's notice and his attention was directed by Manson to the importance of scientific enquiry and of special education in tropical medicine for the medical officers of the Crown Colonies.

In 1898 Chamberlain wrote officially to the Board of Management of the Seamen's Hospital Society requesting them to establish a school for the teaching of tropical diseases in connection with their Albert Dock Hospital. The Board acceded to this request. The school was officially opened on the 3rd October, 1899, in a small laboratory built in the grounds of the Albert Dock Hospital. The cost of these buildings and of their equipment was met from a fund of £12,000 raised at a dinner at the Hotel Cecil, on the 10th May, 1899, presided over by Mr. Joseph Chamberlain.

The school at once proved a successful venture and attracted students from all over the world. The premises had to be enlarged and in 1912, in response to an appeal for further funds by Sir Austen Chamberlain, the sum of £73,000 was raised.

In 1900 the school received recognition as a school of the University in the Faculty of Medicine and in 1920 it was moved from the Albert Dock to more commodious premises in the new Hospital for Tropical Diseases, adjoining University College and in close proximity to the proposed headquarters of the University of London. The building was purchased through the generosity of the British Red Cross Society for the treatment of cases of tropical diseases contracted during the Great War.

Although its life as a separate institution was brief, public appreciation of the work of the old London School of Tropical Medicine is shown by the fact that when it became incorporated in the new School of Hygiene which in 1924 received its first Charter as

the London School of Hygiene and Tropical Medicine, the public had subscribed over a quarter of a million pounds sterling for its maintenance.

The new London School of Hygiene and Tropical Medicine, which H. R. H. the Prince of Wales opened in July 1929, was the outcome of the recommendations made in 1921 by the Committee, under the presidency of Lord Athlone, appointed by the Minister of Health of that day. This Committee, finding that the post-graduate teaching of Public Health in London was inadequate and uneconomic, advocated the establishment of a central institution, affiliated to the University of London, wherein full provision should be made for instruction in all branches of preventive medicine. The Rockefeller Foundation then made a generous contribution which included the cost of this building and its equipment.

The original intention was that it should be a school of hygiene and public health, but the advantages of including under the same roof the teaching of tropical medicine and hygiene was obvious and this scheme was soon expanded accordingly, and the school opened with Sir Andrew Balfour as its first director; he was succeeded in 1931 by the present dean, Dr. W. W. Jameson.

The Ross Institute.—It was inevitable that for such a man as Ronald Ross there should be a permanent memorial at the centre of the Empire.

Sir Charles McLeod and his friends, men with wide knowledge of the needs of the tropics, had been impressed with the ravages of malaria overseas, and the great economic handicap it was to tropical industry; and it was mainly through his efforts that the money was raised and the Institute opened by H. R. H. the Prince of Wales in July 1926.

Overseas activities.—In 1928-29, a visit was paid to India by Sir Malcolm Watson and Major Lockwood Stevens, in order that Sir Malcolm, reviewing more closely the conditions in which malaria existed in many parts of India, should report to the Committee if it were possible to create an organization for the study and control of malaria for the tea industry. As a result of this visit, a scheme was drawn up which met with the support of the late Lord Inchcape and a number of other public-spirited men in London. They guaranteed the funds for three years, and at the end of the period the scheme had been so successful that

the Indian Tea Association made itself very largely responsible for financing the work in the future.

The work in India is under Dr. G. C. Ramsay, O.B.E. It illustrates the value of combining practical and scientific work. Dr. Ramsay has organized seven field research laboratories in Northern India and one in Southern India, and has shown that out of the thirty species of anophelids in Northern Bengal and Assam one only is responsible for the spread of malaria, and that this one requires certain conditions for its larval stage. This gives great hope of preventing malaria at a minimum expenditure; the practical results are already sufficiently impressive.

Co-operation.—In its various overseas activities, the staff of the Ross Institute has established contacts with, and welcomes the co-operation of, medical officers in Government service, with estate medical officers, and with others. To many it is indebted for valuable assistance; but special mention should be made of the co-operation of the Government of India and the Calcutta School of Tropical Medicine in investigating the serological reactions of the blood meals of mosquitoes.

The admirable work on anaemia carried out by the Calcutta School of Tropical Medicine is an instance of how a number of scientific bodies can work in one area together for the benefit of the community.

Mention should also be made of the valuable assistance obtained from the South African Institute for Medical Research. Through the courtesy of its Director, Sir Spencer Lister, one of its staff was deputed to carry out an investigation of the causes of pneumonia in copper mines.

Incorporation.—The incorporation of the Ross Institute in the London School of Hygiene and Tropical Medicine has for some time past appeared to be inevitable. From the historical accounts of the School and the Institute which have already been given, no one will be surprised that, quite apart from the financial and economic arguments, there were strong reasons for the amalgamation of the two bodies. Not only had they a common aim, but their spheres of work were complementary; each would provide something that the other desired; each would supplement the work of the other to the advantage of both, and to the advancement of their common object, the welfare of the peoples of the Empire and of the world.

An Improved Test for Occult Blood, Specially in the Urine

By WILLARD J. STONE, M.D.

and

GEORGE T. BURKE, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CII, 12th May, 1934, p. 1549)

ORTHOTOLIDINE was first proposed by E. B. Phelps in 1909 as a qualitative test for minute amounts of free chlorine or hypochlorites in water. It is a crystalline basic body of the aromatic series obtained by reduction from orthonitrotoluene. It has a melting point of 129-130 centigrade and is quite insoluble in distilled water. It is quite soluble in acid solutions and in alcohol and ether. Ruttan and Hardisty in 1912 described the use of orthotolidine as a test for the detection of blood. They used a 4 per cent solution in glacial acetic acid and added a small amount of perhydrol (Merck) as an oxidizing agent to obtain a blue colour in the presence of blood. They stated

that the solution would detect hæmoglobin in a dilution of one part in 7,000,000 parts of water, in a dilution of one part in 24,000 parts of urine, in a dilution of one part in 100,000 parts of faecal material, and of one part in 30,000 parts of stomach contents.

In the course of a search for a new hæmoglobin colour standard, we have found orthotolidine useful in the detection of minute quantities of blood in urinary sediments. It is safe to say that the average laboratory urine report made by technicians rarely mentions the presence of red cells unless the presence of blood is grossly evident. Red blood cells in the sediment are often crenated or disintegrated in urine specimens a few hours old and are confused with leucocytes. The formed elements, including red cells, are frequently disintegrated in alkaline urine. The continued presence of red blood cells in urinary sediments has important clinical significance in that it may attract attention to glomerular inflammatory changes, which are frequently overlooked in the absence of albuminuria or other gross evidences of disturbance. Such observations have especial significance in latent stages of chronic hæmorrhagic Bright's disease (glomerulonephritis). We have

found frequently that red cells were excreted more or less constantly in patients with evident foci of infection. Such observations have important clinical implications of glomerular inflammation. The presence of a few red cells, leucocytes or casts, in the absence of other symptoms, may have little significance following unusual exercise or exertion.

Addis examined a series of healthy students and found, by counting the red cells in the urine, that for twelve-hour night periods the number averaged 65,000 cells. The individual highest count obtained was 425,000 red cells for a twelve-hour period. This would mean, for an average twelve-hour night excretion of about 400 c.c. of urine, that the number of red cells varied approximately between 150 and 1,000 per cubic centimetre. The persistent excretion of 1,000 red cells per cubic centimetre of urine, in our experience, would not be considered within the limits of normal variation and would point toward some source of chronic glomerular irritation. The important point is that such numbers are not recoverable easily by centrifugation, since disintegration or solution frequently has occurred.

Our experiments show apparently that from 50 to 80 per cent of red cells are recoverable. This point need not be considered as settled, since varying degrees of alkalinity and preservation of specimens, as well as the rate of centrifugation, may influence the result. We have considered that 50 per cent of the cells were recoverable as being a useful average in clinical work. The following experiment will illustrate the point:

To 15 c.c. of normal, neutral or slightly acid urine, which had been filtered twice and which contained no microscopic evidence of blood, 75,000 red cells were added. The concentration then was 5,000 cells per cubic centimetre of urine. The 15 c.c. quantity was centrifuged at 1,500 revolutions per minute for five minutes. The amount of sediment obtained was about 0.1 c.c. or 100 c.mm., from which a count was made of the red cells. The count showed that the sediment contained 400 red cells per cubic millimetre. This would be equal to 40,000 red cells in approximately 0.1 c.c. of sediment representing 15 c.c. of urine. In other words, about 40,000 cells were recovered of the 75,000 cells originally present. Approximately, then, 50 per cent plus were recoverable by centrifugation at 1,500 revolutions per minute for five minutes. This may be expressed in formula as follows:

$$\frac{\text{Number of red cells per c.mm.} \times \text{millimetres of sediment} \times 2}{\text{Number of c.c. of urine used}}$$

For example, 15 c.c. of urine placed in a 15 c.c. graduated centrifuge tube yielded 0.1 c.c. of sediment with 400 red cells per cubic millimetre. The estimation would be as follows:

$$\frac{400 \times 100 \times 2}{15} \text{ or } 5,333 \text{ red cells per cubic centimetre of urine.}$$

The labour entailed in counting the red cells in urinary sediments restricts its usefulness in clinical work. We have found the following procedure useful:

(1) Orthotolidine 1 per cent in chemically pure methyl alcohol. (It dissolves with slight difficulty and keeps at least ten months.)

(2) Glacial acetic acid one part and commercial hydrogen peroxide two parts. (This keeps for three or four months, probably longer.)

(3) Fifteen c.c. of urine is centrifuged at about 1,500 revolutions per minute for five minutes. The supernatant fluid is poured off. A portion of the sediment is prepared for microscopic examination in the usual way. To the remaining sediment two drops of the orthotolidine solution is added plus two or three drops of the acid-peroxide solution. In the presence of blood cells aggregating 100 per cubic millimetre of sediment (approximately 1,350 per cubic centimetre of urine) a greenish blue colour develops, lasting about one minute. In the presence of from 300 to 500 red cells per cubic millimetre of sediment (approximately

4,000 to 6,500 cells per cubic centimetre of urine) a deeper blue colour develops lasting about one minute. In the presence of larger numbers of red cells, aggregating 1,000 per cubic millimetre of sediment (approximately 13,000 per cubic centimetre of urine) as in hæmorrhagic Bright's disease (glomerulonephritis) a deep blue colour develops lasting two minutes or longer.

Undiluted blood serum, 10 per cent sodium hydroxide, strong trisodium phosphate solutions and probably other strong alkalis will give positive reactions. Pus cells or any of the common organic or inorganic constituents found in the urine do not give positive reactions.

CONCLUSIONS

(1) A 1 per cent solution of orthotolidine in chemically pure methyl alcohol and a mixture of one part of glacial acetic acid and two parts of commercial hydrogen peroxide are useful for an approximate quantitative determination of the number of red blood cells in the urine. These solutions are cheap and stable.

(2) In a relatively large series of examinations of specimens of urine examined within six hours after voiding, no positive reaction has been obtained except when microscopic blood was present.

(3) Specimens of urine containing as high as 5,000 red cells per cubic centimetre will in most instances be undetected by the usual microscopic examinations, since such numbers may represent only one or two cells per high power field.

Present Position of Agglutination Tests in the Diagnosis of Enteric Infections

By W. D. O'KELLY

(From the *Irish Journal of Medical Science*, April 1934, p. 145)

TWENTY to thirty years ago the diagnosis of typhoid fever in the laboratory was usually made by the microscopic procedure known as the Widal reaction. Like most tests, it was not perfect. It was often negative in early cases, and sometimes did not become positive in cases clinically typhoid. Moreover, the test involved the risk of infection, for living cultures were used. A satisfactory strain of typhoid bacilli was not always in stock, or, if it were, a fresh culture might not be immediately available at times when enteric fever was not prevalent. Furthermore, if the exclusion or verification of paratyphoid infection was also desired the test was time-consuming, especially when a number of sera had to be tested. Still, the test on the whole behaved satisfactorily in view of the amount of diagnostic work required a quarter of a century ago. It had also the advantage that it could be carried out on the very small amounts of blood withdrawn for tests at that time.

It was known, of course, that killed cultures could be used for the microscopic test, and that even the microscope could be dispensed with if one were prepared to await the result of the macroscopic test. As far as I know killed cultures were seldom if ever used here, but they were on the Continent (Ficker's diagnostic) and in the U. S. A. Then came the European War with, eventually, millions of troops in the field, troops recruited from anywhere and everywhere by people who thought less of the flora and fauna they carried than of their ability to carry a rifle. Enteric fever had always been a danger to soldiers in the field, sometimes more deadly than the bullet. It was obvious that the microscopic Widal reaction was not suitable for diagnosis in armies of such magnitude. Moreover, what appeared a suitable position for a bacteriological laboratory to-day might

be twenty miles or more behind the enemy's lines to-morrow. There was a further complication. The soldiers of the British Army brought with them new weapons of defence, namely, typhoid and paratyphoid antibodies, including agglutinins. This new defensive mechanism achieved one of the greatest triumphs of preventive medicine by reducing enteric fever to the level of a minor cause of invalidity and mortality amongst troops on active service. This achievement was mainly due to the unceasing efforts of that distinguished Irishman, Sir Almroth Wright. But it did not simplify the Widal reaction.

Fortunately Dreyer and Walker had improved the technique of carrying out the macroscopic reaction with killed cultures of typhoid, paratyphoid and other bacteria. The method evolved is now usually known as the Oxford method. Briefly, it consisted of the use of standardized pipettes, tubes and racks, the introduction of the drop-method of dilution, and killed cultures of standard density, agglutination being allowed to take place in a water-bath at 55°C. By this method large numbers of sera could be tested without the delay necessitated by sending samples to a regular bacteriological laboratory. Also it was possible, though not always easy, to differentiate between the sera of inoculated persons and those of enteric cases. Furthermore, Delépine had noticed that the sera of typhoid cases agglutinated not merely *B. typhosus* but also a strain of *B. enteritidis*, no. 7160, whereas the sera of inoculated persons only agglutinated the former. In 1916 Professor T. T. O'Farrell reported to this Section of the Academy on a series of sera in which he had investigated this matter, his results bearing out Delépine's findings. The explanation of this phenomenon will appear later.

With the coming of peace much research was done on the nature of agglutinins produced by infection with members of the enteric and Salmonella groups, it being recognized that whilst the technique of the agglutination test had been simplified, and it had become possible to compare the results of different workers more easily, the interpretation of the results so obtained still left much to be desired. As a result of this post-war investigation certain facts were brought to light. The work of Felix, Arkwright, Burnet and others gave a new significance to certain observations made by Dreyer and Jex Blake, Joos, and Smith and Reagh that there were two types of agglutinins reacting with two corresponding agglutinogens, each antibody agglutinating specifically with its own antigen. Moreover, one antigen was associated with the flagella the other with the body of the bacillus. The flagellar antigens and antibodies were designated by the letter 'H', the somatic antigens and antibodies by the letter 'O'. It is obvious, therefore, that a non-motile bacillus does not possess 'H' antigens and its antiserum cannot contain H antibodies.

Certain details, not essential for the purpose of this paper, may be omitted, but it is necessary to point out that 'H' and 'O' agglutinins differ markedly in some respects. Thus the flocculi resulting from 'H' agglutination are loose and relatively bulky, those from 'O' agglutination finer and more granular suggesting the differences between large, soft snow-flakes and the finer particles of frozen snow. Also 'H' agglutination appears and reaches its maximum more rapidly than does the 'O' variety, and whilst the former may appear at room temperature, the latter requires a much higher temperature for its demonstration. Were these the only differences all would be well, but the real question is the relative importance of the two types. Some would have it that 'H' and 'O' antibodies are of equal value as regards immunity, others aver that the 'O' antibody is the important one and would discard the 'H' antibodies as valueless for diagnostic purposes, as well as for prevention and cure.

Undoubtedly cases of clinically typhoid fever occur, from which *B. typhosus* has been recovered and in the sera of which 'O' antibodies fail to show up in the agglutination test. Similarly, cases are met with in which only 'O' agglutinins make their appearance. Still, in the majority of cases both varieties of agglutinins appear at some stage of the disease, sometimes the 'H' and at other times the 'O' variety being the earlier.

Another important observation was made by Schütze, namely, that by the use of the double or 'mirror' absorption test differences could be brought out between certain Salmonella organisms which might not show up if a single absorption test were made. Then Bruce White studied a series of organisms isolated from cases of food-poisoning with special reference to their antigenic structure, and found how these organisms resembled and differed from one another. The following table embodies his more important findings:

Table of antigenic relationship
(After Bruce White)

Name of organism	'O' or somatic antigen factors	'H' or FLAGELLAR ANTIGEN FACTORS	
		Type	Group
Paratyphosus B.	I, II, 7, 8	— (type)	G. A.
Stanley ..	I, II, 7, 8	S (type)	G. A.
Aertrycke ..	I, II, 7, 8	— (type)	G, A, B, C.
Reading ..	II, 8	D ₁ , D ₂ (type).	G, E ₁ , E ₂ .
Derby ..	II, 7, 8	Q. R.	None.
Enteritidis ..	III, 8	P. R.	None.
Typhosus ..	III, 8(x)	S.	None.
Newport ..	IV, VI, 7	D ₁ , D ₂ (type).	G, A, B, C.
Snipestifer (diphase).	V, VI	W, w ₁ (type).	G, B, E ₁ , E ₂
Snipestifer (monophase).	V, VI	None	G, B, E ₁ , E ₂
Hirschfeld ..	V, VI	W, w ₂ (type).	G, E ₁ , E ₂ .
Sendai ..	XI	T (type)	G, E ₁ .
Paratyphosus A.	XI	T	

The 'O' antigens are on the left, the Roman numerals representing major, the Arabic minor agglutinins or antigens. The 'H' antigens are denoted by letters. A bacillus possessing one of these antigens will, on injection or infection, give rise to the corresponding antibody. Now, take *B. typhosus*. This organism contains 'O' antigens III and 8, and 'H' antigen S. In the blood of a typhoid patient 'O' agglutinins III and 8 and 'H' agglutinin S will develop. If we test with a culture possessing only the 'H' antigen we get the floccular type of agglutination.

Now this result will also happen with a Stanley infection because the antigenic component S also occurs in this organism. If we carry out the test with a culture possessing only the 'O' antigen we get granular agglutination due to the components III and S. We should also get this result in an infection with *B. enteritidis* into the antigenic structure of which the factors III and S enter. But neither a Stanley nor a Gaertner serum would give both coarse and fine agglutination with appropriate typhoid cultures. Another point which emerges from consideration of this table is that to demonstrate the presence of typhoid 'H' agglutinins it is not necessary to use a culture of *B. typhosus*; a Stanley culture will work equally well. If we wish to demonstrate typhoid 'O' agglutinins an enteritidis culture will suffice.

Studying the table further we notice that the 'H' antigens are subdivided into two varieties, namely 'type' and 'group'. This differentiation results from the work of Andrews who studied the antigenic behaviour of individual colonies developing on a plate sown with a pure culture of a *Salmonella* organism. He found that for certain members of this group two varieties of colony grew. One showed wide relationship with other members of the group, the other disclosed very specific agglutinating properties. The former variety of colony, he said, consisted of organisms in the 'group phase', the latter of organisms in the 'type phase'. Organisms in which this phenomenon could be demonstrated were referred to as 'diphasic', and those which did not behave so as 'monophasic'. The American and European strains of *B. supeistifer* are examples of diphasic and monophasic organisms respectively.

Thanks to Gardner, strains possessing these various antigenic components are now prepared at Oxford, and it is possible to test a serum with a series of these cultures, and by a process of elimination ascertain what agglutinins it possesses. It is then usually possible to determine what is the infecting organism. Similarly mono-specific sera are available to enable us to ascertain the antigenic structure and, therefore, the identity of an organism isolated from the blood or excreta of a patient.

In practice a complete analysis of a suspected typhoid serum is not required, but in difficult cases only the closest co-operation between the clinician and the laboratory will enable a proper diagnosis to be made.

The straight typhoid case gives 'H' and 'O' agglutinins and for all practical purposes this denotes the existence of typhoid fever, past or present. When only 'H' agglutination is given either typhoid or Stanley infection (again past or present) is denoted. The clinician can differentiate between the symptoms of enteric fever and food-poisoning. If only the 'O' agglutination appears a Gaertner infection has to be excluded.

The particulars of the agglutination tests made on a recent case of paratyphoid fever will make the method of analysis clear.

Bacterial suspension used	Result	Factors detected (see table)
Typhosus 'H' ..	Negative (1-25)	—
Paratyphosus A 'H'.	Negative (1-50)	—
Paratyphosus B 'H' type.	Positive (1-5,000).	Para B. type.
Typhosus 'O' ..	Positive (1-250)	8
Paratyphosus B 'O'.	Positive (1-1,000).	I, II, 7, 8.
Salmonella 'H' to test for factor G.	Negative (1-50)	—

The case is clearly one of infection with *B. paratyphosus*, B in the 'type phase', showing some 'O' agglutination of *B. typhosus* owing to the common factor, S.

The inoculated case presents certain difficulties. According to some observers T. A. B. inoculation results in the production of 'H' agglutinins mainly, the 'O' agglutinin never reaching a high titre, and quickly falling, whereas in a genuine case the 'O' agglutinin rises higher and persists. In the first place typhoid in the inoculated is uncommon and, secondly, the serum, if from a recently injected person, will show paratyphoid A and B agglutinins. It may, however, be necessary to isolate the causal organism from the blood or excreta in such a case. In persons not recently inoculated a repetition of the test will show a rising titre with the development of 'O' agglutinins. Let me now recall to your minds the Delépine test. Inoculated cases did not react with strain no. 7160. Typhoid cases did. The explanation is that in the latter the 'O' agglutinin reached a demonstrable or significant titre whereas it did not in the former. A glance at the table will show at once the explanation—the 'O' antigen III is common to the typhoid and enteritidis bacilli.

The greatest difficulty presented in diagnostic work in our experience is the case in which the agglutinin titre is low and remains low. Such cases may be mild typhoid, perhaps ambulatory. Their recognition is of the utmost importance in preventing the spread of the disease. In these cases the isolation of the organism from the blood or stools would appear to offer the only satisfactory solution.

Intraocular Foreign Bodies With a Review of Eighty Cases

By DON MARSHALL, M.D.

(Abstracted from the *American Journal of Ophthalmology*, May 1934, p. 416)

THE treatment and prognosis of cases of intraocular retention of a foreign body have long puzzled the ophthalmologist. Despite the development of the ophthalmoscope, magnet, and x-ray, the profession still agrees that the prognosis is serious. As to the proper management of these cases, opinions differ. The oculist has good precedent for removing the foreign body at once, and for leaving it *in situ*; for removing it by the anterior root, or through the sclera; for employing the management as a diagnostic aid, or for carefully avoiding such possible trauma; for waiting for x-ray localization, or for hurrying to the operating room without this information. This article attempts briefly to consider these problems and, as illustration, to present in summary an analysis of 76 patients, or eighty eyes, examined at the University Hospital between 1925 and 1933.

DIAGNOSIS

The importance of prompt and accurate diagnosis is not questioned and has been often emphasized. Nevertheless, poor histories, incomplete routine examinations, and failure to use the x-ray cause many foreign bodies to be overlooked. This is malpractice, and failure to use the x-ray is in many cases negligence, both in the eyes of the law and in the opinion of established ophthalmic practice. Thorough objective examination, together with x-ray (which, however, is not infallible), will usually establish a diagnosis. In the past, before the discovery of x-ray, much faith was placed in the siderscope. Another procedure that still has many proponents is the production of pain with the magnet, as a diagnostic test. During the war, when x-ray facilities were limited, this was a routine

procedure at many stations, and even in civil life it has a place. Derby, claiming that we over emphasize the x-ray, declared that the magnet is the one indispensable test for the presence of an intraocular foreign body. Fuchs gives no warning against the diagnostic use of the magnet. But an opposite view is held by others, who feel that because of its unreliability and the trauma to the eye attendant upon each movement of the foreign body, the magnet is distinctly contraindicated as a means of diagnosis.

TIME OF EXTRACTION

Before the use of the magnet and x-ray, most eyes containing foreign bodies were promptly enucleated. More recently, this haste has been directed toward an early removal of the foreign body. These conditions have been considered to be surgical emergencies, which in the case of fresh injuries could not await an x-ray report. The vast amount of clinical experience and statistical evidence to show that the earlier the foreign body is removed the better the end result, justifies the majority opinion that speed is essential to success, that the foreign body must be extracted at almost any cost.

But there is to-day a growing belief that we should act less precipitately. Fuchs, after a lifetime of experience, advises that we must remove the foreign body early, but must not be overhasty, the purpose being only to effect removal before scar tissue forms. Certainly, in view of the numberless cases on record of retained foreign bodies in quiet eyes, many of them with excellent vision, and in view of the generally poor results that have been obtained in the past, we are compelled to reconsider our management of these cases and are justified in trying new principles. Green pointed to war statistics to show that sympathetic ophthalmia is much less common than was previously supposed. Bulson, after reviewing many cases of long-standing intraocular foreign bodies, concluded that we 'should more often tend to leave the foreign body in position, and the eye under good observation'. He believed that the all-too-frequent loss of vision is due not to the foreign body but to degenerative changes that usually would ensue even though the foreign body were out. Kiehle, continuing this line of reasoning, thought that we exulted too much over the 'successful' removal of a foreign body, while we had really gained nothing for the patient in vision. These authors believe that the act of removal may do more harm than the foreign body itself; that the danger of sympathetic ophthalmia is as great after removal as before; that precipitous treatment is undesirable.

ROUTE OF EXTRACTION

Foreign bodies in the anterior chamber, iris, or lens are, of course, removed through a corneal incision, if not through the original wound opening. Extraction of foreign bodies resting in the vitreous or retina may be attempted by the anterior route, or posteriorly through a scleral incision. Here again opinions differ. There is another group which believes that the route of extraction should be determined by study of the many factors in each individual case, an eclectic path which has been followed in the series herein presented.

SUMMARY OF EIGHTY CASES

In the summary which follows of a study of eighty eyes with intraocular foreign bodies, many of the less important and more detailed figures are omitted for the sake of brevity.

Incidence.—In line with the usual industrial origin of this type of injury, all of the 76 patients but one were males. Forty-seven per cent of them were between 20 and 40 years old, while 17 per cent were under 10 or over 60. The right eye was injured in 55, the left eye in 40, and both eyes in 5 per cent of all cases.

Delay postaccident.—Since most of our patients come from a distance, often referred by their local

physician, they are admitted at varying intervals after their accident. Thirty-four per cent arrived within three days of the accident; 21.5 per cent between 3 and 20 days after; and 20.5 per cent later than one year. In this last group are five patients who appeared, an average of 15 years after the accident, the longest interval being 30 years. The enforced delay in treatment in this series constitutes an important difference from series reported by workers in industrial centres, where only hours need elapse before extraction. A majority, or 65 per cent, of the injuries occurred in the proximity of hammering, or of machinery striking against metal. Yet 12 per cent resulted from dynamite or cap explosions, many of the victims being children.

Pain and vision.—In the interval between the accident and admission, at least 30 per cent of the patients had at some time had more or less pain. Often the pain was a result of ocular reaction rather than of the injury itself. On admission, 73 per cent of the eyes had a vision without correction of 6/60 or worse, and 6 per cent had no vision. Ten per cent had a vision of 6/15 or better.

Findings.—Examination of the eyes at admission showed the following: the foreign body entered through the cornea in two-thirds of the cases, a fraction somewhat higher than in Allport's series. There was moderate iritis in 42 per cent, severe in 16 per cent of cases. Secondary glaucoma was present in 7.5 per cent. In 26 per cent there was complete, and in 40 per cent a partial cataract—all traumatic, of course. At least 20 per cent of the eyes had more or less vitreous opacities, and 5 per cent retinal tears. The uninjured eye showed irritation in 2.5 per cent of cases. In 10 per cent it was found, on further examination, that there were more than two foreign bodies in the eye.

Of the foreign bodies, 61 per cent were in the vitreous, 14 per cent in the lens, 10 per cent in retina or sclera, the remainder in the ciliary body, iris, or anterior chamber. In one case the foreign body penetrated the globe twice and came to rest in the orbit. Fifty per cent of the particles were less than 2 mm. in their greatest diameter, but 13 per cent ranged between 4 and 9 mm. Over 88 per cent were of metal.

Extraction.—Operation for extraction of the foreign body was performed on 70 per cent of the 80 eyes, and in this group the foreign body was successfully removed in 70 per cent of the cases. In 30 per cent (17 cases) of this group, attempts to remove the foreign body were unsuccessful. In many of these 'failures', the attempted removal took place weeks or months after the injury; in some the foreign body was expected and found to be non-metallic; in some, extraction by the posterior route was not attempted, although by the anterior route it had failed. In these extractions the attitude of the surgeon was not always favourable to removing the foreign body at almost any cost. Doubtless more of the particles could have been removed by more strenuous efforts, and thus a greater number of 'successful' extractions listed. Seventy-nine per cent of the extracted foreign bodies were removed by the anterior, and 14 per cent by the posterior route. Seven per cent were removed through the original wound. Eighty per cent of the operations for extraction were undertaken within 60 days after the accident, and 43 per cent within 9 days; but only 20 per cent within 3 days. All of Walker's 350 cases were operated upon within 2 to 8 hours after the injury.

Postoperatively, two cases developed definite retinal detachment. Both were cases in which the foreign body was extracted by the posterior route. Little can be deduced from two lone cases.

Enucleations.—Of the 80 eyes in this series, 68 per cent were saved; 8 per cent were examined but for various reasons not treated; 21 per cent were enucleated at varying intervals after the accident; and in 2.4 per cent enucleation was advised but not performed by us.

A saved eye is cosmetically often better than a prosthesis. On the other hand, in this type of case, it is often a constant source of danger to the other eye. In two cases there was irritation of the uninjured eye on admission; in two more it developed later. Thus sympathetic ophthalmia has a higher incidence in this series than in others reported.

The question of enucleation again gives the surgeon a difficult problem to solve. Allport says that if neither vision nor appearance can be saved, enucleate. Walker urges against postponement of enucleation in cases of retained foreign body or of injury to the ciliary body unless the eye can be kept under observation. Nevertheless, McReynolds claims that it is perfectly safe not to disturb a foreign body that is giving rise to no inflammatory reaction. An eye should, of course, be removed at once if it is evidently ruined, or if it is useless and inflamed. But Sherman and Fuchs advise waiting a week or more before so doing in a badly injured eye, because it may improve surprisingly.

The seventeen enucleations in this series were done in four cases for infection and panophthalmitis; in four cases for sympathetic ophthalmia; in five cases because of violent uveitis; in two cases because the eye was blind and painful; in one case for secondary glaucoma with a useless eye; and in one case because of extensive vitreous hæmorrhage with detached retina.

Hospitalization.—Our patients in most instances came from afar, and could not return to localities or industries where they could be carefully followed and given special treatment. Of necessity, therefore, they were hospitalized longer than industrial patients living in the same city would be. There was no hospitalization for treatment in 5.3 per cent of the cases; and 6.5 per cent were only examined, with treatment not indicated, or refused. In 78.6 per cent of cases hospitalization was given for a total of 4 to 40 days; in 44 per cent hospitalization was for a total of over 20 days; and in 5.3 per cent for a total of 70 to 90 days. Moore, incidentally, advises hospitalization in all cases for removal of the foreign body.

Visual results.—Final vision, after all, is about the most important criterion of results. The main function of the eye is vision; if that is saved little else counts. But in a series of this type final vision is difficult to determine because time is such a vital element, and the longer the interval between accident and observation, the more likely it is that the sight has been lost. The fact that loss of vision results usually from degenerative changes that take place whether the foreign body is in the eye or out, renders it patent that the significance of visual results increases in proportion to the interval that has elapsed since the time of injury and treatment. Kiehle emphasizes the point that available statistics are woefully deficient in observations of visual acuity over long periods of time. Such a long time observation of a series of patients is difficult for any ophthalmologist, whether in private practice or in institutional work. Proof of the benefit of extraction of foreign bodies, and of the safety of leaving them in, depends, of course, on series of patients observed for several years.

In this series replies were received from 30 of the 51 whom we asked about the present status of their eyes. Results, therefore, are as recent as possible. Final vision, so far as is known, of the 80 eyes is:

Results

18.3 per cent have 6/15 or better.

3.7 " say that they can read with the eye.

6.2 " say that they can get around with the eye.

39.8 " have 6/60 or worse.

21.2 " are enucleated.

10 " are unknown.

Useful vision has, then, been attained in a fifth of the cases. Certainly vision in many of the other cases could be improved with refraction and surgical treatment of cataracts.

ANALYSIS

Seeking, in this series, answers to the conflicting questions and opinions on the management of intraocular foreign bodies, we still cannot reach a definite conclusion. There are 8 cases of vision of 6/15 or better with the foreign body in the eye—in 6 of these that vision has been maintained for over one year since the accident, and in 4 of them more than six years. But there are 11 cases of good vision with the foreign body out. To support the method of watchful waiting, we find 15 cases of foreign body in the eye without resultant irritation, 12 of these cases over one year later, and seven over five years later. Yet there are 11 cases of a foreign body remaining in the eye in which irritation *did* develop (although the irritation might have occurred anyway, following extraction). There are 20 cases of foreign body remaining in the eye with poor vision, in contrast to 16 cases of *extraction* of the foreign body with poor visual result. There are 7 cases in which the foreign body was removed and the eye remained *irritable*, but 25 in which it remained *quiet*. To support the contention that immediate results are misleading, that vision should be followed for some time, we find three cases with excellent vision after extraction of the metal, which later became blind from complications. On the other hand, there are 7 cases of long-standing good vision, 5 of them six or more years after the accident. Against the command that we extract the foreign body at once, we find 8 cases of good surgical result, and in most cases good visual result, in which the foreign body was removed from 8 days to 1½ years after the accident, and there are 12 cases in which the foreign body has been in the eye an average of 12 years each, in most of them with no irritation whatsoever.

A study of this series reveals, through the variation in its results, the reason for such diversity of opinion as exists. And, too, it shows why the majority have believed as they have in removing the foreign body, and that rather promptly. For, on the whole, the instances among these 80 eyes, in which the foreign body was removed without overlong delay, were attended with better results in the end, as a group. Yet the great number and variety of exceptions to this rule prove that we have not yet mastered the problem, and that very likely we should modify our principles of management toward less haste, less extraction, and more observation. On one point all statistics agree—the prognosis is in most cases poor; brilliant results are in the minority.

SUMMARY AND CONCLUSIONS

(1) A review is presented of the varying opinions with regard to the proper management of intraocular foreign bodies.

(2) A brief analytical summary is made of 80 cases of intraocular foreign bodies.

(3) Study of the literature, and of a series of cases, supports the contention that ophthalmologists should consider more carefully the disadvantages of hasty extraction of foreign bodies, and should, by more observation and less meddling, avoid strenuous and damaging efforts to extract every foreign body.

(4) The prognosis of a case of intraocular retention of a foreign body is generally poor, and in the individual case cannot be foretold.

Reviews

GREEN'S MANUAL OF PATHOLOGY.—Fifteenth Edition. Revised by H. W. C. Vinos, M.A., M.D. 1934. Baillière, Tindall and Cox, London. Pp. xii plus 928 with 8 coloured plates and 425 figures. Price, 25s.

Green's Pathology has for many years been one of the most popular of students' handbooks on this subject. It gives the student just the amount of information that he requires for understanding the diseases he encounters clinically, and for satisfying his examiners. The present edition is very largely rewritten, but the balance has not been upset. The actual bulk of the book is greater, but this increase is due mainly to the inclusion of a number of new illustrations and not to any great extent to an increase in the length of the text; we say 'to any great extent' because if recent advances in our knowledge are to be included some expansion is essential, e.g., avitaminosis and the diseases of the ductless glands are subjects about which little was known a few years ago, but which have now assumed positions of considerable importance. Other chapters have been added to cover recent additions to our knowledge in regional pathology.

The illustrations are all good, the majority are photographs, some in colour, but, where diagrammatic treatment has been considered essential to demonstrate structure, the drawings have been retained. However, we are told in the preface that one hundred of the latter have been reproduced by photographs; it is a great tribute to modern museum technique, photography and reproduction—and to the editor and publishers of this book in particular—that this has been effected without sacrifice to clarity.

Like many books of its kind it still exhibits curious little embryonic rests in the form of chapters on parasitology—perhaps the editor is bowing to the dictates of the medical curriculum.

We deny that the book is unsuitable for the post-graduate student and research worker, as the editor suggests in his preface; the specialism of the specialist is necessarily limited and in subjects of which he has made no special study, we will often find the concise account given in this book far more helpful than the complete, but confusing, exposition of a monograph. This is primarily a student's book, and an excellent one, but there are few medical men who will not find it of very great value.

AN INTRODUCTION TO PRACTICAL BACTERIOLOGY.—By T. J. Mackle, M.D., D.P.H., and J. E. McCartney, M.D., D.Sc. Fourth Edition. 1934. E. and S. Livingstone, Edinburgh. Pp. viii plus 504. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 9-6

THE considerable amount of revision which has been performed has made this extremely useful and popular book even more valuable than its previous edition. Much new material has been added and the subject-matter has been arranged into three parts to help the student in using the book. The part dealing with bacteriological and serological technique is particularly good, and with the judicious use of small print a vast amount of useful information has been collected within the scope of this book which retains the convenient size of the previous editions. The new technique, originally described by one of the authors, for the storage and distribution of culture media involving the substitution of screw-capped test-tubes, has been fully described. The only criticism that we have to offer, and it is a criticism that applies to many of the textbooks of bacteriology, is that, although recognizing that

the classification and nomenclature of bacteria introduced by the Society of American Bacteriologists is the only one that follows strictly the accepted rules of biological classification, the authors have not thought fit to adopt that classification. The new classification is outlined and the important genera named, but the examples given are still named in the old unscientific way. It is a pity, as the sooner the only systematized nomenclature is followed in textbooks the better for the student and the teacher. In all other respects this is an excellent book and will prove of great value for the student of bacteriology.

C. L. P.

BRUCE AND DILLING'S MATERIA MEDICA AND THERAPEUTICS. An Introduction to the Rational Treatment of Disease. Fourteenth edition, revised. By Prof. Walter J. Dilling, M.B., Ch.B. (Aberd.). 1933. Publishers: Cassell and Company, Limited, London. Pp. x plus 700. Price, 16s. 6d.

THE new and revised edition of *Materia Medica and Therapeutics* promises to be a useful book for the medical students, for in it they will find a fairly complete and satisfactory account of the pharmacological action and the relative therapeutic values of the various drugs used.

This well-known and admirable book needs no introduction. The first edition was published in 1884 and the fact that so many subsequent editions were called for in recent years is a sufficient indication of its continued popularity and usefulness.

On the basis of the British Pharmacopœia, 1932, the entire text has been subject to most careful revision and the present edition is brought up to date. In accordance with the modern views, most of the redundant and less useful materials have been discarded. Remedies not yet officially accepted have been included and such substances as thallium, sanocrysin, uroselectan, atebirin, etc., and various dyes used for diagnostic purposes have received appropriate attention. In addition, there are useful notes on radiation, massage, and an outline of invalid diets, etc. Altogether, the book must be considered a most useful volume for the general reader, largely because of the simplicity and directness of the presentation and also because it is written so definitely with the needs of the students and practitioners in mind.

OBSTETRIC MEDICINE: THE DIAGNOSTIC AND MANAGEMENT OF THE COMMONER DISEASES IN RELATION TO PREGNANCY.—Edited by F. L. Adair, M.A., M.D., F.A.C.S., and E. J. Stieglitz, M.S., M.D., F.A.C.P. 1934. Henry Kimpton, London. Pp. xvi plus 743. Illustrated. Price, 36s.

PRACTITIONERS are continually faced with the problem of the pregnant woman suffering from intercurrent diseases and their difficulty is to know when to, and when not to, terminate pregnancy. Textbooks on obstetrics usually give scanty information on this subject and are of very little help.

The editors have set out to co-ordinate and correlate the medical knowledge concerning the problems of diagnosis, therapy and prognosis of disease occurring coincidentally with pregnancy. They have edited the contributions of thirty-nine contributors—each one an eminent authority and have produced a textbook of medicine written from the point of view of the pregnant mother.

The book is divided into sections dealing with the various systems. Each section is subdivided into chapters—each of which is written by one or two specialists.

Contributors have kept in view that pregnancy may have an effect on disease and that disease may have an effect on pregnancy. So far as is possible an attempt has been made in each chapter to give definite indications as to when pregnancy should be terminated. For this alone the editors deserve every commendation.

Each contributor gives current views on his subject plus those based on his own experience. References are profuse and at the end of each chapter is given a bibliography. The chapter on specific infectious diseases containing twenty-seven pages contains no less than two hundred and three references.

The editors are to be congratulated on producing a textbook which is the first of its kind and is of great value to both the specialist and practitioner of obstetrics.

S. N. H.

A HANDBOOK OF LABORATORY TECHNIQUE.

Part I. (Urino).—By D. Govinda Reddy, M.D. 1934. The Antiseptic Press, G. T., Madras. Pp. 120. Illustrated. Price, Rs. 1-4. Available from the Manager, The 'Antiseptic', Thambu Chetty Street, G. T., Madras

This small book is intended for the use of medical students and young practitioners as a handy laboratory guide.

There are a few points in the book, however, on which the author might have been more explicit. As for example, when describing the method of estimation by Aufrecht albuminometer he advises centrifugalizing 'for not less than five minutes' without giving any idea of the number of revolutions per minute. The result, obviously, will vary according to the revolutions which the machine is put to as well as the time limit.

Taken, on the whole, the book has been written in a clear and simple style and will be a help to those for whom it is intended.

DIABETES: REASONS AND RECIPES.—By E. E.

Claxton, M.B., B.S. (Lond.), D.T.M. & H., and Lucy Burdekin. 1933. John Lane The Bodley Head Limited, London. Pp. xvi plus 188. Illustrated. Price, 5s.

DR. CLAXTON'S book forms one among the many books which are coming in quick succession at the present day for the benefit of the diabetic patients, intended not only to help them in the proper understanding of the disease they are suffering from but also to enable them to vary their diet for themselves without constant reference to their doctors and thus break the monotony of having to take the same meal day after day.

The authors do not claim any originality in the subject-matter but the main object of the book according to them is to enable the diabetics to have varieties in their diet. In this the authors have been successful because the numerous recipes and cooking hints included in the book are likely to satisfy even the most fastidious subject. The chapter on the composition and the choice of diet has been very clearly and lucidly written and should enable the majority of patients to make the correct use of the recipes without altering the food values of the diet.

J. P. B.

URINARY ANALYSIS AND DIAGNOSIS BY MICROSCOPICAL AND CHEMICAL EXAMINATION.—By L. Heltzmann, M.D. 1934. Sixth revised edition. Baillière, Tindall and Cox, London. Pp. xix plus 385 with 131 illustrations. Price, 22s. 6d.

We had the pleasure of reviewing the previous edition of the book about five years ago. The present

revised edition is somewhat larger and a new short chapter on the hormone test of pregnancy is a welcome addition, in view of the recent important work started by Aschheim and Zondek in 1928 and followed later on by other workers such as Friedman and Cosgrove.

The chemical tests described in the book are not only reliable but fairly simple so that most of them could be performed without the necessity of a completely equipped chemical laboratory.

As in previous editions the author has laid great stress upon the microscopical examination of the urine and has emphasized the importance of recognizing the various forms of epithelial cells found in the different regions of the genito-urinary tract. On this point we are in complete agreement with the author because in many of the pathological conditions of the genito-urinary tract, where the chemical symptoms are rather vague, the microscopical examination of the urine, aided by the chemical tests, often helps us in arriving at a correct diagnosis regarding the probable place of the lesion.

We have no hesitation in saying that this book should be classed as one of the standard books of reference on urinary analysis and diagnosis.

J. P. B.

CHOLERA: A MANUAL FOR THE MEDICAL

PROFESSION IN CHINA.—By W. Lien-Teh, J. W. H. Chun, R. Pollitzer and C. Y. Wu. 1934. National Quarantine Service, Shanghai, China. Pp. xxii plus 198 with one colour and 23 half-tone plates. Price, 12s.

This monograph on cholera is one of the best that we have read. It deals with the subject in a practical manner and surveys the cholera problem in a very comprehensive way. Although the book is intended primarily for use in China and the problem as it affects that country has been given more detailed attention, it is a book that will prove of value to those interested in cholera in all parts of the world. It is of particular value to India and of special interest to Bengal. As the authors say in the preface it is at once something less than a treatise and something more than a popular book. It is in fact a handbook on cholera for the use of rational practitioners of medicine. In the introduction the authors state 'the problem of cholera is a live one in China to-day. It is startlingly modern in its impact on the everyday existence of a quarter of the human race. The cholera situation, in short, is due for a final clean-up. Experience has proved that the disease can be made to disappear from a district, a country or a continent. India and China are still hot-beds of infection'. If the problem of cholera is a live one in China to-day it is even more so in this country and the cholera situation is most certainly due for a final clean-up. This book does not attempt to solve the basic measures required to stamp out this dread scourge, but it provides some sort of foundation for a concentrated movement by central, provincial, district, municipal and local authorities to eradicate cholera. The book is divided into four parts, each part written by one of the authors but the whole represents the views of all the writers. Part one deals with the historical, geographical and epidemiological aspects, parts two and three with the laboratory and clinical aspects, and part four with education and propaganda, with an appendix dealing with the spread and control of sea-borne cholera. Each part contains a most excellent summary of important points and a critical survey of the latest work in cholera. There is much in the first three parts that will be of interest to workers in cholera and much that is new in the history of cholera which the authors have extracted from old Chinese works. It is, however, the last part on education and propaganda which is a unique feature of this book. The whole subject of the

education and the development of the conscience of the people is discussed in an exhaustive manner and this part of the book is of particular interest to India. Propaganda, legislative measures are discussed and the planning of an anti-cholera campaign outlined. The necessity for a central organization, including not only government and municipal health officers but also representatives of public bodies and individuals whose advice may prove useful, as well as for the co-operation of the press, is stressed. This part is illustrated by photographs of posters, handbills and pamphlets used for propaganda work, and shows how well these have been designed. Two of the posters used in India have been included in this series. We would particularly draw attention to this part of the book and for this part alone it should be in the hands of all those who are concerned in combating this scourge of mankind, whose 'home' for centuries has been in India and Bengal in particular. We cannot recommend this book too strongly. It is also a valuable summary of the excellent work that has been done and is in progress in China. This is the first of a collection of practical manuals on the commoner epidemic diseases occurring in China that the National Quarantine Service intends to issue. If they are of the type of this forerunner of this series they will be of real service to both science and man, and we look forward to them.

C. L. P.

ALCOHOL AND ANÆSTHESIA.—By W. Burrldge, D.M., M.A. (Oxon.). 1934. Williams and Norgate Limited, London. Pp. 65. Price, 2s. 6d.

THE author of this brochure must be known to many in India for his views on the nature of nervous activity. In this book he has attempted to explain the action of alcohol and anæsthesia in terms of his theories. The chapter on chronic alcoholism contains some interesting ideas. He points out that there is something in the living organism which is always striving to attain and maintain normality. The chronic alcoholic is mentally below par and the effect of alcohol is to bring his outlook up to the standard. Herein lies its danger to such types. This book should prove of interest to those acquainted with Dr. Burrldge's views.

H. E. C. W.

THE CHEMISTRY OF THE HORMONES.—By B. Harrow, Ph.D., and C. P. Sherwin, D.Sc., M.D., Dr.P.H. 1934. Baillière, Tindall and Cox, London. Pp. vii plus 227. Price, 11s. 6d.

To keep abreast of the modern work on the endocrine secretions is to-day well-nigh impossible. The advances in this subject are so rapid that the average textbook is probably out of date on this topic within a year of publication. This book will enable one to call a halt and take a general survey of the field as it stands to-day. The subject-matter as the title indicates is the chemistry of the hormones. This aspect may not be of great interest to the medical practitioner, although the subject is dealt with clearly and with full references, nevertheless he will find here a considerable amount of information on the number, nature and functions of the hormones discovered up to date. The most recent additions to our knowledge come from discoveries connected with the anterior lobe of the pituitary, the ovary, and the cortex suprarenalis. The anterior lobe of the pituitary appears to contain some four or five different secretions, namely—stimulant to ovulation and spermatogenesis, growth stimulant, thyroid gland stimulant, adrenal stimulant and one controlling carbohydrate and fat metabolism. The ovary has been shown to produce a substance œstrin (theelol) which initiates changes in the vagina associated with œstrus, and progesterin (from the corpus

luteum) which acts on the endometrium and produces the changes necessary for the complete menstrual cycle. A preparation has been made from the cortex suprarenalis which appears to regulate the water and salt balance between the tissues and the blood. This secretion also affects the level of the non-protein nitrogen of the blood. In the limited space of a review it is impossible to discuss the important work which has been done notably on insulin in particular. There are however a number of interesting facts which give one food for thought, to mention one only, the similarity in chemical constitution between œstrin, carcinogenic substances and vitamin D. A discussion on the integration of these different hormones is not included; this may be excused, as at the present time it is best left to the imagination of the individual reader. One feels certain however that the healthy organism has some means for co-ordinating their activity so as to insure the constancy of what Claude Bernard called the *milieu interne* of the cells. The book is clearly written and should prove of interest both to biochemists and medical men.

H. E. C. W.

MASSAGE AND REMEDIAL EXERCISES IN MEDICAL AND SURGICAL CONDITIONS.—By N. M. Tidy. Second Edition. 1934. John Wright and Sons, Limited, Bristol. Pp. xii plus 430. Illustrated. Price, 15s.

THIS is an excellent book containing all that is necessary for a student in massage and remedial work. It enumerates all conditions requiring treatment by these means, describes pathology, symptoms, splinting (where necessary) and medical, surgical and physical treatment of each, and supplies notes on electrical and light treatments.

The illustrations and diagrams are particularly clear, while the excellent index considerably simplifies reference. The chapters on fractures are particularly good. The book can be strongly recommended, not only to students, but to the practising masseuse and medical gymnast requiring a book for reference.

P. B.

THE CONSTITUTION AND ITS REACTION IN HEALTH.—By T. E. Hammond, F.R.C.S. (Eng.). 1934. H. K. Lewis and Company, Limited, London. Pp. ix plus 160. Price, 7s. 6d.

It is only within recent years that the term constitution has ceased to be a rather vague definition and has been subjected to a certain amount of analysis. To-day two broad types have been marked off, namely, the hyposthenic and the hypersthenic, although it is seldom if ever that one sees a pure case of either. A complete list of the features associated with each type is not possible in a review; in general however the hyposthenic is of poor physique, lacks physical and mental energy, is introspective and has a tendency to chronic infections, while the hypersthenic is of good physique, is physically and mentally active, is extropective and has a tendency to acute infections which run their complete course. One chapter of the book is devoted to a discussion of those types while the remainder deals chiefly with health in relation to climate, occupation, leisure, etc. There is a considerable amount of common sense although some of it is rather commonplace as far as the medical man is concerned. The book should prove interesting reading however particularly to the intelligent layman.

H. E. C. W.

'LA LEPRE'.—By Ed. Jeanselme (G. Doin & Cie, Éditeurs, 8 Place de L'Odéon-Paris). Quarto with 680 pages, 259 black and white figures and 14 coloured plates. Price, 600 francs

WHILE there are numerous references from other writers the author has made no attempt to write an

exhaustive treatise. The researches of the French School are given in detail and much of the work of the United States and their colonies is quoted, as well as that of Japan and South America.

There are 15 chapters in the book. The first two deal with the definition and nomenclature of the disease. The third chapter, illustrated with curious old engravings, goes fully into the history of leprosy, while the fourth chapter gives a sketch of the geographical distribution. The following sections deal successively with bacteriology, serology, immunity, general pathology, anatomy and ætiology.

Much space is devoted to combined clinical and histological studies of various types of lesions. Chiefly advanced cases of leprosy have been studied, but a brief description is given of the so-called 'tuberculoid lesions' as described by Jadason and others. This section is of great value because of the thorough manner in which the literature is reviewed in the light of the writer's vast practical experience of the disease.

The chapter on prophylaxis deals very fully with the methods adopted in various countries; these are divided

under various groups. Treatment is dealt with very thoroughly and the following introductory paragraph is worth quoting in full. 'There is no specific for leprosy, but it is possible to obtain quiescence of symptoms, an arrest of the evolution of the morbid condition and, possibly, even a radical healing of the infection, by a number of therapeutic means, the combined use of which is essential. The following constitute the hygiene of leprosy: the treatment of concomitant diseases; medical treatment of the disease itself; symptomatic treatment; and the treatment of complications'.

One of the most valuable assets of this handsome volume is the fourteen colour plates at the end. The first four show various clinical types, while the remaining illustrations (four in each plate) give the microscopic appearances of lesions of the skin and internal organs.

While the price of this book may be beyond the purse of the ordinary practitioner, it should at least find its way into every medical library.

E. M.

Abstracts from Reports

A MEDICAL SURVEY OF ADEN, 1933. By LIEUT.-COLONEL F. SELBY PHIPSON D.S.O., M.D. (LOND.), M.R.C.P. (LOND.) D.P.H., D.T.M. & H., I.M.S. CIVIL ADMINISTRATIVE MEDICAL OFFICER, ADEN

HOSPITALS

Government:—Civil Hospital, Crater—principal diseases; medical work among women. European General Hospital, Steamer Point.

Private:—Keith Falconer Mission Hospital, Sheikh Othman.

THE CIVIL HOSPITAL, CRATER

The Civil Hospital, built in 1861-63, is situated in the Crater on rising ground forming a salient from the hillside into the south-west part of the town of Aden, from which it is easily accessible on three sides. It originally consisted of two wards only: since then other wards have been added and at present it comprises several buildings with accommodation for one hundred and twenty-eight cases, and when the maternity and tuberculosis wards which are now under construction are completed, the total accommodation will be for one hundred and fifty-two patients.

Certain disadvantages are inseparable from the nature of its surroundings—noise, flies and dust. Flies and dust are a nuisance throughout the town at certain times of the year, but the accessibility of the hospital to the general mass of the population of the town more than counterbalances these disadvantages.

In 1929 a committee was appointed by Sir Stewart Symes, then Resident and Commander-in-Chief, to enquire into and report on the proposal to remove the Civil Hospital from its present premises to the recently-abandoned British Infantry Barracks on the sea-front. The committee after careful enquiry decided not to recommend such a change, mainly for two reasons, that, apart from the Jewish element, the great majority of the local inhabitants, Arabs, Somalis, Hindus and Indian Mohammedans, were opposed to the change and that the advantages to be gained by the change of site would not be commensurate with the very heavy anticipated expenditure. Sir Stewart Symes, having accepted the recommendation of this

committee to leave the hospital in its present situation, appointed another committee to enquire and report what renovations, structural alterations and additions to the hospital premises were necessary to put the hospital in a position to supply the requirements of all classes of the non-European resident population in the Aden Settlement and of patients from the interior, and to improve the general standard of its accommodation. This committee suggested extensive improvements, consisting of fifteen items for new buildings and five involving repairs or minor alterations to existing buildings. The scheme was sanctioned in its entirety by the Government of India and most of the works proposed by the committee have since been carried out, and it is probable that next year will witness the completion of the whole scheme.

The hospital follows an 'open door' policy, admitting non-European patients whatever their religion or nationality, and no discrimination is made between British subjects and patients of alien nationality. The hospital is maintained entirely by grants received from the Indian Government and the Colonial Office, the income from paying-patients' fees being negligible, and the total annual recurring expenditure is on an average Rs. 50,000.

There is a special female ward with twenty beds served entirely by a female staff and so built as to suit, as far as is possible in a general hospital, the susceptibilities of orthodox Mohammedans. A special ward was built by the late Mr. Menahem Messa, a wealthy Jewish merchant of the town, solely for Jews; it has accommodation for six males and six females and was built in 1897 at the cost of Rs. 10,000, and all the patients admitted into the Jewish ward are dieted and clothed at the expense of Mr. Menahem Messa's heirs. For patients of the well-to-do classes there is a special block containing accommodation for seven patients, where each patient is given a separate room on payment of a nominal charge varying from Re. 1 to Rs. 5 per day, according to the means of the patient. This block occupies a very favoured position in the hospital grounds. There is also under the control of the institution a mental block with accommodation for six patients which will soon be increased to ten. Mental patients are detained here under observation and if certified insane they are either handed over to their relations,

if they are willing to hold themselves responsible for their care, or they are transferred to the mental hospital, Thana, Bombay Presidency, irrespective of their nationality or place of origin. The responsibility for these cases being only rarely assumed by relatives, Arabs and Jews have occasionally to be transferred to the mental hospital in India; this is hardly a satisfactory arrangement, but owing to the fact that the accommodation in the mental block is very limited the patients cannot remain there, and no alternative has yet been devised. Incidentally it may be mentioned that it costs about Rs. 800 to transfer a mental case from Aden to India.

NURSING ARRANGEMENTS

Previous to 1928, the female staff consisted of two ayahs only and the male staff used to attend to the female wards. The first nurse was appointed in 1928, and she was expected to look after the whole hospital in addition to attending midwifery cases in the town. In the year 1931 a fully trained nurse, Miss D. K. Morton, was appointed in addition as sister-in-charge and in the same year a third (probationer) nurse was also appointed, and the hospital thus has now a sister-in-charge, a nurse-midwife and a probationary nurse.

PRINCIPAL DISEASES

The principal diseases for which patients seek admission in the Civil Hospital are :

Malaria.—Most of the malaria patients are from the interior, and the commonest variety of malaria is malignant tertian.

Hepatic cirrhosis.—Patients are often admitted with enlargement and cirrhosis of the liver, enlargement of the spleen and ascites. These patients are mostly from the interior, where malaria and the habit of eating *qat* (*Catha edulis*), an indigenous plant extensively cultivated in the Yemen, and containing a stimulating and mildly intoxicating principle, are extremely prevalent. To what degree either of these factors is responsible for the condition, it is difficult to estimate, but the extent to which *qat* is consumed, sometimes by the more well-to-do in quantities to the value of five or six hundred rupees a month, suggests that its ultimate effect on the organism, by absorption of the toxic principle, may well be harmful. The extent to which *qat* is consumed in the interior where it is very cheap, may be judged from the fact that in Aden, where the cost is high, the octroi revenue from imported *qat* is, in a normal year, Rs. 70,000 per annum, the value of the *qat* itself being Rs. 4,00,000 or approximately £30,000. The writer is making arrangements for the investigation of this drug at the Calcutta School of Tropical Medicine through the courtesy of his colleague, Lieut.-Colonel R. N. Chopra, I.M.S., Professor of Pharmacology.

Pulmonary tuberculosis.—This disease is extremely common both among the local inhabitants and people from the interior. Debilitating climatic conditions, unhygienic surroundings, privation and other existing diseases are all important predisposing causes of the disease.

Veneral disease.—Gonorrhœa is by far the most common venereal disease. Unfortunately, patients seek treatment only when the disease is well established and discontinue it as soon as the obvious signs and symptoms have disappeared. Under the rules of the Aden Settlement, any prostitute who is declared or suspected to be suffering from a venereal disease is required to present herself for admission and remain in the Civil Hospital for treatment until she is certified to be clinically free from the disease.

Dysentery is fairly frequent, and mostly of the bacillary type. Amœbic dysentery is rarely met with in Aden.

The surgical conditions for which patients most commonly seek admission to this hospital are the following:

Vesical calculus is very common. Climatic conditions, hardness of water, infection of the urinary tract, and probably a diet deficient in accessory food substances are the principal predisposing factors.

Fractures form a special problem. The illiterate element of the population is very impatient of any form of restraint. Carefully applied splints are sometimes taken off within a few hours of their application, and in spite of repeated warnings, patients begin to walk before callus is firmly consolidated.

Inguinal hernia is a common condition met with amongst the Arabs and Jews of Aden.

Myxetoma is fairly commonly met with amongst patients seeking admission from the hinterland. Out of thirty-two cases seen during the last four and a half years, thirty were of the black variety and only two of the yellow variety.

Tropical ulcer is one of the most common of the disabling diseases treated in the Civil Hospital. It is met with principally amongst Arabs from the hinterland. Malaria, colitis, privation and tropical climatic conditions generally all tend to aggravate the condition. As commonly described, spirochaetes and fusiform bacilli are frequently found in the discharge from these ulcers, but the real causative agent is not known. The condition involves prolonged hospital treatment; it results in serious deformity and amputation has often to be resorted to in severe cases. **Cancer** is a rare disease among people seeking admission to the Civil Hospital, similarly *appendicitis*, *gastric* and *duodenal ulcers* and *tetanus* are rare conditions. Not one case of *tropical abscess of the liver* has been met with in this hospital for the last four and a half years.

MEDICAL WORK AMONG WOMEN

Medical work among women is a branch of medical activity which is making but little headway, but it presents great possibilities. At the present time progress seems to have been arrested and the difficulty of further advance is mainly on account of the immense barrier which intervenes between medical aid and the women who need it, owing to the existing traditions and customs of the Mohammedan community and to the want of suitable provision for the better class patients in the female section of the hospital by means of family wards composed of separate units.

VITAL STATISTICS

Population.—The total (civilian) population of the Aden Settlement according to the census of 1931 was 45,992, showing an increase of nearly 2,000 on the census figures of 1921. The figures exclude the military and the population of Perim. The following table shows the population distribution by sex, and class :

Number	Classes	Male	Female
1	Arabs	18,388	10,341
2	Indian Mohammedans	2,829	2,393
3	Somalis	2,070	2,107
4	Hindus	1,992	622
5	Jews	2,114	2,006
6	Parsis	236	96
7	Native Christians, Indian, Goan, Somali, etc.	239	207
8	Europeans ..	213	39
	Total ..	28,181	17,811
	GRAND TOTAL ..	45,992	

The local distribution of this population is as follows: Crater, 23,283; Sheikh Othman (including Hiswa, Imad

and Little Aden), 11,051; Maala, 3,849, and Tawahi (including Steamer Point), 7,809.

There is a marked disproportion between the numbers of males and females, particularly among Arabs, which is due to the fact that most of the coolie class, and many Arab traders come to Aden without their women-folk.

STATEMENT SHOWING THE PRINCIPAL CAUSES OF MORTALITY
IN THE SETTLEMENT OF ADEN

(Mean of the four years 1930 to 1933)

Serial number	Causes of death	Mean annual number of deaths
1	Diarrhoea, dysentery and gastro-enteritis.	276
2	Pneumonia	166
3	Phthisis	147
4	Premature and stillbirths ..	128
5	Respiratory diseases other than pneumonia and phthisis.	106
6	Unclassified fevers ..	77
7	Malaria	35
8	Septicemia and cellulitis ..	25
9	Enteric fever	20
10	Cardiac failure	18
11	Cirrhosis of the liver ..	15

Mean death rate for the period equals 29.01 per 1,000 of the population.

CONCLUSION: FUTURE DEVELOPMENTS

The recent developments of medical relief, of hygiene and of sanitation in the settlement of Aden have now reached a point beyond which further progress is very largely dependent on the education of public opinion. The more progressive and educated elements of the community are a very small minority in the great mass of the population, which is backward and intolerant of change of any sort. Even the educated and intelligent minority are not free from the trammels of custom and prejudice and it is thus inevitable that those developments of public health work which depend, as so many do depend, on the acquiescence of the general public, cannot make headway in advance of public opinion. Moreover, in a predominantly Mohammedan community, educationally backward and intensely orthodox, all public health measures, however beneficent in their intention, which affect, or threaten to affect, the home, or even the individual, are immediately suspect and the first reactions they evoke are hostile.

Such measures, therefore, as pre-natal care of women, and infant-welfare work conducted by a medical woman, of indeed any medical work among women other than of a purely domiciliary character (and even this is sometimes resented), such measures as anti-tuberculosis schemes or anti-venereal schemes, which have grown in Western countries and even in some parts of India, to be so important a part of the public health work, are foredoomed to failure if they are launched in advance of a substantial body of public opinion. This is not a plea for a policy of *laissez faire*; it is a warning against that optimism which is blind to realities.

The education of public opinion in Aden, perhaps more than in other Eastern towns, is an extremely slow and often a very discouraging process, but there can be no doubt that it ought to be pursued. Means are now under consideration by which it is hoped public interest may be aroused, and where there is public interest, there is a possibility, later, of public acquiescence, that essential preliminary to any scheme for improvement of the health of the community which makes any demand on individual effort or on

public co-operation. Once this is secured, the way is open for further advance, but even then the watchword of the sanitarian in Aden must always be 'Festina lente'.

REPORT OF THE CHEMICAL EXAMINER TO
THE GOVERNMENT OF MADRAS (LOCAL
SELF-GOVERNMENT DEPARTMENT, PUBLIC
HEALTH). 1933. By LIEUT.-COLONEL CLIVE
NEWCOMB, D.M.F.I.C., I.M.S., CHEMICAL
EXAMINER TO GOVERNMENT

This report which has just come to hand deals with a number of subjects of medical and criminological interest. An excerpt of the statistics of poisoning cases with a few selected examples may prove of value to practitioners.

HUMAN POISONING CASES

The total number of human poisoning cases investigated during the year was 372 with 2,116 articles in which 450 people were affected and 277 died, as against 323 cases and 1,722 articles in the year 1932. In 173 cases poison was found (46.5 per cent). The number of human cases received this year is the highest number on record during any year in this laboratory. Though there has been a large increase in the number of cases received, the number of cases in which poison was detected has not increased proportionately (173 cases in which poison was detected this year as compared with 168 cases in which poison was detected last year). This is probably due to the fact that the routine of sending to the Chemical Examiner every suspicious case has become established throughout the Presidency. Poison found was as shown below:—

POISONS DETECTED

Inorganic

Cases	Cases
Arsenic 16	Hydrochloric acid .. 1
Arsenic and mercury .. 5	Lead 1
Arsenic and snake venom 1	Mercury 11
Barium 1	Manganese 1
Bismuth 1	Mercury and potassium per- manganate 1
Bleaching powder 1	Nitric acid 3
Caustic soda 1	Nitric acid and mercury 1
Copper sulphate 6	Nitric acid and sulphuric acid .. 1
Copper sulphate and lead 1	Sulphates 1
Cyanides 6	TOTAL 62
Cyanide and copper sulphate 1	
Cyanide and carbolic acid 1	

Organic

Cases	Cases
Aconitine 4	Nux vomica 4
Aconitine and poisonous resin 1	Oduvan 5
Alcohol 7	Oleander 25
Alcohol and oleander 1	Oleander and copper sulphate .. 1
Camphor 1	Oleander and tobacco leaf .. 1
Chenopodium oil 1	Opium 27
Chloral 1	Opium and tobacco leaf .. 1
Cresols 3	Picrotoxin 1
Croton oil 1	Strychnine 2
Datura and mydriatic alkaloid 8	Tobacco leaf 1
Eucalyptus oil 1	Unidentified poison .. 3
Luminal 1	
Madar 9	TOTAL 111
Marking nut 1	

Opium still heads the list with 28 cases while oleander comes close next with 27 cases. Next follow arsenic with 22 cases and mercury with 17 cases. There were 8 cases of datura or other mydriatic alkaloidal poisons.

In three cases although a poison was found we could not determine its exact nature.

Madar juice.—We get from time to time cases of fatal poisoning from drinking the milky juice of the plant *Calotropis gigantea*. The symptoms of madar juice poisoning are not very clear as in most cases little information is available as to the nature of the symptoms. It would appear to be not only a gastrointestinal irritant, but also a cerebrospinal poison.

In one case a woman drank the juice at about 7 a.m. The symptoms began at 7-30 with vomitings and purgings followed by convulsions in which she rolled on the ground. She collapsed and died at about 8 a.m. The post-mortem signs were bloody discharges in the nostrils and mouth, the lungs were congested and the heart was empty. Trachea was injected, liver, spleen and kidney were congested. The stomach was congested and contained about 2 ounces of chyme-like fluid. The small intestines were congested, the brain and the membrane were also congested. We obtained the reactions of madar juice from the stomach and its contents in this case.

Eucalyptus oil.—A young girl, aged 16, drank some eucalyptus oil in mistake for her fever mixture. She was brought to the hospital in a drowsy condition. The breath smelt of eucalyptus oil. The pupils were contracted and reacted to light. The pulse was 115 with fair tension and volume and respiration 24 per minute. The stomach was washed out in the hospital and she recovered. Eucalyptus oil was detected in the stomach wash.

Luminal.—An interesting case of attempted suicide by taking luminal occurred. A man is said to have taken 20 grains of luminal and 3 grains of potassium permanganate. Within about 40 minutes he was removed to hospital. On admission he was drowsy and kept his eyes shut, and he talked incoherently, and kept grinding his teeth. When questions were put to him loudly he answered very slowly as if he emphasized every word. There was watering of the eyes. The pupils were equal and reacted to light. He was occasionally boisterous. The pulse was 110 and respiration 28. The stomach wash obtained in this case showed about 1½ grains of luminal. The stomach wash was only 8 ounces in volume, and as luminal is fairly insoluble in water, a small stomach wash like this is not likely to contain the whole of the luminal present in the stomach. The normal dose of luminal is 1½ to 5 grains and up to 12 grains as a maximum dose. Severe symptoms, dizziness, nausea, vomiting, double vision are reported from 4½ grains in one case. Disturbance of speech, ataxia with inability to stand and diminished reflexes followed after 9 grains in one case, and after 13½ grains along with 3 grains of veronal in another case. Coma, loss of reflexes, anaesthesia of skin and severe disturbances of pulse and respiration, and amaurosis continuing for 22 days followed a dose of 36 grains taken with suicidal attempt. Two hundred and thirty grains taken in the course of three weeks proved fatal in one case. The man was charged with attempting to commit suicide but acquitted chiefly on the ground that there was no proof that he had taken a fatal dose or a dose likely to prove fatal. Where, however, a man takes poison and recovers it is generally impossible to prove how much of the poison he did take. In the hurry and excitement of washing out the stomach of a poisoned man some of the stomach wash fluid is very likely to be spilt and lost or the patient is likely to have vomited out a large portion of the poison before he ever reaches a doctor. Moreover some of the poison must be absorbed and some passed on to the small intestines where it is out of the reach of a stomach tube. The exact amount he has taken is therefore generally impossible to prove, and since the man has recovered the part of the total dose found in such of the stomach washes or vomits as have been preserved, is not likely to amount to a fatal dose. So far as attempted suicides are concerned this is not

perhaps a very serious matter, but the same arguments apply to attempted murder by poison.

THE LEPROSY SURVEY OF CEYLON, 1933. BY R. G. COCHRANE, M.D., M.R.C.P., D.T.M. & H. (ENG.)

THIS report which has just been published contains some useful advice in regard to the general policy of treatment in leprosy.

The 'Leper Ordinance' laid down very definitely that every sufferer should be brought under segregation, except where the authorities considered that the home conditions were good enough to justify the granting of 'home isolation'. The Ordinance has left sufficient latitude to allow officers to use their discretion in isolating cases, but the knowledge at the time it was promulgated was not sufficient for them to make use of the loopholes which were wisely provided. One thing, which will be mentioned again later, is the regulation concerning 'home isolation'. In our investigations we discovered that in those cases where regulations of this nature were necessary, the patient either could not or would not abide by them and in those cases not needing isolation the regulations imposed were altogether too irksome. I consider the working of this part of the Ordinance most unsatisfactory.

Modification of leprosy ordinance.—Before we can consider any special methods for controlling leprosy it is essential to consider in what respects the present Ordinance needs modifying. The present system of notifying a case of leprosy is altogether too rigid. In the first place when a person is found to be suffering from leprosy, no matter whether he is an early or late case, an infective or non-infective case, once declared to be a 'leper', in terms of the Ordinance segregation must follow, unless home isolation is granted. If the case, as it occasionally does, happens not to be suffering from leprosy the unfortunate individual seldom can get release from the asylum under three months. While leprosy ordinances are useful they should be looked upon in the same light as an emergency measure, not to be applied unless it is unavoidable. The result of the enforcement of the Ordinance has been threefold:

(1) Neural cases have been admitted, or readmitted, who, according to present knowledge, do not need segregation.

(2) The criteria for the discharge of a patient have generally speaking not been strict enough.

(3) The granting of home isolation, a provision made to avoid segregation, has resulted in an unsatisfactory state of affairs.

The place of institutions.—Ideally there should be provision made for five classes of patients:—

(a) Early infective cases likely to improve under treatment.

(b) Late infective cases not likely to improve under treatment.

(c) Infective cases among children.

(d) Crippled cases who are a charge on the Government.

(e) Paying patients.

Training and propaganda.—Every medical officer in a country where leprosy is prevalent should have an adequate course of instruction in the diagnosis, treatment, and prevention of the disease. It is not sufficient only to be able to diagnose a case, but what is equally important is the ability to determine whether it is one needing observation only, observation and treatment, or isolation.

This training should be in the form of pamphlets and popular lectures and should lay emphasis on the following points:—

(1) Leprosy is an ordinary disease and that there is no shame attached to it.

(2) Leprosy is a mildly contagious disease and that only certain cases need treatment.

(3) Leprosy frequently starts in childhood or early adolescence, but many children who show early signs of a leprotic infection do not need treatment, the signs disappearing by the time adult life is reached.

(4) The importance of watching such children and insisting that they should not be treated as outcasts, but left in school to carry on their studies.

(5) The lack of necessity for dismissing a child with active early neural leprosy. It should be given out-door treatment at a suitable institution and kept at school.

(6) The necessity for the isolation of all infective cases.

(7) The necessity for observing early signs and the importance of periodic examination of these children and need for examining all the child's contacts.

Indiscriminate propaganda is a two-edged weapon, and unless care is exercised and if excessive propaganda is embarked on, the general public are liable to expect more from the results of treatment than are really warranted. In pamphlets and lectures with a view to instructing the public the following points should be stressed:—

(1) Leprosy is an ordinary disease communicated by close contact by a person in the infectious stage; it is neither venereal in origin nor a curse of God.

(2) Only certain stages are infective, and if cases are declared early then the chances of healing are much better.

(3) Every case does not need treatment; there are many forms which are harmless but need watching periodically.

(4) Only those cases dangerous to the public will be segregated; others can be treated either at a special leprosy prevention centre where such exists or at any Government hospital.

(5) Children in the early stages or employees need not leave their school or place of employment, but should be examined periodically.

(6) The necessity for the periodic examination of all persons who have come into contact with an infected individual.

(7) A healthy body is the best defence against leprosy, and the development of a public health sense is one of the greatest factors against the spread of the disease.

All headmen and those who sway public opinion, e.g., the press, should receive information containing the above facts. In the list of diseases taught in school hygiene and to the public, leprosy should be included. Films and posters of an educative nature can be had from the Indian Council of the British Empire Leprosy Relief Association. Lantern slides and a cinema film are also obtainable. A pamphlet for popular use and articles for the press might be prepared and in this way a more reasonable attitude can be developed.

Correspondence

TREATMENT OF SOFT SORE AND BUBO

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I am prompted by the article which appeared in the July number of the *Indian Medical Gazette* to give my own experience in the treatment of soft sore and its frequently resultant bubo.

This was gained in dealing with some hundreds of cases as dermatological specialist at Karachi during the immediate post-war period, in 1919.

Locally, sores were treated with ionization and some such simple dressing as eusol, but this was always considered of secondary importance to vaccine treatment both for sores and buboes.

The latter were never opened even as a last resort. The method of dealing with them was by aspiration, a 5-c.cm. syringe and a medium-sized needle being used.

The latter is entered through healthy skin at least half an inch from the discoloured skin over the bubo and as much pus as possible evacuated. This procedure was repeated as often as pus collected. Even with skin over the bubo thinned to bursting point it was occasionally possible to obtain a cure without rupture and the needle track was rarely infected.

Two chief organisms, *Staphylococcus albus* and diphtheroids are found in this disease.

Cultures from fresh cases were constantly made, killed with carbolic and added to two stock vaccine bottles, one *albus*, the other diphtheroids. A mixture of the two was given.

The results of the vaccine were surprisingly quick in lessening pain and bringing about healing of the sore and subsidence of the bubo especially in the early stages of the latter.

It is noteworthy however that the same vaccine after being stored for six months was found to be worthless.

The conclusion drawn from this, rightly or wrongly, was that it was necessary to constantly reinforce it with fresh culture; in other words that it lost its potency with age.

I came to look on the fresh vaccine as the sheet anchor of treatment, and the opening or bursting of buboes as a disaster.—Yours, etc.,

J. F. JAMES, M.B., Ch.B. (Edin.),
D.M.R.E. (Cantab.), LIEUT.-COL., I.M.S.

COMBINED INDIAN MILITARY HOSPITAL,
RAZMAK,
20th August, 1934.

AN ALLERGIC MANIFESTATION

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR.—My son, aged 20 years, was bathing in cold water at a hilly place in summer, seven years ago; he got urticaria-like eruptions and felt a tingling sensation all over the whole body; he became blind at the same moment; but after two hours the eruptions and blindness passed off and he quite recovered.

Now whenever it becomes too cold he gets urticaria-like eruptions, but recovers soon in the sunshine or by sitting near the fire.

I have tried many medicines, but they have proved useless. Can you throw any light on the pathology and treatment of such a condition?—Yours, etc.,

HARKISHAN DAS, L.M.P.,
Medical Officer in Charge,
Billawer Dispensary.

JAMMU PROVINCE,
16th February, 1934.

[Note.—The history suggests that the case may be one of physical allergy. Bray (1932, *Proc. Roy. Soc. Med.*, XXV, 131) describes a case of allergy to cold in a boy of eight years. Mere putting of a finger into cold water in this case caused severe itching and swelling. The case was successfully treated by repeated injections of small doses of histamine. It might be worth while giving a trial to the same remedy in this case.—EDITOR, I.M.G.]

ROUNDWORMS CAUSING INTESTINAL OBSTRUCTION

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR.—Intestinal obstruction is a condition which calls for active surgical interference. The following case of obstruction caused by worms simulated this condition so much that but for mere chance the patient would have undergone an operation. I had once read of a similar case reported in the *Indian Medical Gazette*, but had never come across one myself, and rarity of its occurrence is my only excuse for reporting the cases.

I was called in to see a girl aged 5 years, suffering from constipation and sleeplessness for the last four days. Previous to my seeing the patient she was advised operation by the physician treating her. I found all

the symptoms of acute abdomen except vomiting. I administered a soap-and-water enema with a few drops of turpentine to allay distension. The enema was rejected and after some time I repeated the enema and this time the child passed a worm with hard faecal matter. This settled it. She was put on paraffin and calomel and santonin powders on alternate days; she passed 75 roundworms and made an uneventful recovery.—Yours, etc.,

G. R. VAIDYA, L.C.P.S.

NAVAPURA STREET, RAJPIPLA,
GUJERAT STATES AGENCY.
21st July, 1934.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUT.-COLONEL W. J. SIMPSON, Residency Surgeon, Mewar, is appointed to officiate as Resident in Mewar and Political Agent, Southern Rajputana States, in addition to his own duties, with effect from the afternoon of the 11th August, 1934, and until further orders.

Major M. P. Atkinson is appointed substantively to be an Agency Surgeon under the Government of India in the Foreign and Political Department with effect from the 31st March, 1934.

Major E. C. A. Smith is appointed to be Superintendent, Central Mental Hospital, Yeravda, on his return from leave.

The services of Major A. C. Craighead, an officer of the Medical Research Department, are replaced at the disposal of the Army Department with effect from the 27th May, 1934.

Major W. J. Webster, M.C., is appointed to officiate as Assistant Director, Central Research Institute, Kasauli, with effect from the date on which he assumes charge of his duties.

The services of Captain H. W. Farrell are placed temporarily at the disposal of the Government of Bihar and Orissa, with effect from the 16th July, 1934.

LEAVE

Lieut.-Colonel J. C. De is allowed leave for one year, with effect from the 1st September, 1934, or the date of availing.

PROMOTIONS

Majors to be Lieut.-Colonels

F. Oppenheimer. Dated 30th July, 1934.

P. Savage and Jamal-ud-din. Dated 1st August, 1934.

H. G. Alexander and P. D. Chopra. Dated 6th August, 1934.

A. S. Fry. Dated 14th August, 1934.

RETIREMENT

Colonel G. D. Franklin, C.I.E., O.B.E., retires 28th July, 1934.

RELINQUISHMENT OF APPOINTMENTS

Lieut. W. M. E. Anderson. Dated 7th June, 1934.

Lieut. H. B. Wright. Dated 7th June, 1934.

Notes

RADIO-MALT

RADIO-MALT is a palatable combination of radiostoleum (vitamins A and D) with measured amounts of concentrated extracts of yeast and malt containing vitamins B₁ and B₂ in standardized proportions. In Radio-Malt these four vitamins, which are lacking most often in the normal dietary, are exhibited in constant standardized amounts and in those balanced proportions which have been proved in clinical practice to be the most suitable for prophylactic purposes. Such constancy and balance cannot be assured in preparations

containing *natural* fish-liver oils, as in such the vitamin content is left to the vagaries of nature and, as a consequence, there is no fixed relationship between the content of one vitamin and that of another. For Radio-Malt therefore certain advantages over cod-liver oil and halibut-liver oil can be claimed.

Furthermore, by most careful study, The British Drug Houses have arrived at methods of exhibiting the vitamins in such a way that they remain stable, with the result that Radio-Malt retains its full activity even after long storage; hence it provides the physician with a simple medium for the daily administration of those vitamins (A, B₁, B₂ and D) of which there is often a serious deficiency in normal dietaries.

In those cases in which a supplementary source of vitamin C is required ample supplies may be assured through the administration of the juices of fresh fruit, oranges, lemons and grape-fruit being particularly rich in this vitamin. Alternatively, this vitamin can be supplied in accurate dosage through the medium of tablets of pure crystalline vitamin C (Ascorbic Acid B.D.H.).

The vitamin content of Radio-Malt is controlled by nutrition tests carried out in the B.D.H. physiological laboratories. The tests include observations on the growth rate, as well as on the cure, or the prevention, of the specific diseases which develop in experimental animals when the diet supplied is deficient in the vitamin under test.

Uses.—Radio-Malt finds an important place in preventive medicine; its use is not restricted to any particular age or sex, and for this reason it has a wide application in general practice.

For example, Radio-Malt is prescribed for pregnant and lactating women in order to provide a sufficiency of vitamins A and D to enable the mother to withstand infection at parturition, and to maintain correct phosphorus and calcium metabolism so that the bones of the foetus and of the child become normally calcified. Radio-Malt also tends to prevent the development of anaemia; further, it checks constipation and the uncontrollable vomiting of pregnancy and, generally, enables the mother to maintain a sufficiency of reserves during the time of extra demand.

THE MODERN MANUFACTURE OF ROLLER MILK POWDER

THE manufacture of roller milk powder has assumed enormous proportions, and its use in the artificial feeding of infants is steadily increasing. The protection which it affords against tuberculosis and epidemic milk-borne disease, and the close approximation of the rennin curd in digestibility to that of breast milk are the main factors in determining this universal demand, which is specially applicable in tropical areas where the safe feeding of infants presents a most difficult problem to mothers, nurses and the medical profession.

Since the introduction of the roller process of powdering by Just Hatmaker, great improvements have been effected in the patents, and as exemplified in the improved methods adopted in the Cow and Gate factories this has now reached a perfect standard of efficiency.

Standards of purity of the raw milk

The dangers that lurk in raw milk are too well known to need stressing. A large proportion is affected with the bovine tubercle bacillus, and it is a prolific carrier of epidemic diseases such as diphtheria, undulant fever and scarlet fevers, and enteritis. The first care therefore is to ensure a supply of clean raw milk. With this object in view the milk from the different farmers on arrival at all Cow and Gate factories daily is submitted to a series of routine tests. These tests include:—

1. Sediment test, in which the milk is forced through a cotton-wool disc which traps the coarse dirt. These pads are dried and examined for report by one of the chemists.

2. Determination of fat by the Gerber method.
3. Determination of acidity.
4. Bacteriological examination and count by the Breed method.

The results are filed under the name of each farmer, so that a complete record is available for reference.

Should milk from any source fail to reach the high standard set by the chief chemist it is rejected, and one of the dairy inspectors is told off to visit the farm to enquire into the cause. Every encouragement is given to the farmer to improve his procedure for the supply of clean milk, and inspectors visit the farms to instruct in the latest methods. Filtering and other utensils are supplied free by the company.

There is in existence a bonus scheme by which marks are awarded for the various points and in accordance with the approach of the milk to the maximum a bonus is paid at the end of each month to those farmers who reach a certain figure in the aggregate. This scheme has also had far-reaching repercussions in the general improvement of the liquid milk supplied for general consumption.

CONTRAMINE

CONTRAMINE, or to give it its full chemical name, di-ethyl-ammonium di-ethyl-di-thio-cabamate, is an organic sulphur compound with a complex molecule. It is non-toxic in the doses recommended.

Indications.—Contramine is valuable in such infections as the chronic complications of gonorrhoea, including stricture, chronic epididymitis, conjunctivitis and iritis; in neuritis its administration will often achieve results unobtainable with any other drug and this is equally the case in the various forms of muscular rheumatism such as fibrositis, teno-vaginitis and arthritis. In chronic skin diseases such as acne vulgaris, acne rosacea, seborrhoeic eczema and chronic dermatitis of varied or unknown origin, Contramine administration has been found unique in its beneficial effect.

Contramine prevents and ameliorates metallic intoxication of any origin; therefore, it may be given with advantage along with arsenical preparations in cases found to be intolerant of salvarsan and its substitutes.

Administration and dosage.—Contramine is usually injected intramuscularly, preferably in the gluteus medius, but never in the superficial tissues. The patient should be made to contract the gluteal muscles and the injection should be made towards the outer and upper part of the bulge of the muscle. Painful gluteal injections are due to the medicament going into the gluteus maximus which consists largely of fibrous tissue.

It is necessary to use a needle at least 2 inches in length and of large diameter but with a sharp point. This ensures the necessary deep injection and quick dispersion of the medicament in the muscle tissues. During the course of the treatment it is preferable that the patient should abstain from all alcoholic drinks.

In neuritis clinicians recommend 0.125 gramme in 1 c.c. every third day until six are used, with high colon lavage daily, the result of this treatment causing complete cessation of pain in the course of about ten days.

In severe cases of metallic intoxication 0.125 gramme may be injected every day till six or more doses have been administered. In other cases two injections each of 0.125 gramme with a week's interval between them usually suffice.

Contramine is a softener of fibrous tissue, and many strictures resisting dilatation may be rendered dilatable by the intramuscular injection at approximately weekly intervals of one dose of 0.125 gramme and two doses of 0.25 gramme. This treatment is advised in cases of chronic epididymitis, but it should be succeeded by a course of vaccines because micro-organisms hidden by the fibrous tissue may be released as the latter is destroyed.

S.U.P. 36

For the treatment of acute inflammatory conditions

ALTHOUGH S.U.P. 36 is employed primarily for the treatment of catarrhal conditions and infections of the respiratory system generally, its use is being extended to all acute conditions with pyrexia; in puerperal pyrexia, the injection of 1 c.c. of S.U.P. 36 on two successive days causes an immediate return to normal temperature which is followed by an uneventful recovery.

Other acute conditions in which S.U.P. 36 has been used with success are hyperemesis gravidarum, pyelitis, broncho-pneumonia in children, venous thrombosis, osteomyelitis, acute cystitis, acute mastoiditis and herpes zoster, whilst in the pyrexia following incomplete abortion and in acute epididymitis timely injections of S.U.P. 36 have been known to cause a reduction of temperature of 103°-104° to 99° within twelve hours.

Further, during a recent epidemic of measles it was found that injections of S.U.P. 36 in doses of 0.005 to 0.0075 gramme prevented catarrhal involvement and cough, all treated cases proceeding to recovery without complications. On the other hand, control cases receiving no injection of S.U.P. 36 manifested the usual symptoms involving inflammatory conditions of the ear, nose, and throat with the accompanying characteristic cough.

Finally, although essentially a therapeutic substance, S.U.P. 36 has been employed with success as a purely prophylactic remedy for the prevention of colds and influenza during the winter months. It is injected also as a precautionary measure before operation in order to diminish or prevent post-anæsthetic vomiting.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

A SIMPLE METHOD OF RECOVERING
TYPICAL CULTURES OF DERMATO-
PHYTES FROM PLEOMORPHIC
GROWTHS

By H. W. ACTON, CIB.

LIEUTENANT-COLONEL, I.M.S.

and

N C DEY, L.M.P., L.T.M.

*(Under a Mycological Enquiry financed by the Indian
Research Fund Association, School of Tropical
Medicine, Calcutta)*

THE preservation of the typical ringworm cultures in a laboratory medium has always been very difficult, as they usually become 'downy'. Therefore the discovery of a means by which they can be made to revert to their true type is a matter of great importance.

When cultures true to type have been kept growing for some time in a laboratory medium, they undergo pleomorphism, in spite of repeated subcultures. In this connection the term pleomorphism was first used by Sabouraud, and it is defined as follows:—The cultures lose all the characters of the type and form *duvets*, i.e., exuberant downy growths; this process goes on indefinitely, even in subcultures, and normally such cultures never revert to their original or true type. Microscopically, they do not usually show any end-organs and, depending on the stage of degeneration, the cultures may contain only mycelia or rarely aeciospores. The mycelia are long, wavy and contain very little plant volutin.

Pleomorphism has been the chief difficulty in the study of dermatophytes and it appears probable that many so-called distinct species are only degenerate forms of species already known. Some species exhibit this character more markedly than others, and this applies to animal microspora particularly. In the case of *Microsporon lanosum* we could never recover the true type from the subcultures of a pleomorphic growth until we employed the method described below.

The saprophytic origin of ringworm dermatophytes has been recognized for a long time, and Sabouraud (1910) first succeeded in growing them on decaying vegetable matter of various kinds, such as moist and dry leaves, rotten wood, seeds and straw and also in mineral solutions. Langeron and Milochévitch (1930) used cereals, such as wheat, barley, and oats, dung, and fungus slopes as their media for the culture of ringworm fungi. These media were found favourable for the growth and development of certain dermatophytes in order to show the various end-organs.

Nannizzi (1926 and 1927) followed Sabouraud's work and showed that these fungi would also grow saprophytically upon animal matter

of various kinds, viz, leather, feathers, bones, and earth containing manure. He used these substances as laboratory media and called them 'natural media' in contra-distinction to the artificially-prepared media usually employed. These dermatophytes grow parasitically in man and animals.

Text-fig 1—Cultures of ringworm fungi on feathers

We have confirmed the work of Sabouraud, Langeron and Milochévitch, and Nannizzi, and have successfully grown ringworm fungi on rotten leaves, wood, bath planks and mats, mud, cereals, leather, feathers and animal manures. They appear to be able to live on these substances for a long time if moisture is present, but eventually they become pleomorphic in the same way that they do on artificial media.

The fungi of the *Achorion* type can rarely be made to grow on natural media, and on artificial media they do not grow as luxuriantly as do the ordinary ringworm fungi but remain true to type for much longer periods, and continue to produce typical end-organs. It thus appears that the cultures that grow most luxuriantly and produce profuse branching mycelia have few if any spores, as the conditions are more favourable for growth of the fungus than for production of end-organs.

We decided to reduce artificially the favourability of the conditions under which the

were made. For the preliminary subcultures of these fungi we selected feathers as being the most nearly comparable to human hair and skin, both chemically and anatomically. The feathers were mounted on plaster-of-Paris

Text-fig. 2.—*Microsporon lanosum* showing mycelia with close septa. The growth is on feathers two months after the inoculation of pleomorphic cultures from Sabouraud's medium. Magnification—1/6 inch objective $\times 10$ ocular ($\times 250$ approximately).

blocks and put in test tubes three-quarters of an inch by six inches with a little water at the bottom to maintain sufficient moisture for the growth of the fungus. The tubes were plugged with cotton-wool and sterilized in the autoclave at 120°C . The feathers were then inoculated on the rachides with pleomorphic cultures from Sabouraud's medium. They grew very satisfactorily on the feathers as long as there was water in the tubes. The growth which was at first of a *duvet* type, began to dry and shrink, and to adhere more and more intimately to the feathers after the water dried up in the tubes (text-fig. 1). In the *duvet* stage they contained only mycelia with or without aleurines, but when they dried they showed mycelial shreds and spores, isolated or in chains. The spores were like those found on infected hair (plate XIV, fig. 4).

At this stage they were inoculated on different standard media, namely, Sabouraud's (maltose peptone agar) medium, liquid maltose peptone, and wheat medium. The result was satisfactory because the fungi were found to have lost their pleomorphism and to have reverted to type (plate XIII, figs. 1, 2 and 3). Liquid

maltose or glucose peptone is a new medium that we have devised; it contains one part of bacto-peptone, two of ordinary maltose or glucose, in a hundred parts of water, and is adjusted to a pH of 7.0 (plate XIII, figs. 4 and 5).

Experiments were performed with pleomorphic cultures of known species and the results are given below in the table

Experiments.—The first series of experiments were undertaken with the pleomorphic cultures of known ringworm fungi, namely, *Microsporon felineum*, *Microsporon lanosum*, *Microsporon pubescens*, *Trichophyton persicolor*, *Microsporon*

Text-fig. 3.—*Microsporon felineum* showing end-organs (aleuriospores and spindles) in liquid maltose peptone medium. Magnification—1/6 inch objective $\times 10$ ocular ($\times 250$ approximately).

fulvum and *Epidermophyton cruris*. These fungi were first inoculated on to feathers and allowed to grow for about eighteen weeks, sufficient water to keep them moist being added from time to time; they were then allowed to become dry. After being kept in a dry condition for one month subcultures were made on the following media:—Sabouraud's maltose peptone agar slopes, wheat, and liquid maltose peptone.

A second series of inoculations, similar to the first one except that the subcultures from the feathers were delayed another week, were made into these various media. The results are shown in the table; there was little material difference between the results of the first and second series.

In a third series, cultures of *Achorion gypseum*, *Trichophyton asteroides* (*gypseum*) and *Trichophyton radiolatum* were inoculated on to feathers and kept growing in a moist condition for about sixteen weeks. They were allowed to dry, kept in this state for a month and subcultured on the same media as the other fungi. The results are also shown in the table.

* Showed end-organs on feathers (spindles).

† Showed aleuries in groups, but no spindles.

It is evident from the table that the production of true-type cultures mainly depends on the stage of the original culture, i.e., whether it contains mycelia or spores, from which we take our inoculum. Spores appear to give rise to the true type which show the characteristic end-organs, and mycelia to the *duvet* type of growth in which no end-organs are seen.

The true type of growth can be recognized in a mixed pleomorphic and true growth by the appearance of dirty-white coarse granules which are rich in end-organs, including spindles.

Reversions to true type in drying cultures.—True-type cultures can also be obtained in Sabouraud's medium, even from a *duvet* growth in the way described below.

If Sabouraud's slopes inoculated with the dermatophytes, pleomorphic at the time of inoculation, are kept, after some time the thinnest parts of the slopes dry, but the growth continues till the whole tube dries up; this takes six to seven months in this country. Before they reach this stage, however, some of the tubes show a uniform layer or isolated areas of dirty-white coarse granules at the dry and thin end of the slope. These granules when examined microscopically show numerous end-organs, including typical spindles, as we found in the case of *E. cruris*, *M. fulvum*, and *M. equinum*. Thus, tubes inoculated on the 16th May, 1933, with *M. equinum* in pleomorphic form and examined from time to time up to two months did not show spindles at all, but on the 17th January, 1934, when they were re-examined by chance among an old stock of tubes that had been discarded after subculture, the typical end-organs were seen (plate XIV, fig. 6) on the areas of the slope showing brownish granules.

This phenomenon can be explained on the ordinary laws of self-preservation of species—when food supplies are abundant the race is mainly concerned with reproduction of individuals (hyphæ), but if food conditions are limited, then the main concern becomes the conservation of the race.

When the fungi get sufficient nutrition and moisture there is so much exuberant growth of the aerial hyphæ and they give out branches so quickly that the end-organs scarcely grow, or do not grow at all. Therefore, when the fungi are seen under the microscope the end-organs are absent, or even when a few of them are present they cannot be seen through the exuberant growth of mycelia.

When the conditions are unfavourable from want of moisture or nutrition or both, the growth is naturally poor, and in order to preserve the species resistant spores, in the form of end-organs which can withstand unfavourable conditions, are formed.

BASAL METABOLISM OF INDIANS IN HEALTH AND DISEASE—ITS CLINICAL SIGNIFICANCE

By J. P. BOSE, M.B., F.C.S. (Lond.)

Diabetes Research Worker

and

U. N. DE

*Chemist, Diabetes Research Department
School of Tropical Medicine, Calcutta*

Introduction.—The subject of basal metabolism has, during the last few years, become of considerable importance in the practice of medicine. The clinical significance of its determination in certain diseases is growing in importance and is slowly beginning to occupy a prominent place in the field of internal medicine. The information which the measurement of the basal metabolic rate conveys, not only adds a very valuable link to the chain of evidence upon which the diagnosis of certain diseases rests (specially those in which a dysfunction of certain endocrine glands is suspected), but, what is more important, it gives us very valuable data for determining the severity of the case, and for indicating the line of treatment to be adopted in the individual case.

It may be said at the outset that the present paper has been written, principally from the clinical point of view, with the object of bringing the subject out of the intricate realm of pure physiology into the domain of clinical medicine. Wherever it has been found necessary to describe the various methods of determination, only the underlying principles of the technique have been described.

(Continued from previous column)

Résumé

I. The specific cultural characteristics of ringworm fungi can be restored by subcultivating from pleomorphic cultures by the method described.

II. Pleomorphic cultures on Sabouraud's media, when allowed to dry and with age, form end-organs and the standard type of growth can then be obtained on subculture.

III. In liquid maltose peptone media made from the chalky part of these drying cultures, ringworm fungi show profuse growth of end-organs.

Definition

Basal metabolism or 'standard metabolism' as it is sometimes called is a term which is used to represent the total energy (heat) output of the body when it is at complete physical and mental rest. We know that the metabolic activity of the body is lowest when it is at complete rest and without food (for at least 14 to 16 hours). Under such condition the activity of the various organs, such as the heart, lungs, liver, kidneys, etc., is reduced to a minimum. At such a time also the metabolism is not under the direct influence of the stimulus—the specific dynamic action—which foods are known to exert. This low rate of energy exchange of the body is called the basal metabolism, i.e., the level of metabolic activity which is purely and simply associated with the maintenance of the automatic functions and the body heat. It may roughly be said that under such resting conditions, approximately 25 per cent of the basal energy (heat) output is due to the functional activity of the heart, the respiratory movements, the liver and the kidneys and the remaining 75 per cent of the basal energy represents the total heat production of the resting tissues such as the skeletal muscles.

History of metabolism

The history of metabolism is closely associated with that of respiration and credit is due to Lavoisier, the founder of metabolic research, who in 1780 thought that oxygen played a very important part in the functions of all the bodily processes. Lavoisier was, however, mistaken as to the origin of the heat production, believing as he did that oxygen combined with hydrogen and carbon in the lungs to form heat. It was more than half a century after his death that it was shown for the first time that the ultimate source of body heat was mainly the oxidation in the body of the three types of food-stuffs—carbohydrates, proteins and fats. The difference in the chemical composition of these three types of food-stuffs would naturally account for the fact that different amounts of oxygen would be necessary to burn them and different quantities of energy (heat) would be liberated. Thus, it appears that since metabolic processes are essentially oxidative in nature, involving the utilization of oxygen, the liberation of carbon dioxide and the production of energy in the form of heat, basal metabolism may be expressed in terms of any one of these three factors, viz—

- ✓(1) the actual amount of heat (calories) produced;
- ✓(2) the actual amount of oxygen consumed;
- ✓(3) the actual amount of CO₂ liberated.

While on this subject a short discussion of what 'respiratory quotient' means would be helpful for the proper understanding of the metabolic processes involved in the oxidation of various kinds of food-stuffs in the system.

The term 'respiratory quotient' was first applied by Pfüger to indicate the ratio of the volume of carbon dioxide expired to the volume of oxygen inspired during the same interval of time. This is expressed by the simple ratio :

$$\frac{\text{vol. of CO}_2}{\text{vol. of O}_2}$$

We know that all food-stuffs, viz, carbohydrates, proteins and fats, when burnt in the system, consume oxygen and liberate CO₂ but the relative amounts of these gases vary according to the kind of material oxidized. Thus, it appears that the determination of

the respiratory quotient will indicate the nature of food-stuffs which is being oxidized in the system. Take for example the combustion of carbohydrates. According to its structural formula, we know that this food-stuff contains two atoms of hydrogen to one atom of oxygen, that is, these two elements are present in the exact proportion to form water and when they are so united on combustion, all the carbon atoms are free to unite with the newly-acquired oxygen; thus,

It will be seen from the above formula that 6 molecules of oxygen utilized in the combustion of the carbohydrates can unite only with 6 atoms of carbon to form 6 molecules of CO₂, i.e., one molecule of oxygen produces one molecule of CO₂. We know that according to Avogadro's law, equal volumes of gases contain an equal number of molecules at the same temperature and pressure and thus the volume of O₂ consumed in the burning of carbohydrates exactly equals the volume of CO₂ given off. The respiratory quotient is therefore

$$\frac{\text{vol. CO}_2}{\text{vol. O}_2} = \frac{6}{6} = 1$$

In the combustion of protein and fat, however, we see, from their respective formulae, that some of the oxygen consumed is utilized for purposes other than the production of CO₂ and for this reason the volume of oxygen used is greater than that of CO₂ liberated. Therefore, the respiratory quotient of each of these two food-stuffs is less than unity. It has been found by experiments that when protein alone is metabolized, the respiratory quotient is 0.8, and when fat is metabolized alone it is 0.71. A respiratory quotient which is intermediate between these figures indicates the burning of a mixture of food-stuffs.

That the conditions hypothesized in the equations above exist in an animal body during the combustion of food-stuffs can easily be shown by observing the respiratory quotient of animals on different diets. A herbivorous animal such as a rabbit, when it is well fed, invariably gives a respiratory quotient of about 1 whereas a strictly carnivorous animal such as a cat gives a respiratory quotient of 0.7.

The determination of the respiratory quotient is particularly valuable in studying the severity of metabolic error in diabetes inasmuch as it affords a reliable index of the degree of defect in carbohydrate utilization. It is well known that in severe diabetes the respiratory quotient decreases—reaching a figure as low as 0.7 in complete diabetes, indicating that oxidation of fat is taking the main part in the maintenance of the metabolic requirement of the diabetic individual. It is also well known that the respiratory quotient begins to increase as soon as insulin is administered.

Food-stuffs as energy producers

Basal metabolism thus furnishes the starting point from which proceeds all computation of man's nutritive needs. It is expressed as the number of units of heat or calories* liberated per hour or per day. The caloric value of any particular food-stuff may be determined by allowing a weighed quantity of the substance to burn in compressed oxygen in a steel bomb placed in a known volume of water at a certain temperature; whenever the combustion is completed, we find out through how many degrees the temperature of the water has become raised and multiply it by the volume of water in litres. Measured by such a calorimeter (as this apparatus is called) it has been found that the number of calories liberated by burning one gramme

* A calorie (large) is a unit of heat and represents the amount of heat required to raise the temperature of one kilogramme of water through 1°C., or more properly to raise the temperature from 0° to 1°C.

of each of the three main principles of food is approximately as follows:

1 gramme of protein	..	4.1 calories
1 " " carbohydrate	4.1	"
1 " " fat	..	9.3 "

Relation of the basal metabolic rate with the surface area of the body

Roughly speaking, we may assume that the metabolic rate is proportional to the surface area of the body except in infancy. The younger the animal, the greater is the proportionate metabolic rate. Basal metabolism is surprisingly constant between the ages of 20 and 50, with a body of average shape and size. It has been estimated that, during this period, the basal metabolism is approximately 39.7 calories per square metre of the body surface per hour in men and 36.9 calories in women. After 50 years, the basal metabolism again decreases.

The measurement of the surface area of the body, though a complicated process, has been much simplified by Du Bois, who devised a simple formula for measuring the surface area of the body based on the height and weight of the individual alone. This is known as height-weight formula of Du Bois and has been checked by several workers and found to be fairly accurate.

This is expressed as follows:—

$$A = W^{0.425} \times H^{0.725} \times C$$

Where A = Surface area.

W = Weight in kilogrammes.

H = Height in centimetres.

C = Constant = 71.84.

There are several other formulæ and charts devised by different workers for finding out the surface area of the body, of which mention may be made of the prediction table of Harris and Benedict. As the subject is complicated and as this paper has been written from a clinical standpoint, the comparative merits of these have not been discussed.

Methods for determining the basal metabolism

We have already said that basal metabolism may be expressed and calculated in terms of any three of the following factors:—

- (1) The actual amount of calories produced.
- (2) The actual amount of oxygen utilized.
- (3) The actual amount of carbon dioxide liberated.

It thus appears that the practical method of determining the basal metabolic rate in human beings falls mainly under the following two heads, viz:

(1) *Direct calorimetry* which consists in placing the individual inside a calorimeter and actually measuring the amount of heat produced in a given time. The first calorimeter of the direct or chamber type was established by Prof. Atwater and Rosa in 1897. Further modifications of this method were made, the latest types of respiratory calorimeters being those of the Nutrition Laboratory at Carnegie Institution in Boston and of the Russel Sage Institute in New York.

The extreme complexity of the method and great expense of an apparatus of this type makes it impracticable for clinical purposes, though, undoubtedly, this method is one of the most accurate for the determination of basal metabolism.

(2) *Indirect calorimetry* by which is meant calculation of the heat production by means of measurement of the respiration gas exchange. This again falls under two heads:—

(a) *Open or gasometric method* in which the subject breathes through valves which automatically divide the

inspired and expired air. The volume of the expired air in an unit of time is then measured at standard temperature and pressure and the composition of both the expired and the inspired air, as regards the oxygen and carbon-dioxide content, is determined by gas analysis. The actual amount of oxygen absorbed and carbon dioxide eliminated during the test is thus determined, correction being made for temperature and pressure. The calorie expenditure of the individual per square metre of body surface is then determined by calculating the respiratory quotient and the calorie equivalent of the oxygen absorbed. The Tissot spirometer, the Douglas bag, and Haldane's gas apparatus are examples of this type.

(b) *Closed circuit method*.—For clinical purposes, the classical methods of determination of the basal metabolic rate just mentioned had to be much simplified so as to be within easy reach of clinicians and at the same time accurate enough for clinical purposes. The credit of finding out such a simple method goes to the American nutritional physiologist, Benedict of the Carnegie Institute. The apparatus devised by him consists of a system of tubes connected with containers for the absorption of carbon dioxide and moisture, and a spirometer filled with oxygen. The person whose metabolic rate is to be determined breathes into a mouthpiece connected with the apparatus by a short tube. Aided by valves his respired air circulates through this air-tight system. The volume of oxygen in the spirometer decreases according to the amount which the person consumes in a definite period of time. By means of a simple formula this quantity can be calculated in cubic centimetres if an allowance is made for barometric pressure and temperature.

Various modifications of the above method have from time to time appeared—the main principle in all these types of apparatus being the actual determination of the amount of oxygen consumed by the individual within a definite period of time. As previously stated, the basal metabolic rate can also be determined by estimating the carbon-dioxide output of the individual, but the oxygen intake method of determination is generally preferred because this method is subject to less error than the former method for the following reasons:—

(1) for a given change in the respiratory quotient, the calorie value of a litre of oxygen varies only by a quarter as much as that of a litre of carbon dioxide;

(2) any accidental acceleration in breathing has much less effect on the rate of oxygen intake than that of the carbon-dioxide output, which is sometimes increased to a great extent;

(3) the carbon-dioxide output is greatly influenced by changes in the acid-base equilibrium of the body.

At the present time, the consensus of opinion among most eminent authorities on the subject of metabolism is that the determination of the amount of oxygen which a subject consumes under certain test conditions is, *clinically speaking*, the best index of his rate of metabolism.

The calculation of the basal metabolic rate by the above method may be done by either of the two following ways:—

(1) *By calculation on the basis of heat production*

It may be assumed that 16 to 18 hours after the last meal, the tissue metabolism is such that the respiratory quotient is 0.82. The calorie value of 1 litre of oxygen under such conditions is usually assumed to be 4.8 calories per litre. The basal metabolic rate can then be expressed in terms of calories per square metre of the body surface calculated according to the rate of oxygen consumption and compared with that of a normal healthy individual of the same age, sex, height and weight.

Thus the heat production (in calories) of the individual would be as follows:—

Oxygen (in litres) consumed by the subject per hour
 $\times 4.8 = \text{Calories per hour.}$

$$\frac{\text{Calories per hour}}{\text{Surface area (in square metre)*}} = \text{Actual calories per square metre per hour.}$$

Therefore

$$\left\{ \begin{array}{l} \text{Normal calories} \\ \text{per square metre} \\ \text{per hour} \end{array} \right\} - \left\{ \begin{array}{l} \text{Actual calories} \\ \text{per square metre} \\ \text{per hour} \end{array} \right\}$$

$$\text{B.M.R.} = \frac{\text{Normal calories per square metre per hour}}{\text{Normal calories per square metre per hour}} \times 100$$

(2) *By calculation on the basis of oxygen consumption*

The actual amount of oxygen consumed in c.cm. per minute is compared with that of a normal healthy individual of the same age, sex, height and weight. The basal metabolic rate may then be expressed in terms of percentage difference between the normal and actual oxygen consumption per minute of the individual.

Thus

$$\left\{ \begin{array}{l} \text{Normal consumption per} \\ \text{minute (corrected for age and} \\ \text{sex)} \end{array} \right\} - \left\{ \begin{array}{l} \text{Actual consumption of} \\ \text{oxygen per minute (corrected for temperature and pressure)} \end{array} \right\}$$

$$\text{B.M.R.} = \frac{\text{Normal consumption per minute (corrected for age and sex)}}{\text{Normal consumption per minute (corrected for age and sex)}} \times 100$$

The apparatus used

In the routine determination of the basal metabolic rate, we have used the closed circuit method, the particular apparatus used being the Sanborn graphic metabolism apparatus. This has been found to be quite easy to work and at the same time quite accurate for clinical purposes. Tests made on the same individual (normal) on different occasions under similar conditions gave uniformly identical results. The senior author has been working on this type of apparatus for the last 12 years and is of opinion that once the technique is mastered and all the precautions are taken against errors, the results obtained are quite accurate. It may also be mentioned that several times each of the authors experimented on the same subject on different occasions with little variation in the result.

Description.—The apparatus consists of a double-walled east-iron cylinder inside which is fitted a jar containing soda lime. There is about $\frac{1}{2}$ inch of space in between the two walls and inside this the oxygen bell fits snugly. The cylinder has two outer openings at the bottom, one being connected with the soda lime container and the other directly with the oxygen spirometer. The inner opening of the soda lime container is fitted with a rubber valve which opens out when air is blown in through the outer opening (during expiration), but automatically

closes when the air is drawn in (during inspiration). The inner opening of the oxygen spirometer is fitted with a different set of rubber valves which open only when the air is drawn in (inspiration) but automatically close when the air is blown in (expiration). The two outer openings at the bottom of the cylinder are connected by means of two pieces of thick rubber tubing which are united at the outer end by means of a metal connector to which a mouthpiece is fitted. Thus, it appears that when the subject breathes in through the mouthpiece, the valve in the oxygen spirometer opens out and he breathes in pure oxygen, and when he breathes out it goes through the soda lime container (which absorbs CO_2 , moisture, etc.), back into the spirometer.

The oxygen bell thus rises and falls as the subject breathes. There is a kymograph attached to the side of the oxygen spirometer which is worked by a clockwork motor placed at the bottom of the apparatus. There is a pen attached to the kymograph which is so adjusted that it moves up and down with the oxygen bell and indicates the exact level of the oxygen in the bell on the kymograph. As the subject breathes, he takes in the oxygen from the spirometer, the level of the oxygen bell thus getting lower and this is indicated by the pen writing on the chart on the kymograph. The kymograph is adjusted in such a way that it goes completely round once in eight minutes.

The difference between the levels of the oxygen bell before starting the experiment and at the end of eight minutes will thus indicate on the kymograph chart the amount of oxygen consumed by the subject during that period, and from that the oxygen consumption per minute is calculated, after correcting for the temperature* and pressure.

Preparation of the subject for the test

The subject must be in a basal state, i.e., he must be at complete physical and mental rest in bed and in warm surroundings and must not be under the stimulating effect of any food or drink. It is customary to do the test in the morning, at least 12 to 16 hours after the previous night's meal. The nature of the test should be explained to the subject fully and clearly so as to allay his nervousness before and during the test. Whenever possible, a preliminary experimental test should be done on the subject to accustom him to the exact procedure of the test.

The subject should lie in bed in a comfortable reclining position. The head and shoulder must be arranged in a comfortable position by means of pillows so that the subject can breathe naturally and has no difficulty in swallowing

* Calculated according to Du Bois formula of a normal individual of the same age, sex, height and weight.

† Calculated from Aub and Du Bois table according to the age and sex of the individual.

* The temperature of the oxygen is recorded by a thermometer placed inside the spirometer through an opening at the bottom.

the saliva which invariably accumulates in the mouth. If this is neglected the subject may sometimes find it uncomfortable and may become choked. It should be clearly explained to the subject that there is no pain or discomfort whatsoever accompanying the test.

Adjustment of the apparatus

The apparatus should be placed on a table a little higher than the bed of the subject. The space between the walls of the cylinder is filled with water to within one or two inches from the top. The oxygen bell is pushed down to its lowest level. Oxygen gas is then slowly introduced into the spirometer from an oxygen cylinder by connecting it with the petcock of the spirometer. As the gas passes into the spirometer the oxygen bell rises up and carries with it the pen attached to the kymograph thus indicating on the chart the level of oxygen volume. To prevent any escape of gas, the metal mouthpiece connector is closed by a rubber stopper and tests for leakage are also made.

The rubber mouthpiece properly sterilized is fitted into the subject's mouth so that the flange of the mouthpiece fits snugly inside the mouth in the space between the lips and gums and no air leaks through the corners of the mouth. The two projections are meant for giving a thorough grip on the mouthpiece, the subject being advised to bite on them. The nostrils are closed by means of the rubber nose-clips which can be tightened or loosened at will. The nose-clip should be adjusted in such a way that the alæ nasi are firmly gripped so as to prevent any leakage through the nose, without causing any discomfort to the subject.

The subject is then connected with the spirometer. Test for leakage is very carefully made by holding a cooled mirror in and about the nose and mouth. In case of leakage the mirror will get fogged. The subject breathes in and out of the spirometer and when the breathing is steady, the kymograph is set in action. The temperature of the gas inside the spirometer is noted by means of the thermometer fitted at the bottom. The barometric pressure is also recorded. The pulse, the respiratory rate as well as the temperature of the subject is noted before and during the test.

As the subject consumes oxygen from the spirometer during the test, the level of the oxygen bell will gradually get lower and lower carrying along with it the writing pen on the kymograph. At the end of eight minutes when the kymograph cylinder has made one complete revolution it is stopped and the mouthpiece and nose-clip are taken off the subject. The height and weight of the subject is taken immediately after the test. The chart attached on to the kymograph cylinder is then removed. A slope line is drawn across the top, showing the average

respiration heights. This line should represent a fair average and should cover the maximum numbers of the respiratory peaks. Readings of the slope line at the beginning and end of eight minutes are taken. The difference is the consumption of the volume of oxygen per minute in cubic centimetres. The volume is then corrected for temperature and pressure and this represents the corrected actual consumption of the subject. The normal oxygen consumption of the subject per minute is then ascertained from tables according to his height and weight, and corrected for age and sex. The basal metabolic rate is then calculated by dividing the amount above or below the normal by the normal and multiplying by 100.

Basal metabolic rate in normal healthy Indians

In finding out a normal standard for healthy normal Indians, the question naturally arose whether they should conform to or materially differ from the standard laid down for the American and the European subjects, owing to climatic and dietetic variations. In order to find this out and to make our own standard for comparison we selected a fairly large and varied group of healthy normal Indian adults—both male and female—living mostly on a mixed diet, and carried out the experiments on them. The results are given in tables I and II, the former comprising the results obtained in healthy Indian males and the latter in healthy Indian females.

An analysis of the above tables (I and II) reveals the fact that the basal metabolic rate in the majority of the cases (about 75 per cent, both in males and females) was either identical with the American standard or varied only within ± 3 per cent; in the rest of the cases the margin of difference was only slightly greater, but in no case was the variation from the standard greater than ± 5 per cent. Thus, for all practical purposes, readings within ± 5 of the standard may be considered as normal.

The results of our experiments (as shown in tables I and II) thus definitely show that the basal metabolic rate of healthy normal Indians, males and females, does not differ materially from that of Europeans and Americans.

It should be stated that the question of whether the basal metabolic rate of Indian subjects differs materially from that of Europeans or Americans has been the subject of controversy for a long time. Mukherjee (1926), experimenting on 15 Bengali medical students, found that the basal metabolic rate was on an average 9 per cent lower than the European standard. Sokhey (1927) found that, in 15 out of 21 subjects examined, the basal metabolic rate was 10 to 23 per cent lower than the Du Bois standards though at the time of communication his experiments were still proceeding. Krishnan and Vareed (1932), working in Madras, found that the basal metabolic rate was 12 per cent lower in men and 16 per cent in women as compared to Du Bois standard. All the above experiments were done by gasometric methods.

TABLE I
Basal metabolic rate of healthy normal-Indian subjects (male) on mixed diet

It is however difficult to believe that such a fundamental thing as basal metabolism should be affected by climate to any great extent any more than the body temperature.

Professor Eijkman (1896) made some experiments with Zuntz respiration apparatus at Batavia in Java and found that the basal heat production in the tropics was the same as in the temperate zone.

Eijkman (1921) in the Dutch Indies also found that there was no difference in the basal metabolic rate between people living in Europe and the native inhabitants there. The number of experiments done by Professor Eijkman are so large that individual differences or idiosyncrasies of the subjects may be ruled out.

Knipping as the result of his observations in Java, Sumatra and other islands of the Dutch East Indies found a decrease of metabolism by 2.5 per cent only as compared to the predilection standard of Benedict. Turner (1926) found no marked difference in basal metabolism depending upon the racial factor.

Hideo Takahira (1925) experimenting on a large group of Chinese and Japanese subjects found no essential difference in the basal metabolism as compared to Europeans and Americans. The findings of Okada, Sakura and Kameda (1926) also agree with those of American standards.

Taking a general review of the whole problem it appears that the observations of the majority of workers who have studied metabolism in the tropics are in agreement with those of the present writers, viz, that there is no essential difference in the basal heat production in people whether living in the tropics or in the cold or temperate zones. Most of the workers are also agreed that the nature of the diet had but little influence on the basal metabolism unless of course it (more particularly the protein content) underwent extreme variations.

The senior author has been making clinical experiments with the various modifications of the Sanborn apparatus off and on for the last 12 years and the results of his experiments clearly show that the basal metabolic rate of healthy normal Indians, living mostly on a mixed diet, does not differ materially from the European and the American standard and this has been taken as a basis for clinical investigation into certain diseased conditions.

Basal metabolism in diseases of the thyroid gland

The determination of the basal metabolic rate is perhaps of the greatest diagnostic value in diseases of the thyroid gland, the severity of which often runs parallel with basal metabolic rate.

The earliest study of metabolism in diseases of the thyroid gland was made in Germany by Friedrich Muller (1893). Magnus-Levy (1895) definitely demonstrated the increased rate of oxygen consumption in hyperthyroid conditions, sometimes going up to 70 per cent above the normal. As a matter of fact he with Du Bois clearly showed that the measurement of the basal metabolic rate in thyroid diseases gives us a very valuable help in gauging the effect of treatment. Boothby and Plummer have used changes in basal metabolism as the chief basis for the classification of the diseases of the thyroid gland. Means and Aub

(1919) made 2,019 metabolic observations on 1,000 cases and came to the following very important conclusions:

- (1) that patients suffering from hyperthyroidism invariably show increased metabolic rate and those with hypothyroidism show decreased metabolic rate;
- (2) that those patients with goitre but no signs and symptoms of abnormal thyroid function show normal basal metabolic rate;
- (3) that, excluding certain well-recognized causes of increased and decreased metabolism, an increase in the basal metabolic rate is strong presumptive evidence of hyperthyroidism and a low metabolic rate is evidence of hypothyroidism.

The increase of the basal metabolic rate in conditions of hyperthyroidism is believed to be due to thyroxin, the active principle of the thyroid secretion. Thyroxin is a remarkably active substance, which is thought to act as a catalyst and to accelerate the potential energy in the tissues and the cells of the organs. According to Lusk a milligramme of thyroxin may cause an increase in heat production equal to the oxidation of 267 grammes of glucose. This, of course, accounts for the rapid rise in the basal metabolic rate following the administration of thyroxin or the thyroid extract. This will be further discussed later on.

Even a casual analysis of tables III and IV will bring out a few outstanding facts:

(1) In table III, which comprises cases of enlarged thyroid without clinical signs and symptoms of hyperthyroidism, the basal metabolic rate in most of the cases was either within normal limits or only slightly above it. In three cases only the results were definitely higher than normal and these were thought to be border-line cases. These cases were asked to report themselves periodically. Only one of them (case 6, table III) has since developed the clinical signs and symptoms of hyperthyroidism of a mild type; the basal metabolic rate done at this stage was found to be moderately high (case 5, table IV).

(2) In table IV the results are very striking. All the cases showed either moderate or marked increase in the basal metabolic rate. In one case (case 10) with marked exophthalmos and other clinical signs and symptoms of marked hyperthyroidism the basal metabolic rate was remarkably high and went up to the figure of +90 per cent.

The estimation of the basal metabolic rate, therefore, enables us to draw a line of distinction between goitre with associated hyperthyroidism and without it, thus giving us a valuable hint as to the line of treatment to be adopted in individual cases.

Basal metabolism in dysfunction of endocrine glands other than the thyroid

The consensus of the present-day opinion is that the thyroid gland plays the principal part in keeping the metabolism within normal limits. The adrenals and the pituitary are also believed to take some part in influencing the basal metabolism in man but the disturbances caused by these glands have not been found to produce uniform and comparable changes in the basal

metabolic rate. Adrenalin has been found to increase the metabolic rate but to a much less extent than thyroxin. The injection of one milligramme of adrenalin in man increases the heat production by about 20 per cent for a short period only; clinical states of hyperadrenalism observed during stages of growth of tumours of the adrenal gland, such as hypernephroma, may be associated with an increase in the basal metabolic rate, but it is difficult to state how much this action is due to the adrenals and how much is due to the associated hyperaction of the thyroid gland due to adrenalin stimulation.

The same is true of the raised metabolic rate obtained in certain cases of pituitary hyperaction as in the early stages of acromegaly.

It is not the object of this paper to go into details as regards the exact interrelationship between the various endocrine glands. It will be enough to say that there is a close interrelationship between the action of the thyroid gland and those of the adrenals, pituitary and the gonads. Removal of the thyroid gland has been found to cause an associated marked depression of the adrenal activity (Bose, 1930). Similar changes also take place in the pituitary and the gonads. The close relationship between the thyroid and the sex glands are also proved by the fact that the thyroid becomes more active and sometimes enlarged during puberty, during menstruation and during pregnancy, and in thyroidectomized animals the sex glands fail to develop.

The literature concerning the effect of the hyperaction or underaction of the adrenals and the pituitary in causing a raised or lowered basal metabolic rate is contradictory and confusing. Most observers seem to think that the apparent influence of these glands on the basal metabolic rate, as observed in certain groups

of cases, is brought about through the medium of the thyroid, which is believed to be the principal factor in controlling metabolism. Owing to the close inter-relationship between these endocrine glands, any disturbance of either the adrenals or the pituitary is reflected on to the thyroid. The somewhat high basal metabolic rate sometimes obtained in the early states of acromegaly and in certain clinical states of hyperadrenia is explained by an associated increase in the thyroid activity brought about by the stimulation of the thyroid by the hyperaction of these glands. The lowered rate of metabolism observed in certain cases of hypopituitarism (such as Fröhlich's syndrome or dystrophia adiposo genitalis), or of hypoadrenia (such as Addison's disease) is thought to be due to the same cause, *e.g.*, associated depression of the thyroid function.

Aub and McKinlay believe that the influence of the diseases of the pituitary gland on the basal metabolism is always brought about through the medium of the thyroid gland. Du Bois's view that there is no uniformity of the basal metabolic rate in the diseases of the pituitary gland is also based on the same theory.

In view of the above statements it seems reasonable for us to assume that diseases which uniformly cause a high basal metabolic rate

may be taken to indicate clinically a condition due to the hyperaction of the thyroid gland, and similarly those which persistently cause a low basal metabolic rate would indicate a condition due to underaction of the thyroid gland. The oral administration of thyroid preparation or thyroxin to the latter group of cases, causing a rise in the basal metabolic rate with the simultaneous improvement in the clinical condition, would certainly be taken as additional evidence in favour of hypothyroidism being the cause of the clinical condition. This is clearly shown in table VI. The markedly low basal metabolic rate in the three cases of ichthyosis hystrix and the fairly rapid rise of the rate after administration of thyroid preparations, with the complete and rapid disappearance of the skin condition, is strongly in favour of the theory that hypothyroidism plays the most important part in the ætiology of this group of skin diseases (*see* tables V and Va). All the cases of ichthyosis and scleroderma were treated on similar lines with excellent results, but the

		35	62	213	297	238		

reason why only three cases have been included in table VI is because the results in those cases have been most striking. The determination of the basal metabolic rate in diseases of the skin, more particularly in ichthyosis and scleroderma, and the administration of thyroid in suitable doses (having regard to the basal metabolic rate) has become a standard and scientific method of treatment at the present day. This

is also corroborated by the studies of Krogh and With in 1923 on the influence of ichthyosis on basal metabolism; also of Hinser and Sehmed in 1904.

It should be mentioned here that some cases of scleroderma, particularly those of tylosis, do not improve permanently and a complete recovery is seldom possible. The reason for this is that the lesion being of long standing had

TABLE VII
Basal metabolic rate in cases of psoriasis

Serial number	Sex	Age	Height in inches	Weight in pounds	CONSUMPTION OF OXYGEN IN C.C.M. PER MINUTE		Basal metabolic rate

already led to the formation of scar tissues in the deeper portions of the skin and caused permanent damage. If these cases had been tackled earlier, the results would probably have been different.

Diseases of the skin giving either normal or varying basal metabolic rates

The above tables comprise a varied group of skin conditions—including psoriasis, pityriasis rubra and leucoderma. In most of these cases the basal metabolic rate is more or less within normal limits except a few which give borderline figures. It seems reasonable to conclude that endocrine imbalance does not play any important part in the ætiology of the above conditions. As a matter of fact, the consensus of the present-day opinion on the ætiology of these groups of cases is that the endocrine imbalance is more apparent than real—the principal cause being either a septic focus or an allergic condition due to a faulty metabolism.

Metabolism in diabetes

The consensus of opinion among the various workers on the subject appears to be that in mild cases of diabetes the metabolic rate varies but little from the normal, but in severe cases it sometimes shows great variations. This appears to be mainly due to either severe dietetic restrictions or to acidosis. Hedon (1927) has noted that the metabolic rate is markedly increased in severe diabetes with acidosis, the chief causes, according to him, being the diet which is extremely poor in carbohydrates but liberal in protein and fat.

Joslin has recently very carefully compared the data of metabolism in diabetes in the two principal eras of diabetic treatment, namely the period before 1914, which is known as the Naunyn era of treatment in which the patient used to be overfed, being put on a low carbohydrate and high protein-fat diet, and after 1914, which is known as the Allen era of treatment in which the patient used to be severely underfed. By analysis of figures in these two periods of treatment, Joslin has come to the conclusion that the average variations in result in these two periods is about the same, i.e.,

whereas the average result in the former period (Naunyn era) was +12 per cent, the same in the latter period (Allen era) was -11 per cent. Thus the comparative constant deviation from the normal zone (which appears to be entirely due to dietetic factors) led him to the conclusion that the metabolism in diabetes, even of a severe type, varies but little from the normal.

As early as 1905, Magnus-Levy was the first investigator to assume that metabolism was increased in diabetes. This assumption was supported by other workers including Benedict and Joslin (1912). Allen and Du Bois (1916) however very carefully tabulated their results and compared them with those of Magnus-Levy, Mohr and Benedict and concluded that the increase of the basal metabolism above the true normal result was generally absent or slight in diabetes.

In 1917 Fatta, who did a large amount of experimental work in metabolism in diabetes, took the view that the apparent increase in the metabolism in diabetes, as found by some of the other workers, could be ascribed to the rich protein-fat and high caloric diet and had probably very little to do with the disease itself. His own opinion was that the increased metabolism was not the rule in diabetes but an exception, and was only found in cases where severe acidosis and a low respiratory quotient exists; on the other hand, marked decrease in metabolism was found only in those cases where there was severe under-nutrition and thus it could be ascribed to the chronic reduction of the food intake and the consequent reduction of oxidation that naturally follows. Wilder, Boothby and Beeler (*Jour. Biol. Chem.*, 1922, 51, 311) after having carefully studied the basal metabolic rate in 31 cases of diabetes and having reviewed the available observations of the other workers could find but few deviations of the basal metabolic rate in uncomplicated diabetes from the normal Du Bois standards.

In the following table, the results of basal metabolism test on 25 cases of Indian diabetes of various grades of severity are given. All the patients were on a balanced diet and all except one (case 24) were free from acidosis; this case however was suffering from a mild grade of acidosis.

It will be evident from the table that the basal metabolic rate in the majority of the cases was within normal limits (± 5 per cent); only in one case (case 24) is slight increase in the rate noticed and this patient, as has already been said, was suffering from slight acidosis.

TABLE X
Basal metabolic rate in cases of diabetes

Serial number	Sex	Age	Height in inches	Weight in pounds	CONSUMPTION OF OXYGEN IN C.C.M. PER MINUTE		Basal metabolic rate
					Actual	Normal

14	"	51	66	130	189	210	— 6
15	"	51	67	148	228	231	— 2
16	"	52	69	120	207	216	— 5
17	"	54	71	145	252	239	+ 5
18	"	56	65	130	205	210	— 3
19	"	59	68	138	213	222	— 4
20	"	60	68	145	223	229	— 3
21	"	68	65	135	196	208	— 7
22	Female	30	62	122	187	195	— 5
23	"	35	63	267	260	270	— 4
24	"	40	70	101	224	200	+ 12
25	"	45	58	116	170	178	— 5

In view of our observations and those of others, it seems quite reasonable for us to conclude that the basal metabolic rate in conditions of diabetes is within normal limits. Any changes in the metabolic rate, either on the high or low side, can be attributed to the nature of the diet, nutrition, and the complications of the case, and has very little to do with the diabetic condition itself.

Summary and conclusions

It must be admitted that even perfectly healthy individuals are so unlike one another that it is impossible to conceive of a fixed normal point as a standard of metabolism. The normal standard, therefore, should be considered to be in a zone with a certain latitude rather than at one fixed point. How wide this zone should be and whether it would vary with the race and the climate has been a matter of much difference of opinion.

The authors have determined the basal metabolic rate in normal and diseased conditions in Indian subjects extending over the last few years and have come to the following main conclusions :—

(1) The basal metabolic rate of healthy normal Indians, males and females, living on a mixed diet does not essentially differ from that of the European and American standards;

(2) A basal metabolic rate within ± 5 per cent of the normal standard should be considered as normal;

(3) The estimation of basal metabolic rate enables us to draw a line of distinction between two types of goitre, namely those with associated hyperthyroidism and those without it, thus giving us valuable help as to the line of treatment to be adopted in individual cases;

(4) The estimation of basal metabolic rate is specially valuable in certain groups of skin diseases more particularly ichthyosis and scleroderma; the results of the authors' experiments clearly showing that hypothyroidism plays a very important part in the aetiology of this group of cases and that administration of thyroid in suitable doses (as determined by the basal metabolic rate) is effective in raising the basal metabolic rate with the simultaneous marked improvement in the clinical condition;

(5) In certain other skin diseases, such as psoriasis, pityriasis rubra, and leucoderma, the basal metabolic rate is within normal limits; and

(6) In diabetes mellitus the basal metabolic rate is within normal limits, the variations in the metabolic rate as sometimes noted being due to the state of the nutrition of the patient and the complications of the disease and having very little to do with the diabetic condition itself.

FURTHER OBSERVATIONS ON THE TREATMENT OF ORIENTAL SORE*

By J. D. WARMA, M.B.B.S.

King Edward Medical College, Lahore

THREE years ago I published a paper (Warma, 1931) in the *Indian Medical Gazette* on the treatment of oriental sore. In the same number the editor summarized the position regarding the treatment of this condition and indicated certain aspects of the subject that would repay investigation.

A further study of the subject was undertaken with a view to elucidating the various points raised in this editorial.

Treatment with berberine sulphate

Solutions of the salt were made with boiled distilled water in two strengths, namely one per cent and two per cent. It was found on experience that the solutions could be stocked in dark stoppered bottles for at least a week without being spoilt in any way. The solutions were, however, boiled in a spoon over a flame each time before use.

The comparative value of the one and two per cent solutions was tested by giving injections into similar types of sore occurring in different individuals. A series of 100 sores occurring in 78 patients was recorded for the purpose, 50 sores getting treatment with each of the two strengths of the solution. Scrapings from the sores were first examined for the presence of leishmania, and, for the purpose of these investigations, treatment was given only in those cases in which the diagnosis was positive.

* Being a résumé (prepared by the editor) of a paper read at a meeting of the British Medical Association, Punjab Branch, on 3rd January, 1934, at Lahore.

Sores of types* I, II and III were given the injections straight away, while sores of type IV were first treated with antiseptic dressings till they became free from sepsis, and, as their condition after this resembled that of the sores of type III, they were classed with the latter. During the course of the treatment by this method, the sores were not treated with any ointment or other local applications, but a hot boric compress was invariably prescribed, to be continued during the intervals between the injections. The injections were given at intervals of a week.

The method of injection has been described previously. Three or more pricks were made each time into the skin with a fine needle fixed on to an all-glass syringe.

The following two tables summarize the results obtained by treating 50 sores each with the one and two per cent solutions of berberine sulphate, respectively:—

TABLE I

Fifty sores treated by berberine sulphate—one per cent solution; grouped according to type and number of injections required

Type of sore	Number of injections needed to effect a cure							
	1	2	3	4	5	6	7	8
I	2	5	2	1
II	5	5	8	1	1	..
III	4	9	6	1

TABLE II

Fifty sores treated by berberine sulphate—two per cent solution; grouped according to type and number of injections required

Type of sore	Number of injections needed to effect a cure							
	1	2	3	4	5	6	7	8
I	2	6	1	1
II	..	2	8	5	3	2
III	3	5	9	2	1

*Type I.—Consisting of a small red nodule covered with a reddish-brown scale.

Type II.—A localized raised area of inflamed tissues covered with a crust, whose surface is cracked or fissured in places, with a serous discharge exuding from it, and the whole mass surrounded by a ring of induration. There is no actual ulceration of the surface of the sore.

Type III.—A raised ulcerating localized area surrounded by a hard indurated red periphery, having a non-purulent serous discharge.

Type IV.—A raised septic ulcer discharging pus, or covered with slough, surrounded by a hard brown indurated periphery.

The results stated above and the observations made during the treatment established the following points:—

There was no difference in time taken by sores of type I to heal, whether treated with a one per cent or a two per cent solution. Ten sores of this type were treated with each solution. The maximum number of injections required in each case was four and the minimum one; and the largest number of sores healed after the second injection in both cases.

In the treatment of sores of type I, therefore, it is quite sufficient to use a solution of one per cent strength.

It was noticed that, with regard to the amount of inflammation and the severity of pain caused by the two solutions in this type of sore, there was slightly greater inflammation caused locally by the two per cent solution than by the one per cent solution, but there was no difference in the severity of the pain felt by the patients as a result of injections with either of the solutions. In fact they did not complain of much pain beyond that attributable to the pricks of the needle.

The sores of type II responded slightly differently to treatment with the two solutions. Twenty sores of this type were treated with each solution. It was found that the two per cent solution gave a better result, especially in such cases where there was an overgrowth of the tissues of the sore due to its very long duration.

With regard to pain and inflammation in this type of sores, it was observed that there was no difference in the result of injections with the two solutions. The patients in this case also did not complain of pain resulting from the injections with either of the solutions.

Sores of type III also behaved differently towards treatment with the two solutions. Twenty sores of this type were treated with each solution. It was noticed that the two per cent solution gave rise to a good deal of inflammation and pain after injection, while the one per cent solution was tolerated easily. The healing was quicker with the one per cent solution than with the two per cent.

The relation between the healing of the sores and the disappearance of the specific infection locally was also investigated in the above cases, while the treatment was in progress. For this purpose, the scrapings and the exudates from the sores were re-examined each week before giving fresh injections. It was found that the healing of the sores was always delayed beyond the period at which organisms disappeared from the local site. The minimum delay that occurred was in sores of type I; and was from a week to 18 days. The maximum delay occurred in sores of type III and ranged between a fortnight to 26 days.

Reference has already been made to the pain caused by injections with berberine sulphate solutions. Injections with one per cent solution

did not produce pain in any case. Injections with two per cent solution produced pain only in cases having sores of type III, and no pain in any other case. As it is no longer considered advisable to treat sores of type III with a two per cent solution, the problem of pain in this form of treatment does not need any serious consideration. The application of a local anaesthetic prior to the injections with berberine sulphate solution is not, therefore, indicated.

Toleration and dosage

The question of the total quantity of berberine sulphate that it would be safe to administer at one time to an adult male was investigated. Tests were carried out by giving injections with gradually increasing quantities of a one per cent solution of berberine sulphate to adult male patients suffering from multiple sores. To begin with a total of 2 c.cm. of a one per cent solution equivalent to a third of a grain of the salt was injected by infiltrating two or more sores at one time. The effect of this on the patient was observed by keeping him under observation for 24 to 48 hours, and, if no ill effects were complained of by the patient, the quantity was increased by 0.5 c.cm. This procedure was repeated each week until definite feelings out of the normal were complained of by the patient. These tests were applied on 10 patients. It was found that 2 of these patients complained of feelings of dullness and heaviness in the head and a general disinclination to work with dryness of the mouth on the day of receiving the injection of 4 c.cm. of the one per cent solution (equivalent to two-thirds of a grain of the salt) which lasted for less than 24 hours. Another 5 patients complained of similar feelings when they received an injection of 4.5 c.cm. of the one per cent solution (equivalent to three-quarters of a grain of the salt). The remaining 3 patients complained of severer symptoms in the way of severe headache, vomiting, dryness of mouth, etc., lasting for a day and a half, on having received a dose of 5 c.cm. of the one per cent solution (equivalent to five-sixths of a grain of the salt), although they had not complained of any trouble on receiving the previous dose of 4.5 c.cm. of the one per cent solution. The total quantity of 4 c.cm. of a one per cent solution of berberine sulphate (equivalent to two-thirds of a grain of the salt) seems, therefore, the safe limit which an otherwise healthy male adult will stand without feeling any toxic effects.

Treatment with preparations of antimony

Those who have to treat cases of oriental sore realize that there are quite a number of cases in which it is not possible to use berberine sulphate. These are, firstly, cases with sores on the eyelids, nose, lips, forehead, etc., where injections cannot be given, and, secondly, cases

with multiple sores, where, apart from the objection of the number of pricks necessary for complete infiltration of all the sores, there is the danger of administering a toxic quantity of the drug.

In view of these difficulties, other methods of treatment have to be employed. For cases of sores on the face, one has no choice at present except to use carbon dioxide snow applications; and yet one knows that extensive scarring with consequent disfigurement results from it. For cases of multiple sores, treatment by intravenous or intramuscular injections of some drug suggests itself; and the choice lies in using tartar emetic or one of the other organic preparations of antimony, of which there are many available.

Some time ago, I received a large supply of a new antimony preparation, for trial purposes. The preparation is named *Espundal*, it is a trivalent aromatic compound and is manufactured by Messrs. Schering of Berlin. It is a white powdery substance packed in hermetically-sealed glass ampoules in doses of 0.2 gramme and 0.5 gramme. The firm also supplies sealed ampoules of sterilized physiological salt solution in quantities of 10 c.cm. each, for the purpose of making solutions of *Espundal*. The solution of the preparation was to be administered by intramuscular injection.

The manufacturers' note, forwarding the parcel of the drug, stated that it had been tried on animals in laboratory tests, and also on a few cases of oriental sore in men met with in some places on the Continent. The reports received from these places had been encouraging. The superiority of the preparation over others of the same kind was stated to consist in:—

(a) The easier method of its administration as it was to be given by intramuscular injection, while most of the others had to be given intravenously.

(b) The administration being absolutely painless.

However, the administration was always found to be very painful, so much so that it was with great difficulty that the patients could be induced to continue the treatment. The remedy could be tried only on ten cases. Four cases were given six injections each at weekly intervals receiving three doses of 0.5 gramme each and three of 0.2 gramme each. Of the remaining six patients, one received four, three two, and two only one injection. In none, however, was the result satisfactory, as the sores did not seem to be affected in any way.

Tartar emetic

I tried 15 cases with tartar emetic solution; they had a total of 50 sores on them. All the cases were adults, 12 being males and 3 females.

The treatment consisted in giving intravenous injections of a two per cent solution in sterilized distilled water, at the bend of the elbow. The interval between each injection was 3 days and the successive doses used were 1 c.cm., 2 c.cm., 2.5 c.cm. and 3 c.cm.

Subsequently 3 c.cm. was given at each injection, up to a total of 12 injections. Before starting the injections it was ascertained that the patient was not passing any albumin in his urine. During the course of the injections, if the patient complains of any ill effects, such as diarrhoea, or skin irritation, the treatment should be stopped for a week or more, till symptoms subside, and restarted with smaller doses given at longer intervals. No such accident occurred, however, in my series. The result of the treatment is given in the table below:—

Cured after 3 injections	1
" " 4 "	1
" " 6 "	2
" " 8 "	2
" " 12 "	4
Left uncured after 12 injections	5
TOTAL			15

Out of the 15 cases treated by this method only 10 were cured in 6 weeks after getting 12 injections. This is not a very satisfactory result.

The generalized nature of the reaction produced in the body of oriental sore

It has already been noted that sores treated with berberine sulphate do not heal for at least two to three weeks after the specific infection has disappeared from the local site. On referring to the symptomatology of the disease one learns that, although general constitutional symptoms are not evident in an ordinary case of oriental sore infected in the natural manner, they are always present, in the form of fever, etc., when the sore is produced experimentally—as noted by Wenyon and others; they have also been complained of by patients suffering from multiple sores. It is more than probable that in ordinary cases of oriental sore also there is some general reaction in the body, and the fact that there are no constitutional symptoms, e.g., fever, only means that the general reaction is not severe enough to produce them. Serological tests, such as the complement-fixation test and the agglutination test, used in bacterial infections have been applied in oriental sore, and definite changes have been observed to take place in the serum. It may be asked how these changes are brought about in view of the

fact that oriental sore is localized and that the causal organism does not circulate in the blood. It seems probable that the causal organism, in addition to the destruction of the tissue cells locally at the site of the sore, produces a specific toxin, which in all cases circulates in the blood, and gives rise to a general reaction. Work on the subject has been scanty and is found scattered in various journals, but it has been surveyed by Taliaferro in his book *Immunology of Parasitic Infections*. The fact that a primary infection in oriental sore confers an immunity to a second sore was known to man long before even the discovery of the protozoal nature of the disease. For instance, we read in the history of the disease that the fair damsels of Bagdad and Mosul have long utilized this knowledge by voluntarily getting themselves injected with the material obtained from the sore on some other person, in order to produce the disease on a covered part of their own body, so that they may escape from getting a sore on the face or other exposed parts.

Recent investigations, however, have shown that immunity does not result from the attack of an 'abortive sore', that is to say, a sore which does not run the normal course. Therefore, attempts to produce immunity with vaccine prepared from *Leishmania tropica* have not been successful.

Professor Row of Bombay was the first to suggest (1912) that, as a result of some tests made by him, he believed that a vaccine prepared from *L. tropica* was helpful in hastening the cure of oriental sore although it did not prevent infection.

Attempts have been made by various workers to use serological tests in aid of diagnosis as well as for differentiation of various members of the genus *Leishmania*. The most noteworthy statement came from Noguchi who in 1924 published a paper, in which he stated that the anti-serum of *L. tropica*, recovered from the actively-immunized rabbit, caused a clear-cut agglutination in a dilution of 1 in 80 and in one case in a dilution of 1 in 200 with *L. tropica* only, and did not at all affect the other leishmania species. Later, in 1926, he confirmed this both by using agglutination and complement-fixation tests. He was perhaps the next (after Row) to suggest that, if a suitable culture medium were devised to obtain the growth of *L. tropica* in pure culture and in sufficient quantity, it would be possible to prepare a vaccine for the treatment of oriental sore.

Recently Dr. J. C. Ray has done a good deal of work on the subject—first in Germany and England, later in India. He published a paper in 1929 in the *Archiv für Schiffs- und Tropen-Hygiene*, in which he stated that he had been able to obtain an agglutinating titre to the extent of a dilution of 1 in 2,500—a result

hitherto possible only in the case of bacterial agglutination. It seems to have been definitely established now from the work of Hindle, Hou, and Patton, and of Ray that complement-fixation tests can reliably be used for diagnostic purposes.

Mayer and Ray (1928), and Ray (1932) have been successful in devising a very satisfactory solid medium for the growth of leishmania.

Ray further claims that, by preparing antigens of a suitable dilution from cultures of *L. tropica*, he has been able to devise a specific intracutaneous test for the diagnosis of oriental sore. This test, he says, is also interesting from the point of view of the treatment of the disease with vaccine, for if the reaction is strong it is an indication that the case will be cured rapidly by vaccine treatment. The test consists of taking the requisite antigen and instilling a drop or two of it into the skin in the form of a wheal and noting the reaction after twenty-four and forty-eight hours. If a red raised infiltrated area is formed at the site of inoculation, the reaction is positive.

Treatment with Row's vaccine

Professor Row of Bombay very kindly sent me some vaccine prepared by himself for the treatment of oriental sore. The following procedure was adopted. The sores were first examined for leishmania and treatment was given only to positive cases. 0.5 c.cm. of the vaccine was taken in a sterile hypodermic syringe, and diluted with an equal quantity of sterile normal saline, and injection made into the subcutaneous tissues of the arm of the patient. The case was seen after 24 and 48 hours for evidence of any reaction—general or local—this if present was treated symptomatically on ordinary lines. The injections were repeated twice weekly, ordinarily, but if there had been a severe reaction as a result of any injection the next dose was given after a week. The second and subsequent doses consisted of 1 c.cm. diluted with the same quantity of normal saline.

Results.—Of the cases treated by this method there were some who did not keep up the treatment after one or two injections in each case. There were 25 cases, however, who completed the treatment and in whom the vaccine can be said to have received a full trial. Nine patients (5 cases of multiple sores and 4 cases of single sores) were completely cured without getting any other form of treatment—general or local, except a simple surgical dressing to keep the sores covered. Thirteen patients showed a definite improvement in the beginning, but no further change was noticed after the third or fourth dose of the vaccine. Three did not evince any improvement at all.

Treatment with Ray's vaccine

Meanwhile Dr. Ray obtained permission to test his vaccine in the Mayo Hospital, Lahore, and he collaborated with me in this part of my investigation.

The sores of all cases were first examined for the presence of leishmania, and only the positive cases were given the vaccine treatment. 0.5 c.cm. of the vaccine (undiluted) is injected into the subcutaneous tissues of the arm. The patient is seen again after 24 and 48 hours for evidence of any reaction—general and local. The reaction when it occurs is both general and local, and is evident in 24 to 36 hours after the injection of the vaccine. It consists in a rise of temperature not exceeding 100°F., and headache; and there is swelling and redness at the site of the injection and hyperæmia of the sores wherever situated. In the absence of a severe reaction, the injections are repeated with double the dose, at intervals of four to seven days, till the sores heal up. Healing of the sores proceeds from without inwards, and they gradually diminish in area. Dry scales finally drop off and the cure is complete. During the period the treatment with vaccine is being given, the sores are not treated with any other local remedy, but are covered with a simple surgical dressing.

Results.—So far, 35 cases have completed their treatment with the vaccine. Twenty-five cases were cured without getting any other treatment and the largest number of injections given in any one case to achieve this end was seven, and the least number of injections given was two. Six more cases showed definite improvement for the first three injections given to them, but did not show any change with the next three injections. Four cases did not show any change, or showed only slight improvement with the first three injections each.

The following conclusions were arrived at regarding this form of treatment:—

Oriental sore vaccine is of considerable value in the treatment of sores of all types.

In most of the cases with type IV sores, or with multiple sores, where treatment by berberine sulphate is not possible and the results of treatment with antimony have not been satisfactory, the treatment with the vaccine is of the greatest value.

In cases with sores on the eyelids, nose, lips, forehead, etc., in which it is not possible to give injections and in which carbon dioxide snow applications result in extensive scar formation, treatment with vaccine has proved a great success.

Even in those cases where treatment with vaccine does not produce any change or only slight improvement, it is advisable to combine it with the other method of treatment used.

Such a combination serves to hasten cure by stimulating the general protective mechanism of the body against protozoal infection, and prevents the delay that occurs in the healing of the sores after the specific infection has disappeared from the local site.

The vaccine is not available for general use as yet. If, as a result of trials to which it is being submitted, its efficiency is established, it is hoped that the manufacture of the vaccine will be taken up in India.

Summary

1. Oriental sore is no longer looked upon as a local disease requiring treatment of the affected site only. A generalized reaction seems also to be present in the body at the same time. As a consequence of this assumption a vaccine has been prepared from *L. tropica* and tried in the treatment of the disease. The results obtained so far from these trials have been very encouraging.

2. Berberine sulphate treatment should never be given to cases where acute inflammation or sepsis is present in sores. Therefore, the most suitable cases for this mode of treatment are those where sores of types I and II are present. Even in cases of this kind berberine sulphate treatment should be combined with the administration of the vaccine. As a general rule a one per cent solution should be used, but the sores should be infiltrated completely. However in cases with sores of type II, where an overgrowth of fibrous tissue is present in the sores, a two per cent solution is recommended for the injections.

3. The maximum quantity of berberine sulphate which can be infiltrated safely in cases of multiple sores occurring in otherwise healthy adults is 4 c.cm. of a one per cent solution equivalent to two-thirds of a grain of the salt.

4. There does not appear to be any need for previous application of a local anæsthetic prior to giving the infiltration with berberine.

5. With regard to treatment by antimony, results obtained by intravenous injections with tartar emetic solution have been more successful than with the other organic preparations of antimony tried so far.

CLINICAL OBSERVATIONS ON 636 CASES OF CEREBRO-SPINAL FEVER TREATED IN THE CAMPBELL HOSPITAL, CALCUTTA, FROM MARCH 1933 TO MARCH 1934

By N. C. KAPUR, B.A., M.R.C.S. (Eng.), L.R.C.P. (Lond.)

LIEUTENANT-COLONEL, I.M.S.

Superintendent, Campbell Medical School and Hospital

A. N. SEN, M.B.

Physician in Charge, Infectious Diseases Ward,
Campbell Hospital

and

B. C. CHATTERJEE, M.B., D.P.H., D.T.M.

Honorary Medical Officer, Infectious Diseases Ward,
Campbell Hospital

DURING the period from 1st March, 1933, to 1st April, 1934, 636 cases of cerebro-spinal fever were admitted and treated in the Campbell Hospital. Information on various points in connection with this disease was collected and is

The largest number of cases occurred during January, February and March. February was the worst month, showing an admission of 94 cases. The average monthly incidence for January, February and March was 76, against 36 for the other months; that is to say, the cold weather was the optimum time of the year for incidence (table A and graph 1).

(b) Sex (table A).—Of the 636 cases, 589 were males and 47 females, i.e., 92.5 per cent and 7.5 per cent, respectively. The overwhelming preponderance of incidence amongst males may to a certain extent be due to the following factors:

- (i) Greater reluctance on the part of female patients to come to hospital.
- (ii) Females lead a more secluded life than males.

However, we are of opinion that in Calcutta the disease affects males to a much greater extent than females.

GRAPH 1
CEREBRO-SPINAL FEVER
Seasonal incidence and deaths

shown in the tables and graphs appended herewith.

Epidemiology

(a) Season.—The disease was prevalent in Calcutta throughout the period under report.

(c) Age (table B and graph 2).—The graph shows the high incidence of the disease between the ages of 15 and 35. Children were far less affected than adults or even old people. The disease was conspicuously rare under four and above 55. 69.5 per cent of the cases that

GRAPH 2

CEREBRO-SPINAL FEVER
Incidence and deaths in the different age-groups

occurred were between the ages of 15 and 35—an age-period when people lead strenuous active social lives and are exposed to a much greater extent to infection.

(d) *Race* (table A).—Out of 636 there were 494 (77.67 per cent) Hindus, 133 (20.91 per cent) Mohammedans, and 9 (1.41 per cent) other castes (Anglo-Indians, Jews and Chinese). This incidence is more or less proportionate to the racial population of Calcutta. We are not able to find any marked susceptibility to the disease in any community.

(e) *Environment and spread of disease*.—The majority of cases came from busties in Calcutta where poverty, overcrowding and insanitary conditions prevail. No special locality was effected. Cases came from all parts of the city. It was seldom found to affect more than one member, either of a family or of an institution.

The disease does not appear to us to be very contagious, as not a single case occurred amongst the hospital staff (medical officers, nurses, students and menials) who attended these cases. Only one case occurred in a junior compounder student of this school, but the infection could not be traced to a patient, as the student had no duties in the wards.

It is not possible for us to give any opinion as regards the rôle of carriers in this disease, but as far as our cases are concerned there does not appear to be much evidence indicating this means of spread. No attendant or convalescent patient was found to be in any way connected with patients admitted into this institution. About 300 doctors, nurses and students worked in this ward during the period under report and there is no evidence to show that any one of them acted as a casual or a chronic carrier.

TABLE B
Age incidence and mortality

TOTAL ..	636	..	424	..	168	44	66.67

We are inclined to believe that the incidence of this disease is more a question of individual susceptibility than anything else, i.e., there are certain individuals in the community who are specially susceptible to the infection and whenever favourable circumstances prevail they get attacked with the disease. Of these favourable circumstances an inflammation of the nasopharynx plays an important rôle.

Symptomatology

Table C shows the incidence of the clinical types and their frequency. The hyperacute mode of onset was found the most common; it occurred in 362, i.e., 56.92 per cent of our cases.

Table D shows the comparative frequency of the various signs and symptoms. The more important symptoms, enumerated in the order of their frequency, were frontal headache, congestion of eyes, rigidity of neck, dilated pupils,

vomiting, coma, initial rigor, muscular tenderness, joint pains, and taches cérébrales.

Of the signs the following were the most commonly noticed:—Kernig's sign (88.84 per cent), Brudzinski's sign (76.25 per cent), lost knee jerks (34.11 per cent) and increased knee jerks (25.45 per cent).

A marked polymorphonuclear leucocytosis was noticed throughout. The average number of leucocytes was 25,150 per c.cm. The average number of polymorphonuclears was 80.9 per cent.

The cerebro-spinal fluid was under high tension in every case in which lumbar puncture was done; in 66 cases it was not done. Five hundred and twenty-one cases showed turbidity and polymorphonuclears were the predominant cells. Five hundred and seventy specimens of cerebro-spinal fluid were examined for the

TREATMENT OF TUBERCULOUS CARIES OF THE SPINE

By T. SESHACHALAM, L.M.S. (Mad.), M.R.C.S. (Eng.),
L.R.C.P. (Lond.)

*Resident Medical Officer, Krishnarajendra Hospital,
Mysore, South India*

TUBERCULOUS caries of the spine is a serious disease and unless diagnosed early and appropriately treated, serious deformities and disabilities will result making the patient's life miserable. The complications of the disease, such as deformity, abscess formation (with secondary infection and sinus formation), and paraplegia, with the resultant further complications of bladder and rectal trouble, are a grave menace to the patient. Cases taken in hand early and appropriately treated offer very satisfactory prospects of cure. The diagnosis of this condition is easy with the modern methods at our disposal.

The spine is made up of a series of small joints which are under the constant and uncontrollable mechanical influence of various muscles attached to the spine. These joints are constantly moving during respiration. The osteogenetic power of the vertebral bones is low when compared with the long bones of the body.

Tuberculous caries of the spine is only a local manifestation of a generalized infection. General treatment, such as open air, improved hygiene, proper feeding and sunlight, is indispensable. The first essential in the local treatment is to obtain absolute rest to the diseased vertebræ and, while this is being maintained, to

(Continued from previous page)

plunger piston head, which can be made to fit as tightly as required by a device at the end of the handle part of the piston, can draw up any solution easily. By this arrangement it is impossible to get any backward leak during the act of injecting the solution, as occurs with most ordinary syringes.

All the twelve cases have been completely cured and there has been no recurrence in any of them up to date. The glands took from three to eight months to clear up. Some of them have been cured for over eighteen months. Although only accessible glands were injected, the affected deep cervical glands which were present in some of the cases have also cleared up. I cannot definitely account for this, and can only presume that this was effected by the drainage of the solution through them. Some of the patients treated were 'positive-sputum' cases, and two of these are still under my care. The lung condition in the cases referred to above has also become 'arrested' under treatment, and the patients are making good progress. It has to be understood that this method of injecting the glands has to be combined with general treatment laid down for pulmonary cases, as most of these had their lungs affected.

improve the patient's general condition by various adjuvant methods. Three conditions are called for—

- (a) recumbency in the dorsal position,
- (b) absolute immobilization of the spine, and
- (c) prevention or correction of the deformity by hyperextension of the spine.

When correction has been obtained the spine has to be immobilized in this position till such time as consolidation by recalcification has been obtained.

The spasm of the back muscles and the muscles of the anterior abdominal wall do not permit of immediate assumption of dorsal recumbency for a long period. This is all the more difficult in cases with complications like a pronounced 'gibbus', a large psoas abscess, or paraplegia. If dorsal recumbency is assumed for a few hours a day and the period is gradually increased daily it is easy to get a willing patient to lie in that position for twenty-four hours. In children and particularly refractory cases and in caries of the cervical vertebræ, the head is fixed by a box splint, or occipital and chin bands. When there is paraplegia both the lower extremities are immobilized by applying weight extension. Once the patient has become accustomed to assume dorsal recumbency, correction of deformity is started. Various contrivances are in use:—(1) Whitman's gas pipe frame is useful in children; (2) treatment by a plaster shell is useful, but is not tolerated by patients and has often been a failure among patients in the tropics; (3) Thomas' splint is cumbersome; (4) Berk's spinal board has given good results.

Sir H. Gauvain has said:—'The simpler the appliances employed the greater the comfort ensured for the patient, and the fewer the complications in the apparatus the better the results will be'.

Having tried the various methods described above I have come to the conclusion that hyperextension in dorsal recumbency can very efficiently be obtained by the introduction of a

Figure 1a.

PLATE XV

Figure 2

Figure 3

Figure 4

wedge in the fracture board (figure 1a). The apparatus is simple, costs next to nothing, and is made of a wooden wedge fixed to one of the fracture boards, so adjusted that the 'gibbus' of the spine rests on the wedge while the patient is lying in dorsal recumbency. When so adjusted the gibbus is supported by the wedge and

Figure 1b.

Figure 1c.

the trunk above and below the wedge rests on the bed and hyperextension of the spine is thus obtained (figure 1c). The height of the wedge is gradually increased until the maximum is reached. This position is maintained for a period of six months or more, under proper hygienic conditions and the attention of the trained nursing staff. This method of hyperextension in dorsal recumbency has given me excellent results and I believe in time should replace all complicated apparatus and particularly the irksome plaster-of-Paris casts.

Lateral radiograms are taken every two months or more frequently to check the progress of the improvement. The deformed spine, with the primary and secondary compensatory curves, straightens itself and maintains the

anterior longitudinal axis. The destroyed, deformed and crushed body of the vertebra (or vertebrae) is corrected. Recalcification and consolidation appear. In the later stages a wedge-shaped, crushed vertebra alters its shape, increases in size and appears like a modified normal vertebra (plate XV, figures 2, 3 and 4).

A maximum period of twelve months and a minimum of nine months is spent in dorsal recumbency on the wedge. Depending upon the progress of the case the wedge is lowered by stages and finally dorsal recumbency on a flat hard bed is maintained for a period of a month or two, when turning over to the side is permitted. Later, the patient is allowed a bed rest for a few hours a day until he is able to sit up. Then he is allowed to leave the bed on a wheeled chair. Walking with a pair of crutches is then resorted to.

Treatment of complications.—Rigidity of the back and abdominal muscles is overcome gradually by position and hyperextension. In the correction of deformity it must always be kept in mind that we are dealing with a tuberculous patient. Hurried and forcible correction of the deformity is unwise and will end in disaster. Paraplegia is mainly due to pressure on the cord by the extradural tuberculous granulation tissue. Rest in the recumbent position and hyperextension results in absorption of granulation tissue and removal of the pressure.

Abscess formation.—It cannot be too strongly stated that tuberculous abscesses should not be opened under any circumstances. Absorption of the abscess while the patient is resting may take place; but there is the danger of the abscess extending and destroying the surrounding tissues. Small abscesses may be left alone for absorption. Aspiration and repeated aspiration while in hyperextension are said to completely eradicate the abscess. Aspiration of the abscess and injection of modifying antiseptic fluids are advocated. I have for the last three years employed repeated aspirations and injections of hot water under tension at 70°C. clipping the aperture to prevent leakage. The second and subsequent aspirations dislodge a more liquid content, and pain and temperature are relieved by the effect of the hot water. Just what the effect is I cannot say but this method has given me excellent results, and I am of opinion that treatment by aspirations and hot water injections has a future.

Case reports

1. Mrs. R., aged 27 years, admitted on 23rd April, 1933, for caries of the second lumbar vertebra with angular deformity, a psoas abscess in the right iliac fossa and dragging of toes while walking. She was put on the wedge immediately. Nine ounces, six ounces and two and a half ounces of pus were aspirated on 15th May, 17th June and 18th July. Patient was allowed to walk on 1st March, 1934. Patient is going about normally now (plate XV, figure 2).

(Continued at foot of next page)

CARCINOMA OF THE STOMACH*

By U. P. BASU, M.B., F.R.C.P. (Ire.)

Visiting Physician, Medical College Hospital, Calcutta

Introduction

ABOUT twenty-five years ago Robson and the staff of the Mayo Clinic suggested on the strength of histological examinations of a very large number of gastric ulcer cases sent for operation that gastric carcinoma was the frequent sequel of gastric ulcer. As certain islands and ingrowths of epithelium often became involved in the fibrous tissues of the ulcers they were of opinion that these were evidences of malignant changes which were the ultimate end of the majority of gastric ulcers. They found many supporters for their views amongst the medical men of different countries, notably among the American workers. Based upon this assumption many textbook writers even to this day hold that quite a good number of cases of gastric cancer originate from malignant degeneration of chronic gastric ulcers. The writer of this paper has made an attempt to ascertain the truth of this statement and he is putting forward the difficulties he met with in carrying out this investigation, the data he gathered together, and his own experiences and observations about carcinoma of the stomach.

Ætiology

Between the years 1914 and 1933, only twelve cases of cancer of the stomach could be collected from post-mortem examinations conducted at the Calcutta Medical College. It will be unwise to form an estimate of the prevalence of this disease amongst the indoor patients from the number of cases thus collected from the autopsies, as such figures will be small compared with the actual admissions for the same disease,

* Being a paper read before the British Medical Association on the 20th of April, 1934.

(Continued from previous page)

2. Mrs. P., aged 30. Admitted on 23rd August, 1933, for caries of the second and third lumbar vertebræ of one year's duration. Had difficulty in standing erect. No psoas abscess. She was put on the wedge. Successive radiograms show recalcification and consolidation (plate XV, figure 3). She is now sitting up.

3. Mr. K., 22 years. Admitted on 30th September, 1933, with a large psoas abscess in the right iliac fossa. Wedge introduced on 1st October. Twenty ounces, eleven ounces and five ounces of pus were aspirated on three occasions. Patient is now sitting up (plate XV, figure 4).

4. Mrs. S., aged 25. Admitted on 10th April, 1934, for caries of the eleventh and twelfth dorsal vertebræ with angular deformity. She was put on the wedge for three months. Deformity was partially corrected. Patient refused further treatment and left. Readmitted with spastic paraplegia and incontinence of urine and faeces. She is now undergoing treatment.

owing to the great scarcity of necropsies that are held on patients who die in Calcutta hospitals. For instance, the total number of medical, surgical, obstetrical, gynaecological and eye cases that were admitted into the Medical College group of hospitals from the beginning of January 1933 up to the 2nd of December, 1933, was 11,815; the number of deaths that occurred during the same period was 1,208, and the total number of post-mortem examinations that were held during the same period excluding the medico-legal cases was only sixty! In an investigation like this the ante-mortem diagnosis can never be accepted on its face value, in the absence of post-mortem confirmation. The writer may be pardoned for the digression when he says that the time has come when there should be some legislation to make post-mortem examination compulsory on every hospital dead body. Indeed that would be a forward step in the progress of medical education in our province. The writer had therefore no other alternative but to confine his remarks on these one dozen cases.

Macleod, Professor of Medicine, London University, reported from the records of St. Thomas's Hospital, London, one hundred and twenty-eight cases of gastric cancer during the years 1921-1924 in which the age incidence was between thirty and forty years in only eleven cases. It is a striking fact that in the writer's small series of twelve cases, in one of whom the actual age could not be ascertained, in no less than seven cases the age incidence was between thirty and forty years. As chronic gastric ulcer is also a disease commonly seen in Bengal between thirty and forty years of age and as the average duration of symptoms of this disease is approximately seven and a half years, the assumption that chronic gastric ulcer undergoes malignant changes does not hold water, at any rate from the point of view of age incidence, for obvious reasons. A careful search through the records of these twelve cases failed to reveal any history which could establish the theory that chronic gastric ulcer is a common precursor to gastric carcinoma. As a matter of fact none of the cases of the writer's series showed any evidence of pre-existing chronic ulcer on histopathological grounds.

Pathology

Three of these cases were scirrhus cancer, three columnar-celled, one epidermoid, and the remaining five of the ulcerative type. Nine were found in the pyloric orifice and the pylorus was stenosed in two cases, the remaining three were at the cardiac end, secondary deposits were present in the liver only in one case, liver and pancreas in two cases, liver and gallbladder in one case, anterior mediastinal glands in one case, pyloric group of lymph glands in one case, and gastric glands in one case.

Symptomatology

It seems that the American observers brought forward this 'ulcer-cancer' bogey purely on the strength of laboratory findings, for clinical observations do not lend support to such a theory. Instead of being afraid to eat on account of pain, which is so characteristic a feature of gastric ulcer patients and which trouble continues and aggravates as years pass by, the majority of stomach-cancer cases of the writer's series were seen amongst gluttons who devoured large quantities of food and would often boast of digesting nails, in whom suddenly the symptoms of dyspepsia set in as an acute disease which arose *de novo*. The early symptoms were diminution of appetite, flatulence and anæmia. The loss of appetite can to some extent be correlated to the diminution or absence of gastric juice in the stomach; for the chain of events that follows is a gradual decrease in the hydrochloric acid followed later by diminution in neutral chloride and pepsin. With the onset of the disease the patients began to feel for the first time that they had a stomach and from this time onwards there was always a sensation of persistent discomfort. Vomiting was generally present and in many cases the vomitus was of a foul odour and was followed by incomplete relief. Hæmatemesis and melæna were present in two cases only and the bleeding was frank and copious in both of them, and not a constant oozing, giving rise to a dark disintegrated blood in the stomach contents, the so-called 'coffee ground' colour. Pain was not a constant association and was present in four cases only. When once it appeared it never left the patient. Food brought on exacerbation of this pain. As the disease progressed, what generally happened in these cases was that the patient rapidly lost strength and weight, the anæmia became profound and was accompanied in some cases by nausea and special repugnance for protein food. Later on, with the appearance of extreme emaciation unaccounted for by the vomiting and the diminished intake of food, the disappearance of subcutaneous fat, and œdema of the abdominal wall, back and ankles, the picture of cachexia was complete; local tenderness over a fairly extensive area was usually present, a hard tender tumour was palpable over the epigastrium in three cases and Virchow's gland was felt in one case.

Diagnosis

Between the three special methods of investigations for confirming the bed-side diagnosis of gastric cancer the test meal findings rank first in order of importance. The ordinary one hour method following an oatmeal gruel is quite satisfactory for the purpose of a diagnosis and the fractional meal is much too exacting and is wholly unnecessary. It is very desirable that the stomach should be washed out thoroughly

before giving the test meal in order to exclude the presence of lactic acid arising from fermentation of retained and stagnating stomach products. Absence of free hydrochloric acid and the presence of an appreciable quantity of lactic acid in the test meal may be taken as definite evidence of cancer of the stomach. The resting juice shows pus cells and red corpuscles. The next method in order of importance for the diagnosis of cancer is the detection of occult blood in the faeces; unlike that of gastric ulcer the peculiarity of occult blood in gastric carcinoma lies in the fact that it persists in spite of treatment, as does the pain associated with this condition. The last in order of importance from the point of view of diagnosis comes the x-ray findings in this disease. The much-talked-of filling-defect which is believed in many quarters as indispensable for a positive diagnosis is never seen in carcinoma of the pars cardiaca as the opaque meal can hardly reach beyond the gas bubbles. Nor does the infiltrating scirrhus cancer project sufficiently into the barium-filled lumen of the stomach to give rise to such a defect. Even when the growth involves the pars pylorica, owing to the difficulty of obtaining a clear outline of this region because of its proximity to the spine and the tendency of the barium to settle away from the pylorus, small filling-defects in this situation are very often overlooked. I quote below three extracts from the reports of radiologists in definite cases of carcinoma of the stomach, to substantiate my contention:

(1) The stomach is dilated and dropped; there is marked spasm of the pylorus; irregularity of the contour is noted in this region.

(2) Meal in the stomach after nine hours; almost complete pyloric stenosis, cause not certain.

(3) Niche in lesser curvature and irregularity in its neighbourhood suggesting ulcer of lesser curvature.

Even when the filling-defect is present it may be due to numerous causes other than cancer, such as faulty media in which the barium is unevenly distributed, secretion imprisoned in the pyloric end of the common fish-hook type of stomach, food remnants, hair balls, gas or faecal matter in the colon, barium in the bowel adjacent to stomach, lordosis and scoliosis, pressure on the stomach, pressure of a deformed costal arch, strong retraction of the upper abdominal wall, spasms, adhesions, extrinsic tumours, distortion and distension of the stomach by ascites, ovarian, cyst or pregnancy, and above all by benign tumours producing lesions in the stomach.

Prognosis

The inevitable end of this disease is death which generally takes place from within a year

to eighteen months from the date of commencement of the symptoms. In the two cases complicated with copious hæmatemesis and melaena, as stated above, the immediate cause of death was depletion of blood from the system.

Treatment

With cancer of the stomach nothing can be done medically and very little surgically. Despite its futility in confirming a bed-side diagnosis, the roentgen rays very often furnish valuable information in deciding the question of operation. The operable zone corresponds to the pars pylorica, the border-line zone to the pars media and the inoperable zone to the pars cardiaca. No doubt operability of a given case depends on the skill and judgment of the surgeon, but, besides this, certain radiological findings speak for or against operation, whether radical or palliative. The location extent and character of the growth are all matters of fundamental importance. The clinician can prevent useless operations, even when they are indicated by the radiograms, if he finds metastases in the rectus sheath, supra-clavicular glands, umbilicus, skin, or peritoneum. Gross metastases in the lungs and bones are roentgenologically demonstrable but they are very rare. An absolute decision for an operation can never be given until the incision is made and perforation or metastasis, which may have remained undiscovered, are excluded. Even when the growth is excised, as in the majority of cases of cancer of the body of the uterus and breast, the ultimate end-results are wholly unsatisfactory and the patient seldom survives the operation beyond a few years. Yet the surgeon is of great assistance in these cases, as, when morphine fails, the knife is the only means of relieving the intense pain and the pyloric obstruction. Deep ray therapy is a failure in this disease, but radium can be applied locally. The medical treatment is purely palliative and depends upon careful dieting and massive doses of morphine when there is indication for the same.

I thank Dr. M. N. De, M.B., M.R.C.P. (Lond.), Professor of Pathology, Calcutta Medical College, for the use of pathological records, and to Dr. S. A. Sharma, M.B., D.T.M., for compiling the record of these cases.

[*Note.*—Whilst admitting that the prognosis in gastric carcinoma is bad, we do not feel that it is as bad as the writer implies. Everything depends on an early diagnosis; and if we were to take this pessimistic view of the eventual outcome of the disease, it would scarcely be worth trying to make this early diagnosis. About 75 per cent of cases are inoperable when first seen by the surgeon, but of those who survive operation 20 to 25 per cent are alive and well at the end of five years. This of course reduces the survival rate amongst those in whom the disease is diagnosed to less than 5 per cent, but with earlier diagnosis this rate is capable of improvement.—EDITOR, *I.M.G.*]

MOLLUSCUM CONTAGIOSUM

A PRELIMINARY NOTE ON THE TREATMENT

By L. M. GHOSH, M.B., D.T.M. (L'pool)

Skin Diseases Enquiry under the Indian Research Fund Association, School of Tropical Medicine, Calcutta
(By kind permission of Dr. E. Muir, M.D., F.R.C.S.,
Officer-in-Charge, Skin Diseases Enquiry)

MOLLUSCUM CONTAGIOSUM is caused by a filter-passing virus, this has been definitely proved by recent work (Wile and Kingrey, 1919) and has been accepted by most workers. The infection is a local one and the disease spreads by contagion. The same workers have shown that the contents expressed from a molluscum nodule contain a virus which inoculated into man can reproduce the disease.

Infection in man is probably by direct contact and also from infected baths or clothing. Epidemics in boarding schools have been traced to a common bath.

Not much work has been done from the point of view of the treatment of the disease and the production of immunity so as to prevent epidemics which may be a serious menace in boarding schools.

The disease is said to be self-limiting. Though this may be so it still runs a long course—at least six months—and within that time there is the danger of infecting several people or of starting an epidemic if it occurs in that boarding school.

Accepting the theory that molluscum is conveyed by a filter-passing virus and the infection a local one, the virus being confined to the molluscum nodules, I prepared a vaccine by emulsifying a nodule and killing the virus by formalin. The result of the injection of this vaccine was very encouraging and in all the cases tried so far the result has been uniformly successful. About a fortnight is required for the complete cure but the improvement is noticed after ten days from the beginning, i.e., after the third or fourth injection. The nodules first shrink, then dry up and drop off by themselves.

We have not had any relapses as yet though six months have elapsed with many cases.

Specificity.—We have not yet been able to determine whether an autogenous vaccine, prepared from the patient's own nodules, is more beneficial than a stock vaccine prepared from the nodules of other patients.

Technique for preparing vaccine.—Having sterilized the skin with a mixture of equal parts of ether and alcohol cut off two or three nodules with a pair of sharp scissors (avoid cutting normal skin). Collect the cut nodules in a small sterile test tube previously weighed accurately in a fine balance. Then find out the weight of the nodules. About 20 milligrammes are required for which two medium-sized nodules will be sufficient. Measure out in a sterile test tube freshly prepared sterile normal saline solution in the proportion of 1 c.cm. per milligramme

of nodule. Grind the nodules well with sterile pumice stone powder or fine sand in a sterile agate mortar until the emulsion is uniform and no tissue is felt or seen—adding the normal saline at intervals in small quantities. When the emulsion is completed add the remainder of the normal saline. The emulsion is then filtered first through krysolgar and then through an L3 Chamberland fine bacterial filter candle. Incubate the filtrate for 24 hours and then test for sterility. This forms the stock active emulsion.

Dilution.—Take 2 cubic centimetres of the stock active emulsion and add 8 cubic centimetres of formalized saline (i.e., normal saline with 0.2 per cent formalin which is about 40 per cent formaldehyde). Test again for its sterility against contamination and the vaccine is ready for injection. As formalized saline is a little painful our next series of cases is being tried with carbolyzed saline.

Injections.—Intradermal injection is given every third or fourth day beginning with 0.1 c.cm. or 0.2 c.cm. and increasing by 0.1 c.cm. or 0.2 c.cm. each time, according to the reaction. Altogether about five or six injections are necessary but the patient begins to feel better generally after the third and is cured or almost cured after the fourth or fifth injection. There are no local and general reactions and no contra-indications.

The work is still being continued along with the work on infective warts on the same lines, but as the disease is not of common occurrence the progress necessarily is slow.

My thanks are due to my colleagues Dr. D. Panja and Dr. N. C. De for their ungrudging help and useful advice.

Case reports

In all the cases reported below intracutaneous injections of vaccine (prepared from molluscum nodules as stated above) were given every third day. In all cases except case I no other treatment was given besides the injection of vaccine.

Case I. H. L., Anglo-Indian, aged 11 years

Previous history.—He had herpes zoster two months ago.

Present condition.—He is suffering from pityriasis rosea and molluscum contagiosum for two weeks. The molluscum nodules were spread over the abdomen and front of the chest and a few were present on the arms.

Treatment.—Pulvis hexamine gr. iijss internally twice daily.

Locally.—Baths of Condy's fluid once daily.

Injections of vaccine prepared from molluscum nodules of another boy named Haridas Lalji were given as follows :—

1st dose—0.1 c.cm., 2nd dose—0.2 c.cm., 3rd dose—0.5 c.cm., 4th dose—0.8 c.cm. and 5th dose—1 c.cm.

The boy began to improve after the third injection and was completely cured after the fourth injection.

Case II. H. P. H., Hindu male, aged 25

Suffering from molluscum contagiosum for two months. Molluscum nodules were present on the forehead, face and upper part of the chest. Condition is still on an increase and fresh nodules are cropping up.

A piece was removed and section confirmed the diagnosis—no other treatment was given except the injections of vaccine as follows :—

1st dose—stock vaccine made from Haridas Lalji—0.2 c.cm.

2nd dose—stock vaccine made from Haridas Lalji—0.4 c.cm.

3rd dose—autovaccine made from his own nodules—0.6 c.cm.

4th dose—autovaccine made from his own nodules—0.8 c.cm.

5th dose—autovaccine made from his own nodules—1 c.cm.

The patient began improving after the third injection and was fully cured after the fifth injection.

Case III. S. D., Hindu female, aged 32

Suffering from molluscum contagiosum for one month. Molluscum nodules were present on the arms, face and trunk.

Treatment.—No other treatment was given except injection of stock vaccine prepared from H. P. H., case II, as follows :—

1st dose—0.2 c.cm., 2nd dose—0.4 c.cm., and 3rd dose—0.6 c.cm., fully cured after the third injection.

Case IV. T. N. D., Hindu male, aged 20

Suffering from molluscum nodules for two months and the disease is still spreading. Fresh nodules are coming up. Molluscum nodules were present on the forehead, face and left axilla.

Treatment.—Injections of vaccine were given as follows :—

1st dose—stock vaccine prepared from case II (H. P. H.)—0.1 c.cm.

2nd dose—stock vaccine prepared from case II (H. P. H.)—0.2 c.cm.

3rd dose—autovaccine prepared from his own nodules—0.4 c.cm.

4th dose—autovaccine prepared from his own nodules—0.6 c.cm.

5th dose—autovaccine prepared from his own nodules—0.8 c.cm.

6th dose—autovaccine prepared from his own nodules—1 c.cm.

Improvement was noticed after the fourth injection and the patient was fully cured after the sixth injection.

Case V. R. K. M., Hindu male, aged 15 years

Suffering from molluscum contagiosum for one month and the disease is still spreading. Molluscum nodules were present on face, neck and forehead.

Treatment.—Injections of stock vaccine from case IV (T. N. D.) as follows :—

1st dose—0.1 c.cm., 2nd dose—0.2 c.cm., 3rd dose—0.4 c.cm., and 4th dose—0.6 c.cm.

The patient was completely cured after the fourth injection.

Case VI. K. L. D., Hindu male, aged 21 years

Duration of the disease is two months and the condition is still spreading. Molluscum nodules were present on the neck, chin and all over the chest in front and back.

Treatment.—Injections of stock vaccine prepared from case IV (T. N. D.) as follows :—

1st dose—0.2 c.cm., 2nd dose—0.4 c.cm., 3rd dose—0.6 c.cm., 4th dose—0.8 c.cm., 5th dose—1 c.cm., and 6th dose—1 c.cm.

Improvement was noticed after the sixth injection, and he was completely cured after the sixth injection.

A Mirror of Hospital Practice

MULTIPLE URETERAL STONES IN A URETEROCELE AND URETER

By N. MANGESH RAO, M.D., C.M., F.R.C.S.I.
 Surgeon, General Hospital, Madras

ANKAYYA, a Hindu male, aged 35 years, was admitted to the General Hospital, Madras, under my care on the 10th February, 1934.

Previous history.—He gave a history of frequency of micturition, burning sensation and occasional attacks of severe colic extending over eighteen years. He had passed small stones especially after the attacks of colic. He had passed in all nineteen stones.

On admission.—A well-nourished adult, complained of pain and tenderness in the left side of the hypogastrium and attacks of right renal colic. Urine was cloudy, alkaline and contained pus cells and some red blood corpuscles.

A roentgenogram showed a chain of stones in the right ureter extending from the sacro-iliac joint and ending in a hood-like mass to the left of the middle line.

X-ray diagram of Ankayya taken after admission.

Cystoscopy on 12th February.—The left ureteral opening was of normal size and in its normal situation. In front of this opening was a swelling with a pin-hole

Photograph of the reconstituted mounted specimen of calculi from Ankayya. (Kept in the Pathological Museum Medical College, Madras.)

opening at its top. A swollen ureter extending from this point upwards and to the right was discernible. The swelling was apparently a ureterocele packed with stones. This was cut into with a diathermy electrode and the opening was enlarged. The patient passed thirty-five stones in the next four days.

Cystoscopy on 17th February.—The right ureteral opening was fairly large but covered by a flap of thin tissue. This was burnt off by a diathermy electrode. A gloved finger was introduced into the rectum and the stones were massaged into the bladder. The patient passed twenty-five more stones in about four days. The last roentgenogram showed no stones. His urine began to clear up after this. He had meantime been put on hexamine, etc.

Cystoscopy on 5th March.—The right ureteral opening was 1 cm. by $\frac{3}{4}$ cm. and displaced nearer to its normal site. The efflux was still cloudy while that from the left ureter appeared normal. Indigo-carmin excretion following intravenous injection commenced in five minutes from the left ureter but was delayed for ten minutes with poorer depth of colour from the right.

The stones were mostly cuboidal in shape, the average dimension being $\frac{1}{2}$ cm. in each direction. The surfaces were smooth, greyish and appeared to be coated with phosphates.

The patient was discharged cured on 12th March, 1934.

Composition.—Total weight—13.95 grammes.

Calcium oxalate .. 74.2 per cent

„ phosphate .. 1.086 „

„ carbonate .. 10.01 „

Uric acid .. 1.277 „

Residue insoluble in 20 per

cent hydrochloric acid .. 3.347 „

Comment.—This is a rare case of multiple cuboidal stones held up as a chain in the ureter.

This was probably due to stricture of the right ureteral opening which must have been the cause of the ureterocele. The appearance and size of stones were suggestive of their being formed in one of the minor calyces. The stricture must have existed for a long time as sixty stones were held up in a dilated ureter, most of them being present in the lower part.

Fifty of these stones have been mounted to resemble the roentgenogram picture and preserved in the pathological museum of the Madras medical college.

I am obliged to the government x-ray institute, Madras, for the roentgenograms.

A CASE OF DEFORMITY OF THE BONES OF THE HAND AND FEET OF A MOTHER TRANSMITTED TO HER CHILD

By S SUBRAHMANYAM

Sub-Assistant Surgeon, Government Headquarters Hospital, Ootacamund

PAPPAMMAL, a Hindu female, was admitted into the maternity wards of the Government Headquarters Hospital, Ootacamund, for confinement (third pregnancy) on 21st April, 1931. She had had three confinements including the present one. On admission she

was found to be suffering from pernicious anæmia. The baby after her first confinement is stated to have lived for only a few months and to have had similar deformities to the mother. The second pregnancy resulted in an abortion. The child on this (last) occasion was stillborn, and the mother herself died on the 24th April about four hours after delivery, as the result of her extreme anæmic condition

Pappammal (mother), wrists and hands, antero-posterior view.

Pappammal (mother), feet and ankles, lateral view.

The following are the x-ray findings:—

The mother

Right foot.—The os calcis is fused with only the metatarsal present. The astragalus navicular and one cuneiform bone are present, the latter two being fused together.

Left foot.—Much the same as the right one except that there is no fusion here between the os calcis and the metatarsal.

Right hand.—The os magnum, trapezoid, and unciform bones are fused together.

magnum and cuneiform bones. There is a bony exostosis in one of the metacarpals.

The child

Right foot.—Only the astragalus, os calcis, one metatarsal and one phalanx are present.

Left foot.—Same as above.

Right hand.—Only three metacarpals with a common finger (with three phalanges) are present. The carpal bones are absent.

Left hand.—Here also there is an entire absence of the carpal bones, and only three metacarpals are present; there are two fingers however, each having three phalanges.

Pappammal's child, wrists and hands, antero-posterior and lateral views.

The scaphoid is rudimentary. There are two metacarpals and phalanges.

Left hand.—The trapezium is diminutive in size and fused with the trapezoid bone. The unciform is also rudimentary and is lying wedged in between the os

My sincere thanks are due to Lieut.-Colonel A. S. Leslie, I.M.S., the superintendent of this hospital, for his kindness in permitting me to publish this case, using the hospital records.

und Krankenhauses in Berlin
(Director : Prof. Burghart)*

EXPERIMENTS WITH THE EXPECTORANT "TUSSIPECT"

by Dr. Hartmut Czerwonka.

The author first discusses the chemical and therapeutic properties of the ammonium salt of primula-saponin; and calls special attention to its power of acting effectively even in minute doses.

The active principle of Tussipeet, the ammonium salt of primula-saponin, has a double effect, because the action of the ammonium salt is combined with that of the saponin in loosening and increasing the bronchial secretion by decreasing its viscosity.

Tussipeet is available as a solution, syrup and tablets. One great advantage, as compared with the usual decoctions, etc., is that the content of active substance is constant. Another point is that the preparations of Tussipeet are cheaper than many other expectorants.

In hospital practice, the author gave one tablespoonful of the following mixture every two hours:—Tussipeet solution, 6.0, Liq. ammon. anisat. 2.0, Syr. simplex 20.0, Aq. dest. ad 200.0 This preparation is found to be most palatable. It can also be combined with other drugs, such as codeine, morphine, etc. The Liq. ammon. anisat. may be omitted if desired.

Tussipeet was given to some 280 patients, for whom an expectorant was indicated. In every case, Tussipeet had the advantage over the infusion of ipecacuanha in that it could be given as long as desired, without causing nausea or any other discomfort. Apart from a few cases in which a slight laxative effect occurred, no evidence of an action on other organs was observed.

Children enjoy Tussipeet syrup. Tussipeet tablets are very useful for ambulant cases.

The author observed specially good effects in the influenza epidemic of 1928-29: many patients were freed from their troublesome cough within a single day. Good effects were also seen in some cases of bronchial asthma, in which, of course, symptomatic treatment alone was insufficient. Even in some cases of pulmonary tuberculosis Tussipeet greatly relieved the troublesome cough.

Finally, the author summarises by stating that the Tussipeet preparations have proved to be good expectorants, have a pleasant taste, and are devoid of any deleterious action, even when given for long periods.

INFANT FEEDING ON SCIENTIFIC LINES

WHEN artificial feeding has to be adopted, either entirely or in part, the "Allenburys" Progressive System of Infant Feeding fully meets the case. The "Allenburys" Series of Foods is arranged on a true physiological basis; it provides a progressive dietary suited to the development of the infant, supplying at the appropriate times the stimuli that call forth, in a natural way, the secretion of the digestive enzymes.

The "ALLENBURYS" MILK FOOD No. 1 is adapted to the first three months of life. It is a scientifically balanced nutrient which when prepared for use, is similar to human milk in composition, physical properties and ready digestibility. *It contains no starch.*

The "ALLENBURYS" MILK FOOD No. 2 is used from the beginning of the fourth month to the end of the sixth month. It is similar to the No. 1 Food except that it contains a proportion of the soluble phosphates, albuminoids and sugars obtained by the digestive action of malt on whole wheat. *It contains no starch.*

The "ALLENBURYS" MALTED FOOD No. 3 is for use from the beginning of the seventh month. It consists of a carefully selected wheaten flour of a high albuminoid content, so treated as to render it easy of digestion, together with a proportion of the diastasic and nutritive constituents of malt. When prepared for use it contains no unaltered starch.

The "ALLENBURYS" MALTED RUSKS are made from special flours rich in protein and provide the infant's first solid food. As early as the fifth month these rusks may be used, a little at a time, to aid the cutting of the teeth. From about the tenth month they may be given as a staple article of diet in conjunction with the Malted Food No. 3.

The "Allenburys" Foods are designed particularly for Infant Feeding and are manufactured by special processes which make them peculiarly suited for this purpose. They are constant in composition and free from any pathogenic organisms.

A copy of our new publication "The 'Allenburys' Foods in Infant Feeding" will be sent post free on request.

NOVEMBER

MALARIA CONTROL IN BENGAL

WHEN Ross in 1898 *et ann. seq.* confirmed Manson's great hypothesis nothing much was known about mosquitoes, but as a class it was believed that they 'bred' in stagnant water, and so the cry arose for drainage and oiling, and viewed 'by and large' these measures have held the field to the present day.

In India the public health authorities from the first, rightly so it seems to us, recognized that the problem was primarily one to be approached from the point of view of the masses of India, and not from that of select communities, and therefore any measures to be applicable must take into account circumstances of the case such as the human equation, finance, and other proper considerations. Such a measure as oiling was thus ruled out, and as a matter of fact it must have been really very difficult to see what antimalarial measures could be adopted, and applied over such a wide area. Nevertheless we think that drainage, and especially the principle of contour drainage, which in very early days had been suggested for antimalarial work by a Malay States planter, should have been given some sort of trial; it was a measure which *a priori* was eminently reasonable and advantageous, and might have been practicable in at least many of the hyperendemic areas of India. Whether it would have been generally successful is another matter, but it should have we think been given a good trial.

In the absence of any proved measure which appealed to Government, the cry arose for research, more research and research all the time. As a result in the intervening years much fine work has been done, particularly in the direction of the classification of the mosquitoes, but has all this research gone for anything in the problem of malaria control amongst India's masses? No, beyond laying the foundations for future practical work, it has left the main problem of the prevention of malaria in India's masses as it was, and nothing more practicable than there was in, say, 1905 has been the result*.

In the meantime from Malaya came the news that jungle-cover over water usually prevented it from being dangerous, and this

was hopeful because in a way it was a new principle that Nature could be called in with prospects of success to assist in defeating the mosquito. One had certainly heard that the 'natural enemies' of mosquitoes should be 'encouraged' but that apparently never went further than paper, or at least not further than encouraging old ladies to put goldfish in their flower-pots. Here however was a biological measure, *de facto* a cheap measure, and applicable to the problem in hand. Yet this discovery has scarcely had more than lip service done to it; we certainly have not heard that it has been even tried where it might have been suitable for the protection of any of India's masses—in fact, not many years ago, a malaria expert on one of the State railways cut down the jungle that there was over a stream in a very malarious station and caused a rise in the malaria index of the station. He was indeed more than ten years behind the times! Ross, it was we think, who said that it takes ten years for a new idea to soak into the public cerebrum: in India the inertia seems more profound.

That is the story of what has not been done in the 35 years since Ross applied the match to the fuse. Now we believe that the first effort in the direction of applying suitable measures to the problem in India has been made; the observations of numerous laymen, notably certain civil administrators and Raja Digambar Mitter, together with those of sanitary officers, such as Colonels Fry and McCombie-Young, culminated in Dr. Bentley's essay on the relationship between malaria incidence and the natural flooding of the land from the rivers and *khals* of Bengal. He believed that a system of irrigation which would imitate the natural inundations from the *khals* would render the people at once healthy and prosperous. Although, as we shall see, his principles might be classed among those of biological control of malaria yet as the primary factor involved in his proposal was the physical inundation of the land, it would perhaps be better to refer to it 'a natural method' of malaria control. The main thing is that it would appear to be a feasible measure on the ground of cheapness, as Nature would do most of the work. Man would have to do some, and this would cost money, but it would be compensated for by the economic advantages of a more fertile land.

Dr. G. C. Chatterjee has lately been solving Bentley's equation in terms of fish; Bentley rather regarded the advantage as due to improved physical conditions—Chatterjee regards the inundations of the plains as only a means of disseminating fish, but otherwise subscribes whole-heartedly to Bentley's teachings which, we understand, the newly-created Rural Commissioner of Bengal, Mr. Townend, is now

* We ought perhaps to emphasize that this remark does not apply to malaria in select communities, such as military cantonments, tea gardens, and railway camps; here of course very useful work has been done and in many instances malaria effectively controlled.

attempting to implement, with Government's approval.

These movements are at last in the right direction, they attempt something big and feasible for the masses of India, and for the same reason the recently-instituted Malaria Survey of India is to be welcomed, for it takes research out of the parish-pump atmosphere into the wide spaces of Nature, where indeed the greatest discovery of the age, to wit, evolution through natural selection, was made. Bentley was no laboratory man and he observed natural events and profited accordingly, and the Malaria Survey of India will do the same. It has often been suggested that malaria survey work should be regarded rather as purely executive work of parochial interest than as

philosophical research, but we hope that this view will not prevail in the counsels of that institution for it would seem to us likely to prejudice their high aims and opportunities.

Another recent movement may be mentioned in conclusion, the attempt to implement the resolution of the Far Eastern Association of Tropical Medicine Congress in Calcutta in 1927 that *sanitary experiments* were desirable to test theoretical considerations. Experiments have recently been carried out in several provinces to test the value of plasmochin under local conditions. It is all to the good that such experiments should be made, and, whether they are successful or not, it is to be hoped that they will lead to further sanitary experiments on a large scale.

SOME IMPRESSIONS DERIVED FROM EXPERIENCE IN CATARACT EXTRACTION*

By R. E. WRIGHT, M.D., C.I.E.

LIEUTENANT-COLONEL, I.M.S.

*Superintendent, Government Ophthalmic Hospital
Madras*

COLONEL WRIGHT reviews in certain of its phases the evolution of changes of technique and ideas in the hospital under his charge in the previous twelve years. The extent of this experience may be gauged from the fact that during this period some 20,000 cataract extractions were performed. Those who have visited the Madras clinic know that the extensive material available there is continuously being used for investigation, and careful observations are recorded up to the time the patient leaves hospital. As the author states 'we were enabled to investigate practically every variety of technique, whether recorded by others or conceived by ourselves, which appeared to provide simplification of method, greater safety in operating, or improvement in end-results'.

Methods which seem worthy of consideration are tried out in large numbers of cases; new procedures are not described and published on the strength of few case records, but subjected to the more exacting test of observation in bulk. Readers of the *Gazette* will probably be familiar with many of the ideas promulgated from the Madras clinic in the past, as recorded in the reports of the Government Ophthalmic

Hospital reviewed from time to time in these pages. Apart from these reports Colonel Wright has published relatively little on cataract in current ophthalmic literature and it is perhaps a pity that the Montgomery Lecture which elaborated some of his views should have been recorded in a journal not ordinarily perused by ophthalmologists. Those interested in cataract work would do well to read the paper in the original, but a few points may be touched on here.

Herbert's method of perchloride irrigation is relied on in hospital cases to prevent sepsis, and bacteriological reasons are given as to why it is not ordinarily expedient to make conjunctival cultures. In view of the irritation produced in certain patients an alternative to perchloride irrigation is approved, namely, preparation of the conjunctival sac by treatment with yellow oxide of mercury ointment and argyrol.

The most important changes which have evolved in the period reviewed are those associated with akinesia and anaesthesia. The blocking of the temporo-facial division of the seventh nerve with novocaine and adrenalin and the retrobulbar injection of this solution has changed the whole aspect of cataract extraction. The skilled assistant so essential to uniform success in India (and presumably elsewhere) 15 years ago is no longer necessary.

The general restfulness of the patient is insisted on and sedative drugs in big doses are used without hesitation; the custom so long prevalent of keeping the patient rigidly at rest is condemned, but the attainment of real quiet in the post-operative period is stressed in detail. For post-operative interference with the eye on the part of the patient Kirkpatrick's new shield is suggested (vide *Indian Med. Gaz.*, LXIX, 464).

* Being a résumé of the Montgomery Memorial Lecture, delivered in the Royal College of Surgeons, Ireland. The résumé was kindly prepared by Lieutenant-Colonel E. O'G. Kirwan, M.B., B.Ch., L.M. (Rot.), F.R.C.S. (Ire.), I.M.S., from a full report published in the *Irish Journal of Medical Science*, October and November 1933.

The evolution of the adoption of intracapsular extraction in the Madras clinic is traced, and an interesting dissertation given on the author's observations in connection with the influence of the zonule capsule barrier on the integrity of the vitreous body. After a careful study of the various forms of intracapsular extraction there has been a 'change of attitude' towards these methods. Twenty years ago capsulotomy was almost exclusively adopted in Madras, but this is no longer the case. To quote from the text 'It is interesting to note here that this change in attitude towards intracapsular extraction proceeded *pari passu* with a similar change in attitude in certain other centres of experimental study all over the world where extracapsular extraction had been previously preferred'. Expression, Barraquer's operation, and extraction by forceps are all employed in selected cases but still not so frequently as capsulotomy. Expression has a very limited application; the Barraquer procedure is said to be superior to the forceps method in respect of a less frequent rupturing of the capsule. It is more suitable for large institutions however and is not recommended to post-graduates on account of the lessened risk and the more simple instrumentation in forceps delivery. The author advocates a modification of Elschnig's forceps. The following portion of the lecture is quoted *in extenso*: 'I feel convinced that the forceps method is the best intracapsular technique for the majority of operators. It is the method I advise post-graduates, who have not had the advantages of working in a well-organized clinic or nursing home, to adopt in all cases to which intracapsular extraction is applicable.'

Its acceptance with these limitations has not yet become generalized, but its popularity is gradually increasing. The choice of method in both intracapsular and extracapsular extraction is influenced by many factors. Experience is the guide in determining the procedure best suited to the individual case. It is a very difficult matter at present to say in what proportion of our cases intracapsular extraction might be successfully employed. I have no doubt that we might employ it advantageously to a much greater extent than in the past. In 1932 I hazarded the opinion that over 50 per cent of our cataract cases are unsuited to intracapsular extraction, but I may have reason in the future to modify this view in either direction.

I will not attempt an exhaustive examination of the contra-indications to intracapsular extraction.

I agree with Barraquer that, in so far as Europeans are concerned, patients should ordinarily be over 55, but this rule is not applicable to Indians and one must judge of the resistance of the zonule by the general

impression of the aging of the body tissues; in this, good judgment depends on experience.

Prominent or bulging globes, especially in fat plethoric patients, are associated with greater risk of disaster, although much can be done in moderate degrees of prominence to make the operation safer by retrobulbar injection of novocaine-adrenalin, firm pressure over the eye with a wet pack for a short time before operation, and canthotomy. It must be remembered that patients with markedly atrophic tissues are more common in the East. I have drawn attention to this elsewhere (*Repts. Govt. Ophth. Hosp., Madras*). On this account the deeply-socketed eye in a shrunken orbit is quite a feature of the Indian clinic. It is not so common in this country (Ireland) nor in other countries unaffected by excessive heat and an acute population food supply problem. Such eyes are much less liable to an escape of intraocular contents, and are eminently suitable for intracapsular extraction provided the posterior segment is in reasonably good condition. Glaucoma is a contra-indication if our technique causes a rise in tension.

If, for example, an increase in tension due to the establishment of mydriasis is not counteracted by other measures such as the retrobulbar injection, it is wiser to carry out extracapsular extraction.

If the section shows the slightest tendency to gape, when with full akinesia and anaesthesia negative pressure is established in the orbit and the globe is socketed well back, an intracapsular extraction is very risky, particularly in eyes with shallow chambers.

Subluxated lenses, traumatic cataracts, many of the complicated cataracts, and cataracts with dense membranous capsules are unsuited to the Barraquer operation although the latter types, in fact the whole hypermature group (except Morgagnian cataracts), are ideal for extraction with forceps.

In Morgagnian cataract the forceps method is quite contra-indicated, Barraquer's extraction is not really suitable, whilst expression is eminently adapted to the conditions which are usually present.

I do not favour intracapsular extraction in high or even moderate myopia if in the latter there is a record of degeneration, in known pathogenic states of corneosclera or posterior uvea, or fluid degenerations of the vitreous.

In chronic anterior uveitis of certain types, e.g., that of hyperglycæmia, it is not contra-indicated, but one must be very careful in cases of peripheral posterior synechiae. It must be admitted that when the patient is seen for the first time with a cataract fully developed it is difficult to be certain of the condition of the vitreous, but one can often obtain probable evidence of changes in consistence and other abnormal states.

Although intracapsular extraction is eminently suited to patients over 55 with apparently uncomplicated cataracts, certain cataracts falling into this group are not so easily extracted with forceps on account of the greater difficulty in pinching up a fold of the capsule, for example, in tumescent lenses and those with large sclerosed nuclei tightly filling the capsule. In the latter variety I prefer starting the lens forward with a needle and following it up (with hook or equivalent instrument in the other hand) as in a forceps extraction. Should this fail it is wheeled out with the needle as an extracapsular delivery. Morgagnian cataracts in which there has been considerable absorption of fluid are dealt with by preliminary capsulotomy with a needle and removal of the small nucleus by gliding it out on an inclined plane between two Smith's iris repositors, one behind the nucleus inside the chamber, the other outside on the cornea.

The nucleus of a burst Morgagnian cataract is dealt with in the same way, unless the nucleus is so small that a corneal keratome incision is possible; this requires good judgment. In such cases the capsular bag is subsequently removed complete with a Kalt's forceps; it comes away readily with lateral swinging movements.

Provided intracapsular extraction is not otherwise contra-indicated the important point is, whether the zonule is sufficiently weak to tear readily. Hence the age limit which Barraquer lays down but which does not apply in India. In the forceps method, if the zonule is strong enough to resist the pull on the capsule, the capsule gives way. In phaco-eresis this does not happen so readily and the pull exerted on the zonule in order to rupture it by movements of the eresiphake may be such as to cause even ciliary detachment. The vibratory explanation of zonule rupture in phaco-eresis by the Barraquer technique as described in certain publications is an elaborate chimera. Ordinarily in weak zonules the humping up of the anterior capsule into the cup when the vacuum is applied is sufficient to put drag on the peripheral capsule and rupture the zonule. If this does not occur the operator must make the necessary movements (preferably in its own plane) to rupture it. In the case of resistant strong zonules in middle-aged and young people the force necessary to effect this rupture may be too great, and should one make a start with the eresiphake in such a case it is wiser to desist and employ forceps than to risk trauma to the vitreous and ciliary body. With experience it is not difficult to know when this forbearance is called for. With the forceps the capsule will always give way before a damaging strain is put on the ciliary body.

The most disappointing thing about intracapsular extraction is the relative infrequency with which immature cataract can be removed

without unjustifiable trauma. One of the greatest difficulties in cataract work is the handling of the central immature cataracts, or any variety of cataract in which the cortex is still firmly attached to the capsule in persons with a strong zonule. This condition may threaten the individual's livelihood and it may be important to extract the lens for this or other economic reasons.

Unfortunately the eresiphake does not help us here any more than expression, delivery with forceps, or capsulotomy. In certain cases of immature cataract where the resistance of the zonule is doubtful it is possible and justifiable to try extraction with the eresiphake. If the application of the vacuum is not sufficient to tear the zonular fibres and reasonable movements thereafter do not succeed in dislocating the lens, the attempt may be abandoned by releasing the vacuum. In such an eye ripening is markedly accelerated and it may be dealt with later by capsulotomy.

Finally, it may be said that there is still some room for all methods and, where large numbers and varieties of cataracts have to be dealt with, individual cases must be treated by any method, or modification of method, which the surgeon thinks best.

Dealing with extracapsular extraction the great importance of irrigation is stressed. The author considers that the full value of this procedure is not appreciated by many operators who do not adopt a technique such as he advocates or understand the employment of vigorous irrigation. [The author refers to Western clinics; in India the method he advocates is largely practised.—E. O'G. K.] Its advantages in congenital and juvenile cataracts is pointed out. One objection to irrigation is dealt with thus: 'An objection to irrigation is sometimes put forward that it causes damage to the endothelium resulting in a persistent keratitis. With the full weight of my experience and that of my predecessors behind me, I can say that this is a bogey founded on operative clumsiness or some unrecognized factor such as a noxious irrigating fluid'.

The capsulotomy is considered in detail and the importance of obtaining an extensive aperture in the anterior capsule emphasized. The difficulty of removing a large central portion of the anterior capsule is discussed. Various methods are recommended—a capsule flap with the knife, subsequently removed by forceps, being one; capsulotomy with suitable forceps is another. The author has designed a forceps for this purpose (made by Down Brothers). The great importance of wearing operating glasses of a modern type, such as Hamblin's, is emphasized. 'Even with glasses, capsular tags may be missed by experienced operators except when set in motion by the stream of the irrigator, but without such glasses the best cataract work is hardly possible'.

In dealing with 'the section' the conjunctival suture is criticized as a means of surgical closure of the wound, nor does the bridge flap act in this way. The latter has advantages but also disadvantages, *e.g.*, greater difficulty of delivery and a greater liability to hæmorrhage into the chamber, which the author deprecates. Corneoscleral suture is held to be the only method of effecting true surgical closure of the deep wound. The author has elaborated a technique but as yet it is not sufficiently simple to be deserving of universal application. This is a serious criticism in his view. A simplification of technique is one of his tenets. A method of dealing with after-cataract with a minimum of trauma is described.

The concluding remarks may be quoted in full:

'In order to bring these observations to a close in proper perspective, it is absolutely necessary to refer, if ever so briefly, to the prevention and non-operative treatment of cataract.

Despite the fact that the surgical removal of the opaque lens with all its ritual appears to play such a prominent part in our hospital routine, we never forget that it is but a valuable makeshift which we employ, *faute de mieux*, until further investigation elucidates the various causes of cataract and enables us to eliminate them. If we assume, and the assumption is apparently supported by census returns, that cataractous changes in the lens are of greater frequency in the Madras Presidency than in Great Britain and Ireland, it is highly probable that this is related to the better conditions of the public health in these islands.

We still speak of senile cataract, although I believe, as do others, that senility *per se* is not productive of the opaque condition of the lens which is ordinarily referred to as cataractous. The true senile change of sclerosis with increasing depths of colour is not incompatible with relatively good vision. There is in fact no such thing as senile cataract, but there is cataract of unknown origin occurring in the aged. In our constant search for metabolic and other disturbances which are commonly associated with lenticular opacities, if not directly productive of them, we have not made much progress in recent years in spite of great biochemical advances. For this reason it is very difficult to devise any scheme of experimental investigation which might throw light on the preventive treatment of cataract. The steady progress of preventive medicine and biochemistry will no doubt eventually enlighten the ophthalmologist if his mental vision is not too unrecceptive.

A consideration of examples will make for clearness. I have held for some time, and recorded elsewhere, that there is a peculiar type

of cataract frequently associated with hookworm disease. In this clinical observation I have the support of my own staff, most of whom are prepared to make a diagnosis of hookworm disease by merely looking at the cataractous eye which they have learned by experience to associate with the waxy pallor, œdema, etc., of advanced ancylostomiasis. Fortunately hookworm "disease" is relatively infrequent in hookworm infection, but the toxins, which in bulk produce the clinical picture of hydræmia, anasarca and a pearly cataract, may readily, when acting in smaller quantities, start opacities in the lens which, with increasing hookworm infection or some other influence altogether, assume a progressive character. The importance of the association between hookworm disease and cataract—if it is substantiated by statistics—is obvious. One need only refer to literature on this subject (*e.g.*, Annual Reports of the Rockefeller Foundation and Annual Reports of the Public Health Commissioner with the Government of India) to realize the enormous importance of ancylostomiasis. Over 70 per cent of the population in the Madras Presidency shows hookworm infection. I doubt if the average ophthalmologist in this country (Ireland) has the faintest conception of the scale on which efforts are being made in the world outside the British Islands to combat hookworm infection, or of the economic significance of ancylostomiasis.

Hookworm infection, however, as a preventable cause of cataract, may seem to those of you who live here as of very remote interest; but we also see a very common metabolic disturbance frequently associated with cataractous changes (and, of course, with vascular changes, too), which brings our thoughts closer to those widely distributed if somewhat obscure endotoxic conditions which may well be operative in this country; such, for example, as we associate with vascular disease. I refer to hyperglycæmia, the frequency of which in southern India is probably related to the local peculiarities of diet. Limitations of time and space do not permit further excursions into the interesting problems associated with the possible prevention of cataract.

As regards the non-operative treatment of cataract I have little to say. We have tried deep intraorbital cyanide injections in incipient cataract with mixed results. We have tried drugs, dieting, ductless glands, but know of nothing which will stop the course of a cataractous process. On the other hand, I have occasionally observed the cessation of a cataractous process, which might readily have been ascribed to a specific line of treatment, had such treatment been in operation.

Considerations such as those in the earlier part of this section make the surgical treatment of cataract appear of secondary importance,

although for a long time to come, the removal of the opaque lens will make its appeal in

varying degrees to the urge of the mercenary, the craftsman, and the healer within us'.

Medical News

ASSAM GAZETTE

(The 19th June, 1934)

No. 2469 L. S. G. In exercise of the power conferred by section 11 of the Assam Medical Act, 1916 (Assam Act 1 of 1916), the Government of Assam are pleased to declare that the term of office of the following members, who have been nominated or elected to constitute the Assam Council of Medical Registration under sections 4 and 5 of the said Act, shall begin on the 11th June, 1934 :—

- | | |
|---|-------------------|
| 1. The Inspector-General of Civil Hospitals, Assam | President. |
| 2. The Director, Pasteur Institute and Medical Research Institute, Shillong | Member nominated. |
| 3. The Director of Public Health, Assam | " " |
| 4. The Civil Surgeon, Khasi and Jaintia Hills | " " |
| 5. The Chief Medical Officer, Welsh Mission Hospital, Shillong | " " |
| 6. Dr. Brajendra Nath Bhat-tacharyya, M.B. | " " |
| 7. Dr. F. C. McCombie, M.D., B.S., M.R.C.S., L.R.C.P. | " " |
| 8. Dr. Lalit Kumar Barooah, L.M.F. | " " |
| 9. Dr. G. D. Madhok, L.R.C.P. & S., L.R.F.P. & S.L.M., D.F.H., D.T.M. | " " |
| 10. Dr. Kumudini Kanta Banarji, M.B. | Member elected. |
| 11. Dr. Dibakar Hazarika, M.B. | " " |
| 12. Dr. Sarat Chandra Chakravarty, L.M.F. | " " |
| 13. Dr. Bimal Ranjan Dey, L.M.F. | " " |

THE PARKES MEMORIAL PRIZE FOR 1935

THE Parkes Memorial Prize, consisting of approximately thirty guineas in money with a gold medal, will be awarded annually to the writer of the best essay on a subject connected with hygiene.

The competition is open to the medical officers of the Royal Navy, Army, and Indian Army, on full pay, with the exception of the professors and assistant professors of the Royal Naval Medical School, Greenwich, and of the Royal Army Medical College, London, during their term of office.

The subject for the essay for the 1935 Parkes Prize will be optional, each competitor being allowed to select any subject dealing with naval or military hygiene. All essays submitted will receive equal consideration, with the proviso that the subject chosen must have a direct bearing on naval or military hygiene or on both.

Essays to be sent in to the Secretary of the 'Parkes Memorial Fund', Royal Army Medical College, Millbank, S. W. 1, on or before the 30th June, 1935. Each essay to have a motto, and to be accompanied with a sealed envelope bearing the same motto and containing the name of the competitor.

The committee reserve the right to withhold the award should, in the opinion of the assessors, no essay attain a sufficiently high standard of merit.

THE ELEVENTH ALL-INDIA MEDICAL CONFERENCE, 1934

THE Eleventh All-India Medical Conference will be held in Delhi during the ensuing Christmas week. Subjects concerning the vital interest to the medical profession in India, *e.g.*, Rural Medical Relief, Health Insurance Scheme, Indian Medical Council Act, etc., will be discussed in the conference. The scientific section of the conference and the exhibition will no doubt be of special interest to all medical men and women. In order to make this conference thoroughly representative of the medical profession of India, it is requested that all members of the profession should join the conference and take part in the deliberations.

For particulars please write to the organizing secretary, Eleventh All-India Medical Conference, D. M. A. House, Darya Ganj, Delhi.

A CENTENARY APPEAL FOR THE MEDICAL COLLEGE HOSPITALS, CALCUTTA

THE following appeal has been issued by Sir Bijoy Prosad Singh Roy, Minister for Local Self-Government, Bengal, on behalf of the Medical College Hospitals, Calcutta :—

The Calcutta Medical College will be celebrating its centenary early next year. It was established by Lord William Bentinck by an Order-in-Council dated 28th January, 1835. About fifty years ago the number of indoor cases treated were 2,325, outdoor cases 35,484. The confinements in the hospital were only 55. The corresponding figures for 1933 were indoor cases 15,931, outdoor 162,243 and over 2,000 confinement cases. Such has been the growth of the Medical College Hospitals from its small beginnings when the first clinical hospital attached to the College consisted of 30 beds and a small outpatient dispensary. To-day the Medical College and its associated hospitals have expanded into an immense institution dealing with practically all branches of modern medicine and providing incalculable benefit not only to Calcutta but also to Bengal and even beyond. During this 100 years many distinguished men attached to the College have made notable contributions to the advancement of medical science particularly as regards tropical diseases.

Much money is now needed to modernize the Calcutta Medical College Hospitals and among its many pressing requirements is the abolition of the present unsatisfactory arrangements in the emergency rooms by the construction of a proper casualty department and wards with up-to-date equipment and adequate nursing arrangements. The recurring expenditure of this department amounting to Rs. 25,000 per annum the Government have decided to bear, provided the capital cost for the building and equipment can be raised through public donations. Even this will not suffice to bring this institution to the standard of a modern hospital organization. Much still remains to be attained if it is to maintain its position as a pioneer. An outstanding example in this respect is its deficiency in radium.

In matters of public charity, especially with regard to medical aid and medical education, Bengal has

been in the past a leader to the rest of India, and has built up a tradition of splendid and efficient service. The services of Bengal in this direction have received widespread appreciation. The Calcutta Medical College and Hospitals now appeal to the generosity of Indians and Europeans alike, and also to the several generations of medical men who have passed out through their doors with success, and who now hold prominent positions in various spheres of life in India. The financial needs are very urgent, and, despite the present financial stringency, we do not believe that this appeal will be in vain. There is no subject which should be closer to the heart of a country than the health and welfare of its people.

Donations may kindly be sent either to the Treasurer of the Imperial Bank for credit to the Medical College Centenary Fund or to any of the following gentlemen:—

Sir Badri Das Goenka, *Kt.*, *C.I.E.*, 145, Muktaam Babu Street, Calcutta; Sir Hari Sankar Paul, *Kt.*, 1 and 3, Bonfield Lane, Calcutta; Kumar H. K. Mitter, 1, Jhamapukur Lane, Calcutta; Mr. J. N. Basu, Temple Chambers, 6, Old Post Office Street, Calcutta; Mr. Sitish Ch. Mitter, 2, Loudon Street, Calcutta; Mr. Sudhansu K. Mitter, 34/1, Elgin Road, Calcutta;

Dr. Charubrata Ray, 13, Hindusthan Road, Calcutta; or Lieut.-Col. T. C. Boyd, Principal's House, Medical College, Calcutta.

The signatories to the appeal include:—

Bijoy Prosad Sinha Roy, Rabindra Nath Tagore, Prodyot Kumar Tagore, Deva Prosad Sarbadhikary, M. N. Roy Chowdhury of Santosh, S. C. Nandi of Kachumbazai, Nilratna Saikar, E. C. Benthall, Badri Das Goenka, Kedar Nath Das, Hari Sankar Paul, Hasan Subhawardy, Upendra Nath Brahmachari, S. N. Mallik, Nalini Ranjan Saikar, W. M. Craddock, Shiyama Prosad Mukherji, S. D. Gladstone, C. G. Arthur, Chas. G. Cooper, H. H. Burn, P. N. Tagore, J. N. Basu, Moongtungal Thaparia, Arthur Moore, Tusar Kanti Ghosh, Promotho Nath Roy, Eric Studd, Haridhan Dutt, H. K. Mitter, Kamala Ranjan Roy, J. Reid Kay, G. D. Birla, D. P. Khaitan, D. C. Ghosh, Satis Chandra Mitter, M. A. H. Isphani, D. J. Cohen, Kumar Krishna Kumari, M. A. Momin, Bimala Ch. Law, A. K. Fazlul Haq, S. K. Mitter, Ratan Mohan Chatterjee, D. P. Goli, Thomas Crawford Boyd, R. Knowles, L. M. Banerji, K. K. Chatterji, E. H. Vere Hodge, A. A. E. Baptist, Ekendra Nath Ghosh, N. Pan, P. Serological Diagnosis of Latent Malaria

By E. D. W. GREIG, *C.I.E.*, *M.D.*, *D.Sc.*, *F.R.C.P.* (Edin.)
C. E. VAN ROOYEN, *M.B.*, *Ch.B.* (Edin.)

and

E. B. HENDRY, *B.Sc.*

(From the *Lancet*, Vol. I, 30th June, 1934, p. 1393)

A. F. X. HENRI has demonstrated the property of malarial sera to flocculate solutions of iron methyl-arsenate and melanin pigment contained in ox choroid membrane. The former test he termed 'ferro-flocculation'; the latter, which was found to be more sensitive, 'melanoflocculation'. Henry maintained that the phenomenon was due to the interaction of melanin pigment, which behaved as an antigen, and a corresponding antimelanagglutinin developed in the sera of malarial subjects. He regarded the reaction as specific for malaria and of value in the recognition of the latent infection when parasites were absent in peripheral blood. Several continental workers have confirmed the latter observation and we have obtained similar results.

A number of difficulties have however been encountered owing to the unsuitability of crude aqueous suspensions of ox choroid membrane for use as antigen, arising from its instability and the large amount of ox tissue derivatives contained in it other than melanin pigment. The test as employed by Henry merely signifies that the serum examined has or has not agglutinated the antigen in a single low dilution. No provision was made for assessing the degree of positivity exhibited by different sera or the same specimen at various stages during the course of an illness. We have attempted to overcome these difficulties by the substitution of human hair for ox choroid membrane as a source of pigment, and by alterations in technique.

TECHNIQUE OF THE NEW TEST

The melanin pigment solution is derived from human hair by hydrolysis with 50 per cent HCl, followed by concentration *in vacuo* and purification by dialysis in a collodion membrane. This has been found to give a pure and stable suspension of pigment. A set of nine dilutions of patient's serum is prepared ranging from 1:2 to 1:512 in distilled water. To each is added an equal volume (0.4 ccm.) of pigment solution, and the series is incubated at 37°C. for 5½ hours before the

reading is taken. Positive results are observed as white granular precipitates forming at the foot of the tube; the degree of positivity is determined by noting the highest dilution of patient's serum showing precipitation.

The rise and fall of the reacting principle in human malarial sera with melanin pigment may thus be quantitatively ascertained during an attack. The method was tested on benign tertian infection induced in cases of G.P.I. Preliminary observations showed that the reaction appears about the 5th to 7th day following infection, although no parasites may be seen at this stage and the patient is afebrile. The maximum titre of 1:128 is reached about the 4th week and then rapidly declines following the administration of drugs. Control tests on 129 different non-malarial sera gave only two non-specific positive results.

It is probable that the phenomenon is not due to the interaction of antigen and antibody, for it can be shown that positively reacting sera may be inactivated by heating to 55°C. for half an hour and that the repeated immunization of rabbits with melanin pigment fails to produce an agglutinin response. The occurrence of a reaction with positive sera and dioxypheylalanine shows that the reaction is due to the melanin and not to any other substance.

Observations on the lipid phosphorous content of the serum during the course of the infection show that its amount tends to vary inversely with the reacting titre of the serum to melanin pigment. We suggest that the term melanoflocculation test should be dropped and melanoprecipitation reaction substituted.

Typhoid Vaccine: Potency and Virulence

(From the *Lancet*, Vol. II, 28th July, 1934, p. 203)

RECENT years have witnessed an exuberant growth in our knowledge of the antigenic structure of bacterial cells. The resulting literature offers a formidable meal even to the professed immunologist, who must perforce attempt its digestion. But those whose interest lies on the practical rather than on the theoretical side, noting that exuberance has in this case justified its literal significance of fruitfulness, will desire to master those elements of the newer

knowledge that have an immediate bearing on the practical problems of immunization. In our present issue Dr. Felix and Miss Pitt record their latest observations on the factors involved in the virulence of the typhoid bacillus as tested in mice. In earlier studies they showed that strains of high virulence have, in the living state, the curious property of being relatively inagglutinable by sera that contain a high titre of antibodies acting on the 'O' somatic antigen, which is one of the most characteristic components of 'smooth' strains. In their present paper they show that this inagglutinability is associated with the possession of an additional antigenic constituent, that can be clearly differentiated from the ordinary 'O' antigen by selective absorption of the corresponding antibodies. Mice immunized with a vaccine containing this additional antigen in an active form are rendered resistant to the injection of highly virulent bacilli. Mice immunized with a vaccine from which this antigen is absent remain susceptible to virulent strains. Antisera prepared by immunizing rabbits with living virulent bacilli protect mice against infection with these strains; antisera prepared by immunizing rabbits with killed virulent bacilli, or with avirulent smooth bacilli, have no such protective action. It would seem that heat-killed virulent bacilli have suffered an impairment of the antigenic potency of the particular component associated with high virulence sufficient to inhibit its capacity for inducing efficient antibody formation in the rabbit, but insufficient to prevent the induction of active immunity in the mouse. If a relatively avirulent strain is used for testing—in which case the lethal dose of living organisms does not fall far below the lethal dose of killed bacteria, so that death must be regarded as resulting from toxæmia rather than from bacterial invasion of the tissues—it is found that the ordinary antisera, containing the 'O' antibody, are at least as protective as the sera obtained by immunization with living virulent bacilli. The new antigen and its corresponding antibody would thus seem to be concerned particularly with the reactions that inhibit tissue invasion.

Dr. Felix has clearly added another observation of great practical importance to those that already stand to his credit in this field. Whether the sharp distinction that he draws between this new antigen, as determining virulence, and the ordinary smooth somatic antigen, as being mainly concerned in toxicity, is fully justified, and whether the facts that he has demonstrated in the case of the typhoid bacillus have analogies in other bacterial species, only the future can show. The essential significance of his findings lies in the demonstration that it is not enough to prepare our vaccines from smooth strains, as we had already learned to do, but that one smooth strain differs from another in its antigenic structure, and that we must select smooth strains possessing the right kind of antigen if we wish to protect against attack by strains of high virulence.

These observations of Felix and Pitt offer an explanation of the interesting results recorded by Perry, Findlay, and Bensted in a series of reports from the pathological department of the Royal Army Medical College. These workers had already been led, on the basis of a considerable series of experiments, to the conclusion that virulence for mice, rather than mere smoothness in the usually accepted sense, offers the best criterion of immunizing power. In their latest paper they offer additional and more detailed evidence in support of this view, showing that none of the commonly accepted tests for smoothness—colonial appearance, stability in saline, a negative Millon reaction, or the agglutinability of killed cultures by an 'O' antiserum—can be relied upon as a proof of immunizing value. They note, in agreement with the findings of Felix and Pitt, that their virulent and highly immunizing strains are, in the living state, relatively inagglutinable with an ordinary

'O' antiserum, though one at least of their agglutinable strains has shown a quite definite immunizing capacity. Those who have a liking for tradition will learn with pleasure that the famous 'Rawlings' strain of typhoid bacillus, which has played so honourable a part in the history of antityphoid inoculation, has, after a temporary lapse into senility and ineffectiveness, been successfully rejuvenated, and is now the most potent of the tested strains.

The Significance of Leucorrhœa

By ALBERT SHARMAN, M.D., B.Sc., M.C.O.G.

(From the *Medical Press and Circular*, Vol. CLXXXIX, 4th July, 1934, p. 10)

LEUCORRŒA may be defined as that degree of vaginal discharge (other than blood) sufficient to soil the clothes or necessitate the use of a sanitary napkin, and considered by the patient as an appreciable departure from her normal state. A small quantity of vaginal discharge is normal, and its features are best studied in the healthy virgin. It consists of a thick, white, highly acid fluid (pH 4.2 to 4.8) derived via the vaginal epithelium. The latter contains no glands, and therefore the word 'secretion' is, strictly speaking, a misnomer. The acidity is due to lactic acid, which results from the utilization of glycogen, present in abundance in the epithelial cells, either by the action of Döderlein's bacilli or by non-bacterial enzymes. Microscopic examination of the discharge shows a homogeneous bacterial flora of Döderlein's bacillus and desquamated vaginal epithelium. The cervical secretion is thick, mucoid and clear, normally scanty in amount, and is constantly and definitely alkaline, ranging in pH from 8.0 to 9.0. The secretion elaborated by the uterine endometrium is somewhat like water in colour and consistence, is alkaline in reaction, and of very little importance clinically.

Leucorrhœa is a very common complaint, and is most frequent in married, parous women. It is also encountered in married nulliparæ, in virgins and in children. The very mild degrees of excessive discharge, pre-menstrually or temporarily during conditions of depressed general health, are of little clinical moment. Leucorrhœa is a symptom producing frequently much discomfort and distress, and by reason of its profuseness or persistence may make life miserable. Many women, however, are not anxious to discuss the symptom with their medical practitioner until matters reach such a stage that, despite their own efforts at treatment, the persistence of discharge compels them to seek advice. This delay, coupled with the fact that many women regard quite a considerable amount of vaginal discharge as normal, has the effect of frequently making the complaint one of long duration, when advice is first sought. It is, therefore, of importance that the general practitioner should have a clear understanding of the pathogenesis and treatment of the condition.

SOURCES OF DISCHARGE

An excessive discharge *per vaginam* may reasonably arise from any one of three sources—vagina, cervix or uterus—and it is essential to consider the possible lesions and factors which may be productive of discharge from each of these sites.

Least commonly is the corpus uteri responsible, and in these cases polypi, submucous fibroids or endometrial carcinoma may be found. Infection of the uterine cavity as a source of leucorrhœa is extremely uncommon. This has been conclusively proved by histological and bacteriological examination of the endometrium in a large number of cases. The general view that endometritis is a common condition and is frequently the cause of leucorrhœa is quite erroneous. Very rarely indeed is the Fallopian tube the source, but a watery discharge *per vaginam* may be encountered in tubal carcinoma.

Cervical infection following childbirth, abortion or gonorrhœa is much the most frequent cause. The pathology responsible for these discharges consists of redundant hypersecreting glandular tissue, sometimes associated with insufficient drainage of the secretion. The commonest organisms found (excluding gonococci) are diphtheroid bacilli, coliform bacilli, staphylococci, varied anaerobes and Gram-positive diplococci. On inspection, the cervix may be seen to be eroded or lacerated, or hypertrophied or ulcerated. Chronic endocervicitis is very frequently present. The lacerated and infected cervix may be the precursor of carcinomatous change, and where there is suspicion that the latter may be present, biopsy is essential. Syphilitic or tubercular ulceration of the cervix is uncommon, but this possibility should be borne in mind. A tubercular cervical lesion is rarely primary, but may be associated with tubal or uterine tuberculosis.

The vagina is a frequent source of leucorrhœa, most commonly the discharge being of infective origin and secondary to endocervicitis, but sometimes non-infective. Rare pathological conditions in this site which may produce the symptom are carcinoma, benign tumours, tuberculosis and adenomatosis vaginæ. Probably the most common form of discharge in the infective group is that due to the *Trichomonas vaginalis*. Although this parasite was first described by Donné in 1836, very little attention was paid to it as a pathogenic agent and as a cause of leucorrhœa until recent years. A considerable literature on *Trichomonas vaginalis* vaginitis has now appeared since 1928, particularly in America. The *Trichomonas* is a flagellated protozoon which varies considerably in size, being usually larger than a polymorphonuclear leucocyte, but smaller than an epithelial cell, and is best studied by means of hanging-drop preparations or by diluting a drop of vaginal discharge with a drop of normal saline on an ordinary glass slide. The organisms may readily be seen on account of their characteristic movements with the ordinary high-power lens. The discharge in this condition is almost invariably copious, watery, yellowish, finely frothy or foamy, and irritating. The vulva is frequently inflamed, and portions of the vaginal wall are covered by small, punctate, hyperæmic or granular areas. With the exception of the *Trichomonas*, vaginal parasites as a cause of leucorrhœa are not of much importance. *Oxyuris vermicularis* may be found, especially in the vagina of neglected infants. Fungus infection of the vagina is rarely encountered. A simple catarrhal vaginitis may be productive of excessive discharge. In women who have passed the menopause, this may be very persistent, and its causation is closely associated with the great diminution or complete loss of the vaginal defensive power, which is intimately related to atrophy of the epithelium, loss of glycogen and scantiness or disappearance of Döderlein's bacillus.

Leucorrhœa in young virginal women is often a difficult problem in practice. Mild degrees of this are not uncommon, and the condition readily clears up on general medical or tonic treatment and, indeed, with no treatment whatsoever. When excessive and persistent it becomes very disturbing, liable to produce neurosis, and requires careful investigation.

With a few rare exceptions, virginal leucorrhœa may be divided into two groups: (1) infective, and (2) non-infective. In the infective group the majority of the cases are *Trichomonas vaginalis* infections, although such conditions as yeast or monilia vaginitis may be encountered.

Among the non-infective cases there is a group in which hormonal disturbance is strongly suggested, either by the individual's make-up or by gross menstrual dysfunction, such as prolonged or almost complete amenorrhœa. In other cases there is no obvious evidence of endocrine imbalance and no distinctive clinical features are noted. Sometimes the complaint dates from puberty, and excessive discharge may be noted before menstruation first commences. The laboratory

findings in the two categories of cases of leucorrhœa are summarized in the following table:

	Non-infective	Infective
Secretion	.. White, viscid, cheesy.	Grey-yellowish, fluid, frothy.
Smear	.. Grade I flora (epith. cells and Döderlein's bac.)	Grade II or III flora. (Pus cells, trichomonas and mixed bacterial flora).
Culture	.. Döderlein's bacillus.	Profuse, mixed.
Reaction (average pH)	4.4 (4.2 to 4.7).	5.6 (4.9 to 6.0).

Vaginal discharge may be encountered in children, when it is frequently due to gonococcal vulvo-vaginitis. The susceptibility of the vagina in these cases is probably dependent on the absence at this stage of any protective vaginal mechanism; for it has been shown by Cruickshank and Sharman that after the first month of life, throughout childhood, until puberty, the bacterial flora of the vagina is sparse and varied, glycogen is absent from the cells of the vaginal epithelium, and the normal discharge is scanty or absent, and, when measurable, alkaline in reaction. Contrasted with this, it is to be noted that gonorrhœal vaginitis does not occur in the first two to three weeks of life, when a simple homogeneous flora of Döderlein's bacilli associated with a highly acid non-purulent 'secretion' is present in the infant.

Leucorrhœa in pregnant women is not uncommon. Cruickshank and Baird (unpublished) have shown that in a series of pregnant women complaining of vaginal discharge, while *Trichomonas vaginalis* infection was not uncommon, in 39 per cent of the total cases the evidence was that the symptom was due entirely to an increased amount of the normal physiological 'secretion'. The causative factor in this process is hormonal; and is probably due to the progressively increasing elaboration of oestrin during pregnancy.

INVESTIGATION

Investigation of a case of leucorrhœa should consist firstly of inspection of the vulva, when the presence of redness or excoriation of the labia, or injection of the orifices of Bartholin's duct or of the urethra should be noted. The naked-eye characters of the discharge should be observed as to colour and consistence. In simple vaginitis it is usually thin or semi-purulent; in venereal disease it is thick and irritating; and in malignancy it is frequently watery, malodorous and blood-stained. When thin, yellowish and finely frothy, it suggests *Trichomonas vaginalis* infection. Fresh-drop examination, in saline, of the discharge will reveal these flagellates when present.

In all cases of doubt as to the nature and source of leucorrhœa, the reaction (H-ion concentration) should be estimated. This is very simply done by the use of a colorimetric apparatus such as the capillator (British Drug Houses) which gives information of much value. If the pH of the discharge is less than 5.0, it can be assumed with certainty that the discharge is of purely vaginal origin. A highly acid reaction such as this excludes gonorrhœa. On the other hand, if the pH of a vaginal discharge is greater than 6.0, it points strongly to the probability that the discharge is of cervical origin. A direct smear should be made and stained for bacteriological examination. The recognition of particular types of organisms present in the vagina is seldom of much value, especially in the non-virgin; but it is more convenient and helpful, in judging the nature of a discharge, to follow the plan of recognizing three types of bacterial flora, or three grades (I, II, III) of 'cleanliness' (reinheitsgrad). Grade I consists of a homogeneous bacterial flora of Döderlein's bacillus, occasionally accompanied by yeasts and a highly acid (pH 4.0 to 4.4), whitish, cheesy secretion consisting of desquamated vaginal epithelium. Grade III, corresponding to Döderlein's pathological

flora, contains several types of bacteria, such as diphtheroids, enterococci, staphylococci, vibrios and coliform bacilli, and is accompanied by a less acid and even alkaline discharge (pH 5.6 to 7.6). Grade II is intermediate between these two. Döderlein's bacillus being present in association with one or more other bacterial types, while the pH of the secretion usually varies from 4.6 to 5.6.

The vaginal wall may show evidence of inflammation. The cervix should then be inspected for the presence of erosion, ulceration, laceration or ectropion of the lips. When the cervix is infected a smear should be made and examined for the presence of gonococci. A careful bimanual pelvic examination will give information as to the condition of the uterus, tubes and ovaries. Only when other causes can be excluded and an intra-uterine cause suspected, should the cervix be dilated and the uterus curetted.

TREATMENT

Treatment depends largely on the diagnosis of the source of the discharge. When this is due to a neoplasm, involving uterine body or cervix or the vagina, it must be removed. Where cervical infection is present it should be treated by cauterization or excision of the infected area or by amputation of the cervix. In cases of vaginal infection treatment consists in the local application of antisectics to the vaginal wall, generally in the form of douches or instillations. *Trichomonas vaginalis* vaginitis is very resistant to treatment, which must be thorough and persistent. Iodine, acriflavine, biniodide of mercury and tincture of green soap are probably the most satisfactory agents. Particular care should be paid to treatment immediately after menstruation, on account of the tendency to recurrence at this time.

With regard to cases of discharge of non-infective origin, local treatment is not likely to influence the condition. Theoretically, hormone therapy might prove of value; but we have tried many preparations and are not satisfied with their efficacy in this direction. Numerous varieties of tonic and vitamin preparations have been given, but the results have been inconstant and on the whole unsatisfactory. General medical treatment, however, may be employed. The tendency in non-infective cases to spontaneous remission and cure must be taken into account in assessing the value of any treatment. The important point is that it should not follow along the therapeutic lines necessary in cases of the infective category. It must always be borne in mind that leucorrhoea is not a disease, but an expression of disease, that is, a symptom, and that the precise exciting cause must be determined. It is useless to perform a dilatation and curettage of the uterus in the great majority of cases, for it is based on an erroneous conception of the source of the discharge, and may even be followed occasionally by infection. It must, therefore, be emphasized that in deciding the method of treatment in every individual case, both a careful clinical examination and a full laboratory examination of the discharge are essential.

Pulmonary Tuberculosis after Sunbaths

By A. HOPE GOSSE, M.D. (Cantab.), F.R.C.P. (Lond.)

and

G. S. ERWIN, M.B., Ch.B. (N. Z.)

(Abstracted from the *British Medical Journal*, 7th July, 1934, p. 15)

In view of our opinion from the experiences gained from this clinical study we venture to draw the following conclusions:

1. It is dangerous for anyone who has had hæmoptysis, especially if recent, to sunbathe until tuberculosis of the lungs has been excluded by a thorough examination, including an x-ray examination of the chest.

2. It is inadvisable for people who have recently lost weight, or who are feeling abnormally tired, or who have other suspicious symptoms to sunbathe without the same precautions.

3. Sunbathers who feel tired or feverish, or who perspire at night after a sunbath, should take their temperature, and, if it is above 99°F. in the evening, no more sunbaths should be attempted until they have been passed as fit.

[In view of the popular theory regarding the value of unlimited exposure to the effect of sunrays, particularly in this disease, the conclusions arrived at by these writers should be of interest to medical men in this country.—Editor, I.M.G.]

Glaucoma

By H. B. STALLARD, M.A., M.D., F.R.C.S.

(From the *Practitioner*, Vol. CXXXII, May 1934, p. 573)

GLAUCOMA is the term applied to a complex group of ocular conditions the distinctive feature of which is a rise of intra-ocular pressure. For clinical convenience glaucoma is classified as primary and secondary, and either of these groups may culminate in acute congestive manifestations or progress in an insidious chronic state from the initial symptoms and signs to the final stages of absolute blindness and pain. An intermediate stage between the acute and chronic states is described by some authors as 'sub-acute', but as such is within the fluctuating bounds of this disease it seems to me that this does not merit a separate label of classification.

Pathology

In a limited space it is impossible to touch upon the fringe of the complex ætiological problems of glaucoma other than briefly. A mass of experimental and clinical work has been done in attempts to elucidate the cause of primary glaucoma, and although many valuable contributions to this subject have been made the truth still evades us. Elliot described the filtration angle as the 'cockpit' of glaucoma and the cupped optic disc as its 'graveyard'. An appreciation of the structure and function of the tissues in the vicinity of the filtration angle is essential to an understanding of many of the features of glaucoma. The balance between the production and drainage of the intra-ocular fluid, the part played by the intra-ocular blood pressure and blood volume, the distensibility and compressibility of the ocular tunics, the physical states of the vitreous and lens, the hydrodynamics of moving intra-ocular fluids, the effects upon the ocular contents of certain abnormal chemical constituents in the blood, toxins, hormones and the interaction of the sympathetic nervous system are among some of the important problems concerned in the solution of the cause of glaucoma. Controversy persists about the manner in which the intra-ocular fluid is formed and drained from the eye. Probably it is produced by a process of filtration through the capillaries of the ciliary body and secretion through the ciliary epithelium: the fluid destined for the anterior chamber is believed to be formed from the pars plicata of the ciliary body and that which passes into the vitreous from the pars plana. The fluid circulates forward behind the iris, through the pupil and into the anterior chamber and also some passes posteriorly into the vitreous. Drainage is probably effected in the filtration angle by a combination of suction by the backward and inward displacement of the scleral spur on contraction of the longitudinal and circular fibres of the ciliary muscle and by the osmotic pressure exerted in the canal of Schlemm, which is in intimate communication with a deep scleral plexus of veins. Relaxation of the ciliary muscle allows the scleral spur to move forwards and outwards again and the ligamentum pectinatum by its elastic recoil

to become approximated to the filtration angle. It is probable that some drainage takes place along the perivascular lymphatic sheaths of the central retinal vessels at the optic disc. Aqueous fluid entering the open anterior crypts of the iris is drained along the perivascular lymphatics of the iris stroma.

The essential cause of an increase of intra-ocular pressure is obstruction to drainage at the filtration angle. In acute congestive glaucoma, this is effected by oedema and turgidity of the body and engorgement of the iris, in chronic glaucoma by the swelling of the vitreous or the lens pressing forward the iris root and ultimately causing this to adhere to the posterior surface of the periphery of the cornea. The production of a vascular crisis leading to engorgement of the capillaries of the uveal tract will initiate a rise of intra-ocular pressure. Such a state of affairs has been produced experimentally by Duke-Elder, who, by raising the intra-ocular pressure above that in the ophthalmic artery for a variable duration, found that within 30 seconds of releasing the pressure there was vaso-dilatation of the iris vessels, increased permeability of the capillaries and a histamine-like substance in the aqueous. By stroking the iris with an intra-ocular cannula similar events accompanied by a rise of intra-ocular tension were observed. Duke-Elder explains the acute vascular crisis, increased permeability of the intra-ocular vessels and destructive rise of intra-ocular pressure as due to the liberation of histamine and the dissemination of its influence over the uveal tract by a system of axon reflexes. The instillation of histamine into the conjunctival sac of a cat will cause a rise of intra-ocular pressure and a vaso-toxic substance has been obtained from the aqueous in acute glaucoma and is probably related to histamine. Some cases of glaucoma are comparable to an oedema of the uveal tract. Maynard reported 20 cases of glaucoma in epidemic dropsy in Calcutta.

Anatomical factors disposing to glaucoma are a small globe, rigidity increasing with age, prolongation of the ciliary processes allowing the lens to move forward, increase in size of the lens which continues to grow after the rest of the eye has ceased to enlarge, and sclerosis of the ligamentum pectinatum. Hereditary and familial predisposition plays a part in some cases. Infantile glaucoma (buphthalmos) is due to defective development of the filtration angle and its structures. There is a faulty line of iris cleavage and the canal of Schlemm may be absent.

These are by no means all the facts implicated in the aetiology of glaucoma. In the early stages of the disease it is impossible to detect any histological changes by any methods at our disposal to date. The material available for examination is mainly eyes badly damaged by long-standing disease. In the earlier stages the iris root is applied to the posterior aspect of the periphery of the cornea, but can be separated from it. Aqueous is absorbed through the iris crypts and from the stroma passes through the ligamentum pectinatum into the canal of Schlemm. Later adhesions occur, but drainage is still effected along the iris stroma. Finally, the iris becomes adherent, atrophic, bunched up with a semi-dilated pupil and no absorption takes place through the crypts. Ectropion uveæ and the formation of new vessels on the anterior surface of the iris follow. Atrophic changes also occur in the ciliary body, the ciliary processes becoming drawn out and hyaline deposits occurring in the sub-epithelial connective tissue. The choroid is flattened and atrophic and there is perivascular lymphocytic infiltration around the venæ vorticosæ and proliferation of the living endothelium. Degenerative changes occur in the nerve fibre and ganglion cell layers of the retina, and the lamina cribrosa becomes displaced backwards, producing cupping of the optic disc. Through lack

of adequate nutrition the lens becomes opaque and finally the eye is blind and painful.

Secondary glaucoma is an event in a number of intra-ocular diseases. Some of the more important of these are inflammation of the anterior part of the uveal tract, traumatic cataract, dislocation of the lens, intra-ocular hæmorrhages and neoplasms, certain post-traumatic and post-operative states, in fact, any pathological condition which impedes the drainage of the intra-ocular fluid from the filtration angle by mechanically blocking it.

Clinical features and diagnosis

Symptoms.—The necessity for the early recognition of glaucoma is paramount, and like other surgical emergencies, it should be ever in the forefront of the practitioner's mind. Tragedy and disaster follow in the wake of a missed diagnosis. The greatest care and patience must be expended in eliciting the history, and often this is indefinite and vague. Any person in the fifth, sixth and seventh decades of life complaining of neuralgic pain in the eye or its vicinity requires the most conscientious investigation of his symptoms and physical signs. In a typical case the pain is neuralgic in type; it is felt in the affected eye, the frontal, temporal and malar regions, and may radiate to the vertex; its onset is generally in the early morning after rising, passing off in a few hours as the patient moves about, and returning later in the day towards evening when he is fatigued, to be eventually relieved by sleep. The severity of the pain varies from a mild headache to the agonizing pain which prostrates the victim of an acute attack of glaucoma and causes him to vomit, become collapsed and have an irregular pulse. During an attack of pain the vision is impaired owing to corneal oedema, objects appearing 'misty', 'steamy', or 'foggy'. For the same reason lights are surrounded by 'rainbow fringes' or 'haloes'. Occasionally 'blue flashes' are noticed during a rise of intra-ocular pressure. The character of some sufferers becomes appreciably changed, they show irritability of temper, are depressed, introspective and difficult to reason with. I have known a man's temper and disposition agreeably reversed after a trephine operation.

Signs.—The incidence is slightly higher in women than in men, and the former are more liable to an attack of acute congestive glaucoma than the latter. Jews, Egyptians and certain races of Negroes are more prone to this disease than other nations. Glaucoma is prevalent in India. In some instances a familial predisposition to glaucoma is of a simple dominant character, continuous in descent and transmitted by both sexes. Rossi, working on anthropological measurements, states that the glaucoma patient corresponds nearly to the brachycephalic Alpine race. The disease is more prevalent in persons with small corneæ and small globes such as hypermetropes but the myope is by no means immune. In primary glaucoma the anterior chamber is shallow and the periphery of the iris is approximated to the posterior aspect of the cornea, narrowing and partly occluding the filtration angle. In the early stages of the disease the pupil is round and active and the iris crypts and stroma normal. In acute congestive glaucoma the pupil is semi-dilated, oval and inactive owing to the compression of ciliary nerves by the increased intra-ocular pressure and to the vascular engorgement and oedematous condition of the iris and ciliary body. In the late stages of chronic glaucoma the pars iridica retinae is drawn round the pupil on to the anterior surface of the iris, forming a chocolate-brown ring with an irregular outer border, so-called ectropion uveæ. The iris stroma becomes atrophic and flattened, and new vessels appear on its anterior surface.

When the intra-ocular pressure is raised the cornea becomes hazy from oedema of the epithelium and the substantia propria. In the higher degrees of pressure

small vesicles form in the corneal epithelium and may rupture. The cornea in an acute attack of glaucoma has the appearance of ground glass, is dull and lustreless. Associated with this there is marked congestion of the conjunctival and ciliary vessels in the vicinity of the corneo-scleral junction, the lids are oedematous, the globe is tender and feels stony hard on palpation. The intra-ocular pressure can be estimated clinically in two ways: (1) by digital examination with the forefingers placed on the upper lid over the globe, when the eye is closed, and used in the manner of palpating for fluctuation, and (2) the employment of the Schiotz tonometer. The former is of value only as a rough estimate of the grosser changes in intra-ocular pressure, for even with considerable experience it is difficult to detect by this method small but nevertheless significant rises in intra-ocular pressure. The Schiotz tonometer is by no means an instrument of scientific perfection and accuracy, and at the best it gives a rough estimation of the compressibility of the globe, but it is useful for the purpose of comparison with readings taken at intervals and it affords a more exact standard than digital examination. A few drops of holocaine, 1 per cent, in the presence of a little weak acetic acid, are instilled into the affected eye. The lids are retracted and held over the upper and lower orbital margins by the operator's forefinger and thumb in such a manner as not to cause any pressure on the globe. The patient is directed to look straight up to the ceiling and not to squeeze or move his eye. The tonometer is gently applied to the cornea and readings recorded with several weights applied to the piston. Owing to daily variations in the intra-ocular pressure in glaucoma it is well in a suspected case to record readings between 9 and 10 a.m. and 5 and 7 p.m. or at such other times as may appear necessary from the facts of the case. The condition of the intra-ocular pressure is the clinical feature of primary importance, and chiefly on this rests the conduct of the case. It is the earliest sign in glaucoma, appearing before any other change. During sleep it rises, culminating in the early morning and lessening with muscular exercise during the day. Troncosco's gonioscope is an instrument which used with a contact glass over the cornea and sclera enables the surgeon to examine the state of the filtration angle magnified by 32 diameters, and on the findings to determine the mode of treatment to be tried.

In the prodromal stages of glaucoma there is a delay in the development of dark adaptation, a dulling of the sensitivity to dim light and a slowly rising light minimum sense. Special apparatus is necessary to record this alteration in the light sense and is outside the scope of routine clinical application. Later events show changes in the field of vision, such as crescentic enlargement of the blind spot, defects in the nasal part of the field, paracentral scotomas, generalized contraction of the peripheral field of vision and, finally, loss of central vision and blindness. Cupping of the optic disc has already been referred to as the 'graveyard' of glaucoma (Elliot). To wait for it to appear as a physical sign is analogous to waiting for the autopsy. The pallor of the optic nerve head, which so often accompanies this sign, is a testimony to the death of nerve fibres and is an unfavourable prognostic sign.

The diagnosis of secondary glaucoma demands a wide knowledge of ophthalmology and the pathological states that may produce a rise of intra-ocular pressure. The employment of the slit-lamp and corneal microscope in the diagnosis of early cases has often revealed changes which suggest that the glaucoma is secondary in nature and not primary, as was at first suspected by other clinical methods of examination.

In secondary glaucoma the anterior chamber is sometimes deeper than normal owing to the accumulation of aqueous rich in colloids that cannot drain

by osmosis through the normal channels of exit from the eye. Blood, pus and soft lens matter in the anterior chamber may suffer a similar fate. Iritis, cyclitis, cataract, dislocated lens, vitreous and choroidal haemorrhages, intra-ocular neoplasms, central vein thrombosis and diabetes under insulin treatment are among some of the more important pathological conditions to be searched for.

A careful differentiation of primary and secondary glaucoma is essential in deciding upon the treatment of a case, particularly is this so in iritis in which the pupillary margin becomes adherent to the lens capsule, rendering the pupil irregular in outline and obstructing the free passage of aqueous from the posterior to the anterior chamber. In early cases of iritis the slit-lamp will reveal some inflammatory cells in the anterior chamber, punctate precipitates of leucocytes on the posterior surface of the cornea ('k. p.'), oedema and vascular congestion of the iris stroma. The use of atropine in primary glaucoma spells disaster and the employment of eserine in iritis is not helpful.

Treatment

Acute glaucoma.—An acute attack of glaucoma must be regarded as a surgical emergency of a very serious character requiring prompt measures to reduce the intra-ocular pressure. Miosis is aimed at by the instillation of eserine drops, 0.5 or 1 per cent, at five-minute intervals for half an hour and then half-hourly until the intra-ocular pressure approaches the normal or operative treatment is imminent. Eserine should also be instilled into the other eye twice daily, for it is probable that early chronic glaucoma may be present and not yet have been detected. The patient is put to bed, and morphine may be necessary in many cases on account of the severe pain; it may also assist on account of its miotic effect. Heat in the form of continual hot bathings, an electrically-heated eye-pad or the application of medical diathermy is of value. The technique of the medical diathermy is briefly as follows:—The small active electrode is circular and is covered with several layers of cotton-wool wrung out in saline, applied evenly to the closed lids and held in place by a rubber head-band, which must be thoroughly dried before use. The different electrode, also covered by a similar pad, is applied to the forearm. Then the current is switched on and strength in the secondary circuit gradually increased until a comfortable sensation of warmth is experienced by the patient; this varies between 300 and 600 milliamperes. The duration of treatment is five minutes. Before the electrodes are disconnected the meter is brought back to zero and the main current switched off. Several such applications of medical diathermy will reduce the intra-ocular pressure from about 70 to 40 mm. Hg. in many cases. Two or three leeches applied to the temporal region on the affected side play a time-honoured part in the immediate treatment of acute glaucoma.

The intravenous injection of hypertonic saline solution has proved to be effective in reducing the intra-ocular pressure for a number of hours and thereby enabling the surgeon to operate under more favourable conditions. 50 c.cm. of 30 per cent. saline can be used alone or combined with gum arabic to raise the colloid content of the blood and to increase its osmotic pressure. The injection must be given slowly with the patient in the recumbent position. Complications in the nature of giddiness, collapse, and a fall of blood pressure have occurred when the injection has been made too rapidly. This method of treatment is contra-indicated in patients suffering from nephritis, a low blood-pressure, and a feeble constitution. After the injection intense thirst is felt, but it is necessary to limit the intake of water by the mouth. The oral or rectal administration of salines is uncertain in its effects.

If after one or two hours the intra-ocular pressure is not considerably reduced and the pupil not fully contracted an iridectomy should be performed as soon as possible. A general anæsthetic is often necessary, but in some cases the operation can be performed after careful infiltration of Tenon's capsule with novocaine and adrenaline. If the intra-ocular pressure falls to normal and there is satisfactory miosis an iridectomy is still indicated as the patient is liable to a recurrence. It is a more satisfactory operation after an acute attack of congestive glaucoma than trephining or other procedures which have as their object the formation of a filtering cicatrix.

Chronic glaucoma.—In the early stages of the disease and before there is an enlargement of the blind spot or nasal field defect, treatment by the miotics, eserine (0.25-5 per cent) or pilocarpine (0.5 per cent), instilled twice daily, may be given a trial and the patient kept under careful supervision. Pilocarpine is less irritating than eserine, but probably slightly less effective. It is a useful alternative in cases in which eserine irritation occurs. Massage of the globe in the morning and evening is helpful in promoting the drainage of the intra-ocular fluids, and anything productive of cerebral congestion should be avoided. Records of the intra-ocular tension and the visual fields should be made at frequent intervals, the former are better recorded in the morning as soon after rising as possible. The patient should be warned of the danger signals associated with a rise of intra-ocular pressure and of the importance of seeking immediate medical attention, also of the bilateral nature of the disease. Failure to keep the intra-ocular tension within physiological limits by miotics is an indication for operative treatment. To wait for visual field loss, cupping of the optic discs, and other classical signs of the later stages of the disease is to invite disaster.

There is no entirely satisfactory operation for the relief of chronic glaucoma. Many procedures have been devised to effect a filtering scar for the drainage of the intra-ocular fluid from the filtration angle through the corneo-sclera or the sclera and into the sub-conjunctival tissues, where absorption takes place. Of these, Elliot's corneo-scleral trephine with peripheral iridectomy is the best in the majority of cases. Lagrange's sclerotomy, Herbert's trap-door sclerotomy, and cyclodialysis are indicated in some instances. Iridectomy in chronic glaucoma without attempting to make a filtering scar is unsatisfactory, as the iris in the vicinity of its root has already become firmly adherent to the back of the cornea, where it obstructs the filtration angle and at operation tears away at the anterior limit of this zone of adhesions and so fails to open the filtration angle. The types of scar produced in the corneo-sclera after trephining are variable as regards their size, appearance and efficacy in filtering. Some become dense and ineffective after several months and the operation has to be repeated if the intra-ocular tension rises. Others are thin and ectatic and occasionally suffer late infection. About 50 per cent remain satisfactory for five years. The extended use of the gonioscope in practice may afford the ophthalmic surgeon additional help in deciding the type of operation indicated. After operation it is still necessary for the patient to present himself for periodic examination at monthly or two monthly intervals. In the late stages of glaucoma the eye becomes blind and painful. Excision of the globe is necessary in most cases, and, indeed, is justified as a few contain an unsuspected sarcoma of the uveal tract which, in the later stages of glaucoma, has not been recognized on account of opacities in the lens and media. If excision is refused, some relief from pain may be obtained by injecting 1 c.cm. of 2 per cent novocaine, followed five minutes later by 2 c.cm. of 80 per cent alcohol far back into the orbit, the puncture being made at a site between the lower border of the

external rectus and the outer border of the inferior rectus.

Secondary glaucoma.—The treatment of secondary glaucoma is that of the underlying ocular condition. In iridocyclitis atropine, heat, salicylates; and the treatment of focal sepsis are important. The presence of soft lens matter or blood clot in the anterior chamber may necessitate a paracentesis and wash-out of the anterior chamber after the intra-ocular pressure has been reduced by medical treatment. Dislocation of the lens into the anterior chamber associated with glaucoma requires extraction. For iris bombé iridotomy or iridectomy is necessary. When a malignant intra-ocular neoplasm is detected the eye should be excised. The treatment of secondary glaucoma often presents many difficult problems. The main therapeutic principle is to reduce the intra-ocular pressure by medical means and to be wary of surgical measures in inflammatory cases. If such become necessary, to interfere as little as possible in achieving the effect aimed at by the operation.

Infantile glaucoma (buphthalmos).—A condition of raised intra-ocular pressure occurs in infants owing to congenital defects in the formation of the filtration angle, such as a failure of the line of cleavage between the iris root and the periphery of the cornea, absence or malformation of the canal of Schlemm, intra-uterine infections resulting in anterior uveitis and peripheral synechiæ occluding the filtration angle. The ocular tunics are relatively soft and elastic in infancy and become stretched considerably by the raised intra-ocular pressure. The cornea is larger than normal, has a wide base, is prominent, thicker in the centre than at the periphery, and may show grey lines on its posterior surface from ruptures in Descemet's membrane. The sclera is thin and stretched, and all the dimensions of the globe increased. The anterior chamber is deeper than normal and the filtration angle occluded by the adhesion of the iris root to the periphery of the cornea. The canal of Schlemm may be small, narrowed, malformed or absent. The iris is flattened and atrophic. The lens is displaced backwards and much flatter than normal. The optic disc is cupped, the uveal tract, retina and optic nerve show atrophic changes characteristic of glaucoma. This condition is progressive, and treatment by miotics is useless. Surgical procedures, such as trephining, Herbert's sclerotomy, iridectomy, and other manœuvres are disappointing in their results. Both eyes are often affected, but sometimes one only.

Conclusion

The onset of glaucoma is in most cases insidious and must be searched for carefully in any person over 40 years of age complaining of neuralgic headaches. Sometimes the symptoms are very slight and appear negligible to the patient. Failure to recognize it and to establish early treatment leads to disastrous consequences. The most important sign before all others is the raised intra-ocular pressure, which is detected only by careful observations made on a patient suspected of glaucoma in the morning and evening, or at such times as symptoms are experienced. The disease is generally bilateral, and it is imperative to keep the patient under observation for the remainder of his life. The results of surgical treatment are on the whole satisfactory in 60 to 70 per cent of cases, although the prognosis will depend much upon the stage at which the disease is effectively treated and other factors peculiar to the individual case. Much patience, tact and fortitude are needed by the medical practitioner in piloting the patient through all the changing phases of his mental reactions to the disease, beginning with his initial amused indifference to the situation and ending in some instances with his pathetic terror as realities begin to cast their dark shadows over him.

Diet and Endocrine Deficiency

By H. GARDINER-HILL, M.D., F.R.C.P.

(From the *Practitioner*, Vol. CXXXII, January 1934, p. 92)

A VERY brief review of the metabolic functions of the endocrine glands will convince the most sceptical that dietetic problems are intimately associated with endocrine defects. There is, for instance, the well-known effect of the thyroid on the basal metabolic rate, and the important part played by iodine in the genesis of simple goitre. The secretion of the parathyroids is intimately connected with calcium metabolism, particularly as regards its deposition and mobilization from bone. Of the pituitary hormones and their metabolic functions less is known, though pituitrin from the pars intermedia, probably secreted through the posterior lobe, has well-known effects on water and sugar metabolism. Pituitary hormones also have suspected relationships with fat metabolism, though the evidence is far from convincing. There is some reason to suppose that one of them is connected with the distribution of circulating fat. Recently some animal experiments have been described, in which an extract of the anterior lobe appeared to play a significant part in the production of ketosis. Next there is insulin, the hormone of the islet tissue of the pancreas, and its well-known effect on carbohydrate metabolism. In discussing the metabolic functions of the suprarenals, and particularly the cortical hormone, we are on less sure ground. Cortin is known to be an important factor in maintaining the efficiency of the muscular system. Clinically, this is well illustrated by the severe asthenia of Addison's disease, in which it is deficient. Experimentally it is known that injections of the cortical extract produce a marked increase in the power of doing work in normal subjects, both human and animal. Some authorities have suggested that the adrenal cortex is concerned with fat metabolism. It appears to be a storage depot for lipoids. Then, it is to be remembered that clinical observations have repeatedly emphasized the frequent occurrence of obesity in, what has been termed, the adreno-genital syndrome. The effect of the sex glands on metabolism is also little understood, but it is a well-known fact that metabolic disturbance follows castration. This review will give an indication of the lines on which a clinical discussion of the relationship between diet and endocrine deficiency should proceed.

Simple goitre, iodine and dietetic deficiency

In the field of thyroid disease a close relationship between diet and endocrine deficiency is found in studying the ætiology of simple goitres. These may be of three main types—the diffuse colloid, a simple hypertrophy; the nodular adeno-parenchymatous, in which hyperplasia is predominant; and, thirdly, the lymphadenoid goitre of myxœdema.

We will take the first two types for consideration. Probably the nodular adeno-parenchymatous gland is a later stage of the diffuse colloid, in which attempts at compensation have failed. Thyroid deficiency may be found with either in the later stages, though far more commonly with the nodular than with the diffuse. The evidence associating lack of iodine in the diet with the prevalence of these goitres is most suggestive, though there is every reason to suppose that they may also result from other causes. Simple goitre is rare in communities where the diet contains a sufficiency of iodine. There is much evidence, on the other hand, to relate the prevalence of goitre in endemic areas with deficiency of iodine in soil or water. The well-known results of iodine prophylaxis in endemic areas in America, Switzerland and New Zealand provide additional proof that iodine must be an important factor in the prevention of goitre,

and its end-results—thyroid deficiency. Some recent work suggests that the presence of iodine protects, rather than that lack of iodine is the cause of such goitres. It seems to be immaterial which view is accepted, if the importance of iodine as a factor is admitted. In endemic areas, prophylactic treatment consists of the addition of iodine, or iodides, to the diet. In ordinary communities, sufficient iodine is present in the diet for the maintenance of normal thyroid function. A mixed diet containing an abundance of fish, fruit and vegetable should ensure adequate supplies of iodine.

A third type of simple goitre, to which attention has been drawn, is the lymphadenoid goitre of Williamson and Pearce. It is chiefly of interest as the gland found in association with myxœdema, and for the fact that McCarrison has been able to produce it experimentally in rats, by feeding them on a diet deficient in vitamin A. All the symptoms of fully-developed myxœdema can be controlled by thyroid extract, and dietetic measures are not usually necessary. If, however, a considerable degree of obesity has developed before the diagnosis of myxœdema has been made, and treatment with thyroid extract instituted, dietetic restriction, such as is recommended subsequently in the section dealing with obesity and given in conjunction with thyroid extract, will be found to produce more satisfactory results.

Tetany, hypoparathyroidism and calcium deficiency

In the field of parathyroid disease there is also a close relationship between dietetic problems and endocrine deficiency. A study of tetany shows that it may be associated with a number of different conditions—hypoparathyroidism, rickets, over-ventilation of the lungs, gastro-intestinal disturbance, vomiting with loss of hydrochloric acid, and diarrhoea. It is only with the first two pathological states that we are here concerned, and in both the characteristic feature is a depression of the level of the blood calcium, such as is not found in the other groups. Hypoparathyroid tetany is usually seen clinically after surgical operations on the thyroid, though it is a rare complication. Idiopathic hypoparathyroidism is also known to occur. In some types of rickets depending on a vitamin D deficiency, tetany may be found with low serum calcium, similar to that following parathyroidectomy.

What then are the respective rôles of the parathyroids and vitamin D in these disturbances of calcium metabolism? Bone deposition and denudation seem to depend on the presence of the parathyroid hormone, its principal action being to mobilize calcium stores from the bones. Vitamin D, calciferol, on the other hand, seems to be more concerned with the absorption of calcium through the intestinal wall. In the vitamin D deficiency of some forms of rickets, the result of lack of exposure to the sun of either the diet or the individual, with blood calcium low, and characteristic changes in the bones, vitamin D administration restores the blood calcium to normal. So far as present evidence goes, it seems that the level of the serum calcium is maintained by these factors, controlling in the one case the absorption of calcium from the gut, and in the other the degree of bone deposition and denudation.

These data emphasize the important part played by parathormone, vitamin D, and supplies of calcium in the diet, in the treatment of clinical tetany with low serum calcium. Fortunately, tetany of this type is rare. The condition of post-operative hypoparathyroidism provides an example of the different forms of treatment required. In the acute post-operative condition, a high calcium intake is the most important consideration. In mild and chronic cases regular daily calcium supplies, with cod-liver oil or calciferol, should keep the individual free from symptoms. In more severe cases, however, and especially those in which parathyroidectomy has been complete, or almost

complete, the usual rules applying to endocrine deficiency diseases must be observed. Regular and continuous treatment with the deficient hormone must be carried out. It will probably suffice to administer to such patients parathormone, in doses of five to ten units daily, with high calcium diet and vitamin D.

Disturbances of carbohydrate metabolism and endocrine deficiency

Two clinical syndromes, diabetes and glycosuria, have to be considered under this heading. The former is a true endocrine deficiency, the result of under-functioning of the islet tissue of the pancreas, to which the term hypo-insulinism can be applied. The precise action of insulin is not completely understood, but we know that, following its administration, the blood sugar is lowered apparently the result of a withdrawal of glucose by the tissues. Insulin appears to control the storage of muscle glycogen, and probably also of liver glycogen. The most striking feature of the diabetic is the loss of power on the part of the tissues to utilize glucose. This is shown by hyperglycemia and glycosuria. When the amount of carbohydrate utilized falls below a certain level fat katabolism is also affected, fatty acids are imperfectly oxidized, and ketosis develops. These changes can be corrected by the administration of insulin. Moreover, if coma from ketosis has supervened, sufficient glucose given with insulin will restore normal fat metabolism. The modern treatment of diabetes with insulin is a great therapeutic advance and the insulin-treated diabetic, in whose case appropriate adjustments of diet have been made, compares favourably with a normal individual. The main problem is to provide adequate supplies of carbohydrate, and to ensure its utilization. In the past, it was the custom in treating diabetics to restrict severely the intake of carbohydrate, whilst the limit of fat was fixed by the necessity of avoiding ketosis. Within the last few years, however, this practice has changed, and there is now a tendency to swing over to a more normal carbohydrate intake adequately covered by insulin.

Glycosuria, without symptoms of diabetes, is found in other endocrine syndromes, though it is doubtful if in these conditions it is attributable to a true endocrine deficiency. An example is the glycosuria found with pituitary lesions, such as the basophile adenoma of Cushing. It also occurs in the adreno-genital syndrome, with changes in the adrenal cortex. In the early stages of both conditions the individual tends to become obese, whilst later on glycosuria develops. These are the fat, bearded diabetics of Achard and Thiers. Even when glycosuria develops, however, weight is not lost, and ketosis remains absent, in spite of carbohydrate starvation. It would appear that the storage mechanism for carbohydrate is defective without the usual symptoms resulting from decreased output of insulin. Perhaps there is an increased output of some antagonistic principle from the pituitary or adrenal, which counteracts the action of insulin. At any rate, pituitrin and adrenalin will overcome the effects of insulin hypoglycemia. The treatment of obesity and glycosurias of these types is largely a dietetic problem.

Cachexia and endocrine deficiency

Under the heading of endocrine, or endogenous, cachexia are usually included a group of not very rare conditions, of the underlying pathology of which little is known. They are characterized by extreme emaciation, loss of appetite, severe constipation and gastro-intestinal hypofunction, which can be demonstrated radiologically, endocrine features, such as amenorrhœa and often hypertrichosis, cardiovascular asthenia with hypotension, slow pulse and a peculiarly sluggish circulation, with cyanosis of the extremities. Possibly the group includes several different syndromes. Anorexia nervosa of psychological origin

must be differentiated. In the typical case of endogenous cachexia the picture of endocrine disturbance predominates. Simmonds has described one type, the result of anterior lobe pituitary deficiency from infarction. These individuals are wizened in appearance, wasted, and the sex functions are in abeyance. Another type, with hypertrichosis and vascular asthenia, has been attributed to deficiency of the adrenal cortex, and appears to be the reverse of the adreno-genital fat syndrome already referred to. The adrenal pathology, however, of this condition has not been worked out. Though the background in these cases is one of endocrine disturbance, they all without exception show a remarkably sub-normal food intake, and attempts to correct this are generally the most difficult problem of their treatment. Replacement therapy with prolactin has been reported favourably upon, in the pituitary type. Insulin therapy *plus* glucose, however, is probably the most hopeful line of treatment in the others. Cortin is under trial.

Obesity and endocrine deficiency

Dietetic problems and endocrine deficiency are closely related in obesity. Endocrine obesity may occur as the result of thyroid deficiency, with structural lesion of the pituitary, such as the adenomata of all types, and in Fröhlich's syndrome due to a craniopharyngeal pouch cyst, in the adreno-genital syndrome and in deficiencies of the sex glands, especially those resulting from their surgical removal. Thyroid obesity appears to result directly from a deficiency of the active principle of the thyroid secretion, and the resulting lowering of the basal metabolic rate. Both the obesity and the basal metabolism can be corrected by the administration of an amount of thyroid extract equivalent to that which is deficient. The sex gland obesities may also result from a true deficiency of secretion, though there is seldom any alteration in the basal metabolism in these cases. The relationship of the pituitary to obesity is by no means clear. It is usually considered to be a result of deficiency of the secretion of the posterior lobe and intermedia, but the administration of pituitrin seldom produces any striking change in the clinical condition of the patient. In the adreno-genital syndrome it seems extremely doubtful if the obesity is due to a deficiency of secretion at all. The clinical and metabolic features rather suggest some hyperactivity of a storage mechanism, which, in the later stages of the disease, tends to become defective.

It must be briefly mentioned that endocrine obesity, with gross structural lesions such as these, is relatively rare, compared to the large number of obese patients who exhibit similar endocrine stigmas. In the majority of the latter, there is a family history, not only of obesity of the same type, but also of the same endocrine stigmas. The most likely explanation seems to be that these individuals have inherited some functional endocrine disturbance of a minor but similar type to that seen in the organic syndromes.

Though our present knowledge of the underlying metabolic disturbance in endocrine obesity is so incomplete, a practical experience of any of these various conditions will show the very important part played by food intake, both in their development and treatment. If the principle be accepted that the body weight cannot be maintained without ingestion of food or water, and there seems no reason to doubt it, a lowering of the intake will result in loss of weight, even in endocrine obesity. In endocrine cases, however, this treatment should not be employed without replacement therapy of the deficient hormone, or deterioration in health ensues. If, for instance, in the obesity of hypothyroidism, with its low basal metabolic rate, the diet of the individual is lowered, the basal metabolism will be lowered further, with exaggeration of the hypothyroid symptoms. These, however, and the obesity can be corrected by dietetic measures, given in conjunction with thyroid extract.

Various dietetic schemes have been introduced for the treatment of obesity, simple and endocrine, the essential feature of the majority being that they are sub-caloric. It is important to remember that the intake of a working individual cannot be lowered below a certain level, with the maintenance of good health. If, therefore, a rapid loss of weight is desired, such as can only be obtained by severe restriction of diet, then it is advisable to carry out such initial treatment in bed. In fact, the principle of losing weight rapidly in bed, when in endocrine cases replacement therapy can also be accurately controlled, and then of maintaining a stationary weight, by regulation of diet and dosage accordingly, when the patient gets up and about again afterwards, will probably give the best results in the treatment of these conditions.

Summary

To summarize this article, it is apparent that a close relationship exists between dietetic problems and endocrine deficiency. This is well illustrated by observations on iodine in simple goitre, and vitamin A deficiency in lymphadenoid goitre. Calcium supplies, vitamin D, and parathormone are intimately associated in the metabolism of calcium, while insulin is the controlling factor in carbohydrate metabolism. In some instances, obesity and cachexia are due to endocrine deficiency, though the part played by diet in these conditions is at least equally important. As regards general principles of treatment of the series of conditions under consideration, the essentials seem to be replacement of the defective glandular secretion, with reorganization of the metabolic disturbance by appropriate dietetic measures.

The Inheritance of Diabetes

By PRISCILLA WHITE, M.D.

ELLIOT P. JOSLIN, M.D.

and

GREGORY PINCUS, D.Sc.

(From the *Journal of the American Medical Association*, Vol. CIII, 14th July, 1934, p. 105)

Is it possible to predict the onset of diabetes in a given individual at a given time? This question was uppermost in our minds, 17th December, 1931, for while we were treating a 5-year-old girl for diabetic coma her solicitous similar twin sister waited nearby. Surely, we thought, if the theory of the inheritance of diabetes is correct here is an instance in which the prediction is possible. Our patient had just developed diabetes and the second twin should develop the disease and likely within a decade. 10th April, 1934, the first child returned to the clinic with her twin sister. Three weeks previous to this the second twin had developed the symptoms of diabetes and her mother had found a red reduction with the Benedict test. At the clinic the diagnosis was confirmed, for the urine was found to contain 4.6 per cent of sugar and the blood 0.28 per cent.

The conception of the inheritance of diabetes is not new, for it was first described by Morton in 1696 and has been emphasized by many students of the disease. Inconsistencies in the series of reports are bound to arise, first, because of the short duration of the life of diabetic patients prior to the use of insulin, so that the data of family histories have been incomplete and the mode of transmission has not been demonstrable, and, second, because some schools believe in the manifold origin and character of the disease and others in its unity. The former may thus select for analysis only those patients who have a positive history of inheritance, and the latter will analyse consecutive case histories. We ourselves believe in the unity of the disease—unity of symptoms, manifestations, complications and the underlying cause.

On this conception of the unity of diabetes our own analyses have been made.

The evidence of the inheritance of diabetes rests primarily on three facts: (1) the concurrence of diabetes in homologous twins, (2) the greater incidence of diabetes in the relatives of a diabetic person than in a control population, and (3), indirectly, on the demonstration that mendelian ratios are found in large series of case histories selected at random and in smaller series of families tested for accuracy of diagnosis and for latency of the disease.

The concurrence of diabetes in twins has already been described in the literature. This has obviously suggested the inheritance of the disease, since in 80 per cent of the cases reported the twins were of the homologous type. No analysis of dissimilar twins has been made, but from such a comparative analysis much can be learned, for, if the disease is inherited, the incidence of diabetes in both similar twins should obviously exceed the incidence in dissimilar twins. The latter, in fact, all conditions being equal, should show the same inheritance as that found among ordinary brothers and sisters.

An analysis of our own data shows that forty-one of our diabetic patients have a twin. Of this group thirteen pairs were known to be similar and thirteen dissimilar. We were compelled to exclude fifteen sets of twins because of the death of one of the twins in infancy. Among nine of the thirteen sets of similar twins both were diabetic, whereas in only two of the thirteen pairs of dissimilar twins were both diabetic. The incidence among the siblings of control, diabetic and twins populations is compared in table II.

It is evident that an overwhelming excess occurred among the group of similar twins.

The age incidence of diabetes must be considered here, for perhaps the excess in the similar twin group could be explained on the basis of greater age. This is not the case, for although 45 per cent of the individuals in the similar twin group were in the age incidence zone of 50 years, 35 per cent of the dissimilar twins were of the same age, and the median age of the two groups was in the same decade. The family history of diabetes in the two groups of twins was nearly identical, since there were three instances of parental diabetes among the dissimilar twins and two among the similar twins.

The statistically significant difference between the occurrence of diabetes in a diabetic and a control population was that 2 per cent of the parents of our control population had diabetes whereas 8 per cent of the parents of our diabetic patients had the disease. Diabetes occurred ten times more frequently in the brothers and sisters of diabetic patients than in the control group. Criticism of such data is often given that perhaps we selected unfairly against diabetes. This is not actually the case and is substantiated by the control series of German and English investigators.

Expected mendelian ratios of the simple recessive type were found in our three types of crosses (diabetic \times diabetic, diabetic \times carrier, carrier \times carrier). Among 800 odd consecutive families studied, ninety-eight diabetic patients (or 4 per cent) were found in the 2,309 siblings of the carrier \times carrier cross; forty-eight (or 10 per cent) in the 475 siblings of the diabetic \times carrier cross, and eight diabetic children (24 per cent) in the thirty-three instances of the diabetic \times diabetic cross. If our data had been complete we would have expected more—16 per cent in the first, 40 per cent in the second and 100 per cent in the third—but this could occur only if all members of the families had attained old age. The significant fact is this: The expected ratios were 1 to 2.5 to 6.1, and the actual ratios were 1 to 2.4 to 5.7.

It is on this point and the concurrence of diabetes in homologous twins that the validity both of the initial hypothesis of inheritance and of the mendelian type of transmission rests, for if the basic aetiology

For overcoming chronic malnutrition

A report (Journ. of State Med., Jan., 1934) suggests that urban populations exist in a state of chronic undernourishment, not, perhaps, in respect of the quantity of food taken but of its deficiency in one or more of the essential vitamins.

This state of deprivation is cumulative in action, its deleterious effects being manifest in reduced resistance and consequent increased susceptibility to colds, influenza and other diseases of the respiratory system; disorders of the digestive tract, dilated stomachs, ulcers and similar lesions are often the outcome of chronic vitamin deficiency, as also are badly-formed, irregular and carious teeth.

Radio-Malt is a powerful weapon with which to combat this menace of chronic malnutrition; a spoonful or two per day ensures a sufficiency of the essential vitamins in correctly-balanced proportions.

RADIO-MALT

(Standardised Vitamins A, B₁, B₂ and D)

of diabetes were due to an infection, trauma or nutritional state it is highly improbable that such an excess would occur in homologous twins and less than one chance in a million that the three ratios would be fulfilled in this manner. Actually we have identified only one-fourth of the diabetic patients expected, and the next step has been the attempt to find the missing patients. There are two sources. Some may have occurred in those individuals who died of other causes before developing diabetes and some will be

found among people who have not reached the diabetic danger zone of middle life. The remainder of the problem depends on the time or age behaviour of the disease and the non-diabetic lethal factors. The validity of time behaviour or age incidence of diabetes is undoubted, for in each consecutive thousand of our cases, our cases compared with those of other clinics, and in American clinics as compared with European clinics the incidence behaviour is essentially the same. From these two factors the potentiality for developing diabetes in parents and children has been predicted.

Although these data seem obviously convincing, besides dealing with a population whose status is changing—once diabetic always diabetic, but once non-diabetic not always non-diabetic—another source of confusion is possible. Dependent on case histories,

TABLE II

Incidence of diabetes in a control, diabetic and twins population

Type of population	Number of individuals	Per cent of siblings with diabetes
Control	.. 153	0.6
Diabetic	.. 523	6.0
Dissimilar twins	.. 13	16.0
Similar twins	.. 13	70.0

some individuals classified as diabetic may be non-diabetic and some classified as non-diabetic may actually be diabetic. Therefore, a series of control and another of diabetic families were studied for symptoms and tested with routine blood sugar tests and with tolerance tests.

Relative hyperglycæmia was characteristic of the families of diabetic individuals, no matter whether the examinations were routine or by tolerance test: 14 per cent in the 169 persons tested by routine and 25 per cent in the 95 persons examined by tolerance test were diabetic in type, as compared with 2 per cent in the control population. These cases were not classified as diabetic and not utilized in our calculations, because we have dealt only with clinical cases of diabetes and not with potential diabetes. Time alone will reveal the significance of the latter observations. The tested selected families on the basis of clinical diabetes confirmed the consecutive case histories.

CONCLUSIONS

1. Each member of similar twins developed diabetes more than four times as frequently as each member of dissimilar twins; namely, 70 per cent of the former and 16 per cent of the latter.

2. The incidence of diabetes in the relatives of a diabetic population is significantly greater than in a non-diabetic group.

3. Mendelian ratios were found in a consecutive series of diabetic cases and in a selected mendelian population tested by histories and blood sugars.

4. Many blood relatives of diabetic patients have symptomless hyperglycæmia the significance of which is unknown. These instances occurred when one would expect diabetes to develop according to mendelian inheritance.

5. We believe that the potentiality for developing diabetes is transmitted as a simple mendelian recessive trait and that the secondary factors which permit the expression of the gene can best be studied among predestined diabetic patients; namely, homologous twins of diabetic patients and the offspring of two diabetic patients.

Reviews

OPERATIVE GYNÆCOLOGY.—By Dr. H. V. Penham and Dr. J. Amreich. Authorized translation made by L. K. Ferguson, M.D. Volumes I and II. 1934. J. B. Lippincott Company, Philadelphia and London. Pp. xxvi plus 245 in volume I and viii plus 246 to 779 in volume II. Largely illustrated, mostly in colour. [Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta.] Price, Rs. 78-12 for complete volumes

It seems quite impossible to avoid the word monumental in reviewing this work, mainly because of the magnificent lines on which it has been conceived and executed, but also because it is no mere record of a passing phase, but is likely to remain as a permanent contribution to the science of gynecological surgery for many generations, and because of the associations of the word, reminding us that the senior author did not live to see his work completed.

The first volume constitutes an introduction to the subject and deals with such matters as the anatomical relationship of the various structures in the pelvis, pre- and post-operative complications and their treatment, antisepsis and asepsis, anaesthesia, and preliminary surgical procedures, such as opening the abdomen. The second volume describes actual surgical operations. Despite the size of the book, strict selection has had to be exercised in the choice of the procedures described, because of the minute details of technique into which the authors have entered. The treatment of cancer of the cervix by radical abdominal and vaginal hysterectomy constitutes the central feature of the book, but the surgical treatment of many other conditions is discussed and described.

The book is not in any sense a textbook of gynaecological surgery for the student or general practitioner, but it is a handbook (in the German sense of the word) for the young surgeon, especially—but not only—the gynaecological surgeon. No book is capable of turning a raw student into an efficient surgeon, but if any book could effect this change, this would be the book; the illustrations are so detailed, yet so realistic, that whilst turning the pages one finds oneself transported to dissecting room or operating theatre, as the case may be. In the written descriptions of the different procedures no detail is too obvious or too unimportant to escape minute treatment. In surgical books the opening of the abdomen is often dismissed in a few words or lines, but not so in this book; it is described on 31 (large quarto) pages with 37 illustrations.

The young English-speaking surgeon may consider himself very fortunate that this book is available in his language, and if he cannot afford a trip to Vienna, he will find that by purchasing and reading this book he will gain many of the advantages of such a trip at a much smaller expenditure of time and money. For this, much credit is due to the publishers, the authors, the translator and by no means least to the artist, Karl Hajek, for his beautiful illustrations.

SYNOPSIS OF PHYSIOLOGY. Third Edition.—By N. J. Vazifdar, L.M. & S., F.C.P.S., Captain, A.I.R.O. 1934. Ideal Books Company (Medical Publishers), Bombay. Pp. 617, with 96 illustrations. Price, Rs. 7-8

PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM AND SPECIAL SENSES. Sixth Edition.—By N. J. Vazifdar, L.M. & S., F.C.P.S., Captain, A.I.R.O. 1934. Ideal Books Company (Medical Publishers), Bombay. Pp. 341, with 39 illustrations. Price, Rs. 5-8

THE volumes have been nicely got up and printed on good paper. The subject-matter has been carefully compiled and brought up to date, although a little more attention to histology is desirable. Nevertheless the books will be of great use to students in revising before examination. The tables are useful and will be found convenient for ready reference.

The volume on the *Central Nervous System and Special Senses* is the older of the two publications. It is already deservedly popular and needs no further commendation. This part of physiology is difficult to learn but Dr. Vazifdar has been able to alleviate this to some extent.

It is hoped these two volumes will be greatly appreciated by students.

P. D.

MODERN TREATMENT IN GENERAL PRACTICE.—Edited by Cecil P. G. Wakeley, D.Sc., F.R.C.S., F.R.S.E. 1934. Published by the Medical Press and Circular, London. Pp. viii plus 426. Illustrated. Available from Messrs. Baillière, Tindall and Cox, London. Price, 10s. 6d. [Messrs. Butterworth and Company (India), Limited, Calcutta, have the exclusive right of selling in India, Burma, Ceylon, Federated Malay States and Straits Settlements]

TREATMENT to-day is much more than merely writing a prescription; the developments in different branches of medical science have led to the recognition of other fields in therapeutics. In order, therefore, to cover the subject of treatment, it is not sufficient merely to review the action of drugs; the disease must be studied, its causation, its symptoms, its prognosis and its complications, all assist in determining the treatment.

The editor is to be congratulated for bringing out in a handy volume all the latest information and discussions on treatment of the various diseases, both surgical and medical, commonly met with by the practitioner. The articles in this volume have

been written by specialists. Etiology and symptoms are briefly discussed and only so far as they affect treatment. Indeed, the book is in all respects what its editor claims for it—a book written for the general practitioner and designed and intended to set forth concisely and lucidly the latest progress made in medicine and surgery.

The book is very well arranged and the discreet employment of the headings in heavy type makes reference very easy. It is written in a style at once readable and convincing and fills a distinct place in the literature on treatment and ought to find a place in the library of every medical practitioner in this country.

R. N. C.

STUDIES IN BLOOD FORMATION.—By T. D. Power, M.D., M.R.C.P., D.P.H., D.P.M. 1934. J. and A. Churchill, Limited, London. Pp. vii plus 124. Illustrated. Price, 8s. 6d.

IN the introduction the author apologizes for the nature and variety of his investigations; surely no such apology is necessary (here, at least), but we are not at all sure that some apology for their publication in book form is not due. In our opinion it would have been far better to have published the results of his investigations in some appropriate scientific journal. As the author admits, these are various and incomplete. In places the data are far too slender to base heterodox conclusion upon, and in others the experiments reported suggest the exercises of a student.

Malaria therapy, sulfofin, thyroxine and the inevitable Indian ink (spelt in at least three different ways) have been used as stimuli to produce the changes that he studies. The Indian ink bottle appears to exert an irresistible attraction on the embryo hæmatologist, but the results obtained with this medium are usually more spectacular than helpful.

Nevertheless, the book will be read with considerable interest by hæmatologists. Even if they do not agree with his conclusions, they will undoubtedly find many of the author's ideas stimulating, and to readers of this class we can recommend the book.

L. E. N.

PRACTICAL METHODS IN BIOCHEMISTRY.—By Frederick C. Koch. 1934. Baillière, Tindall and Cox, London. Pp. viii plus 280, with 17 figures. Price, 10s.

TO write a practical book on laboratory methods is not difficult, it is quite otherwise however with a good one. Originality in such a book is not easy to attain, usefulness to the practical worker is rather the ideal to aim at. The outstanding merit of this book is the detailed description of the chemical basis of the qualitative tests. So often such tests are described empirically. The pages on the reactions of carbohydrates in an alkaline medium and their reducing properties are particularly instructive and the introduction of graphical formula makes the text much easier. Another valuable addition to the book is the appendix. Apart from a number of receipts for making standard reagents there is (to mention one item only) a detailed description of the chemistry of oxidation by permanganate—a reagent used by so many and understood by so few, particularly in clinical medicine. The chapter on the blood pigments however falls short of the author's standard in the rest of the book. The recent work of Anson, Mirsky, Keilin *et al.* on the exact chemical relationship of the various hæmoglobin derivatives, *e.g.*, hæmo-chromogen and the hæms should have been given. There is also perhaps one excusable omission. A page or two or even a note on oxidation reduction systems might have been written as the subject is becoming of increasing importance on biochemical work. The

St. Bartholomew's Hospital Operation Table

Latest Model, with Improved Safety Mechanism for obtaining the Trendelenburg position.

This table is used throughout St. Bartholomew's Hospital, and in over *six hundred* other hospitals in all parts of the world. Built from suggestions made by Sir Holburt J. Waring, with subsequent improvements, it is a table suitable for all operations in a general hospital.

A hydraulic oil pump, worked by a pedal lever, enables the heaviest of patients to be easily raised or lowered. The whole table top can be rotated freely on the base, a short lever fixing it in the desired position. Two heavy ball-bearing wheels at one end and a rotary ball-bearing castor at the other end, permit of its being easily removed from the anæsthetic room to the theatre. The head and leg flaps can be adjusted to any angle by means of the fine adjustment, spring lever and quadrant action, which eliminates any possibility of injury to the fingers.

A Children's Model can now be supplied.

Other Fittings include :

Lithotomy Crutches	Shoulder Rests
Adjustable Back Elevator	
Douching Funnel	Arm Table
Anæsthetic Screen	
Two Arm Supports	Pelvic Supports
Head Support	Head Clamp
Instrument Table	
Sponge Rubber Cushion, etc.	

Illustrated booklet giving full particulars will be sent on application.

Clive Buildings, CALCUTTA

mathematical theory is allied to that of pH measurement and the chemical basis of oxidation and reduction as an electron transfer (so well described in the appendix) could both be incorporated into a small chapter or annex to that on hydrogen ion concentration. In spite however of these criticisms the reviewer intends keeping this book at his right hand in the laboratory.

H. E. C. W.

VENEREAL DISEASES: ITS PREVENTION, SYMPTOMS AND TREATMENT. Fifth Edition.—By H. W. Bayley, M.C. 1934. Chapman and Hall Limited, London. Pp. xv plus 260. Illustrated. Price, 10s. 6d.

This is a little book, consisting of 260 pages, in which a very concise account of venereal diseases is given. It is divided into five sections. Section I deals with the preventive aspect of venereal disease. Section II deals with the diagnosis and treatment of syphilis. In keeping with the importance of the disease it is the largest section in the book and very well written. It contains a few paragraphs on the malaria treatment of neurosyphilis and the treatment of cardiovascular syphilis. Section III deals with the diagnosis and treatment of gonorrhoea in the adult as well as with ophthalmia neonatorum and vulvovaginitis of girls. Section IV deals with non-specific lesions such as soft sore, bubo, phagadema, warts, etc. There is scope for improvement and elaboration of this section. Section V deals chiefly with the organization of the consulting room, methods of examination of patients and of specimens obtained from them. On the whole the book may be considered a useful and up-to-date one, though concise. It contains several illustrations, some of which are good. It can be recommended to students and practitioners who are not specialists in the subject.

K. V. K.

THE TREATMENT OF SYPHILIS: FOR USE OF THE MEDICAL PROFESSION. Published by Messrs. May and Baker, Limited, London. Pp. 66. Illustrated

This is a small handbook on the treatment of syphilis which is written chiefly with a view to advertise some of the antisyphilitic remedies such as Novarsenobillon, Tryparsamide, Metarsenobillon and Stovarsol sodium, Acetylarsan, Bisglucol, Bistovol, Neocardyl, Rubyl and Ametox manufactured by May and Baker, London. It contains valuable information regarding the use of these drugs. Practitioners using these drugs may find the book helpful.

K. V. K.

EXTERNAL DISEASES OF THE EYE.—By D. T. Atkinson, M.D. 1934. Henry Kimpton, London. Pp. xviii plus 704, with 479 engravings. Price, 35s.

This book is devoted for the most part to diseases of the anterior segment of the eye which the author very rightly considers to be the most important part of ophthalmology as they are seen more often than other varieties of ocular diseases and can be diagnosed without the use of special and expensive apparatus.

The book comprises fifteen chapters devoted to the history of ophthalmology, diseases of the eyelids, the lachrymal apparatus, the orbit, the conjunctiva, cornea, sclera, iris and ciliary body. In addition there are chapters on glaucoma, diseases of the crystalline lens, diseases of the external muscles of the eye, the hygiene of the eyes, history taking and case records, and finally remedies used in the treatment of external diseases of the eye.

Owing to the close association of ophthalmic and intra-nasal diseases a small portion of the book is devoted to a short description of nasal pathology and the treatment of intra-nasal conditions involving the eye.

The book is profusely illustrated with photographs of actual cases from wax models and from drawings made by the author himself. Many of these are excellent but some are poor, too small, and fail to show what the author set himself out to demonstrate.

The subject-matter contains little that is new and that which cannot be obtained in ordinary textbooks, the chapter on fungus diseases being an exception is excellent. Many of the operations and operative technique described would not be accepted in India more especially those on cataract and glaucoma.

The book can hardly be described as a reference work for ophthalmologists, but will prove useful and interesting to students and the general practitioner.

E. O'G. K.

HEALTH-GIVING DISHES.—Compiled by B. Brupbacher-Bircher. Edward Arnold and Company, London. Pp. xvi plus 239. Price, 6s.

As is pointed out in the preface, during the last few years more and more attention has been directed towards dietary, both in health and in disease. It is not however emphasized that, though we have now fully appreciated the fact that a diet of beefsteak alone is not an ideal one, we are also beginning to realize that a pure vegetarian is usually a deficient one. The fact is, a 'balanced' vegetarian diet is a luxury that only the rich, or the exceptionally-placed, can afford to indulge in and still maintain maximal health. However, those who have a fancy for a vegetarian diet, and are prepared to spend the time and money on preparing the various dishes described therein, will find this book, which is nothing more or less than a receipt book, of value and interest.

POCKET MEDICAL DICTIONARY OF THE PRINCIPAL WORDS USED IN MEDICINE AND THE COLLATERAL SCIENCES.—By the late G. M. Gould, A.M., M.D. Tenth Edition. Revised by C. V. Brownlow. 1934. (Over 40,000 words). H. K. Lewis and Company, Limited, London. Price, 10s. 6d. (with thumb index, 12s. 6d.)

THERE can never be such a thing as a completely comprehensive medical dictionary, as, even if it were possible to collect together the information necessary, many new words would be added to the language whilst the book was being printed. Failing completeness, utility is the next quality to be aimed at.

Consisting of over a thousand pages, this dictionary contains 40,000 words, and it will go into an ordinary-sized pocket, though not into the breast pocket of the morning coat of the fashionable physician, without causing him acute mental distress.

This dictionary has now reached its tenth edition and sixty-fourth printing. It only needs to be said that 800,000 copies have been sold. Any words of praise that we could muster would be of little value in the face of these hard and eloquent facts.

Few changes have been made in this last edition; inevitably new words have been added and a few corrections made. Certain tables of arteries, bones, etc., which were previously in the body of the dictionary have now been collected at the end and are placed there in alphabetical order, and other tables have been added. This is a distinct improvement. It is a very complete little dictionary and most excellent value for the money.

SEX DIFFICULTIES OF THE MALE.—By K. M. Walker, F.R.C.S. 1934. Jonathan Cape, London. Pp. 264. Available from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 3-12

Old wine in a new bottle—under a new and in many ways more satisfactory title, Kenneth Walker has given us what is in effect a second edition of a successful book, *Male Disorders of Sex*. The change of title will ensure a wider public for this book, which before attracted mainly the medical profession;

anticipating this the author has met his non-medical readers half-way and has translated some of his technical into more popular language, and has here and there added explanations. Nevertheless, the book is written primarily for the medical man and student, and may therefore be considered as a serious contribution to the medical sex literature of the day; as such it is particularly welcome.

Not only has the author attempted, but he has achieved, a book that can be read profitably, and with pleasure, by both the medical man and the intelligent layman. It is scarcely necessary to detail the scope of the book, but perhaps one should mention that the two longest chapters are on impotence and sterility,

and that these chapters are written principally from the medical point of view. The chapter on the difficulties of marriage—useful as it will be to the medical man—should be read by every educated man who is contemplating matrimony, and by many of those who have achieved it, but who have brought 'to marriage not knowledge, but a collection of social taboos, and personal prejudices that for them have the sanctity of revealed religion'.

The writer has a masterly style so unusual in this form of literature. Except in the minor matter of punctuation, we have no criticism whatsoever to offer, and we can whole-heartedly recommend the book to our readers.

Abstracts from Reports

LEAGUE OF NATIONS (INFORMATION SECTION). THE LEAGUE OF NATIONS AND LEPROSY. BY DR. ET. BURNET, JULY 1934

This article by Dr. Burnet should broaden one's outlook on the magnitude of the leprosy problem not only in India but all over the world. The institution of a centre for leprosy investigation in South America where race, customs and general climatic conditions differ from those prevailing here should open up the possibilities of new discoveries in virtue of its peculiar qualifications. As this new centre will be under the direction of the League of Nations, this will ensure its activities being correlated with those of other centres in the East.

In turning its attention to leprosy, the League of Nations has taken up one of the problems which have caused the greatest concern to the human race. Leprosy is a celebrated disease. From the remotest antiquity it has afflicted the world and the great geographical discoveries from the fifteenth to the seventeenth centuries have widened its domain. It has never ceased to be an object of terror to the peoples, a problem for the medical profession and a source of worry to governments. It was in order to cope with leprosy that the isolation of infectious patients was invented. In the Middle Ages it occupied a place at least as important as tuberculosis in the modern world. Many people, especially in Europe where they believe themselves to be no longer threatened, imagine that leprosy is now of interest only to dermatologists and specialists of exotic diseases. The truth is that there are at least 5 million lepers in the world, that in many countries leprosy is actively endemic with an occasional epidemic flare-up, and that, owing to the great amount of travelling and trade exchanges in the modern world, there is a steady, although not a very considerable, stream of infection coming into Europe.

The *British Empire Leprosy Relief Association* (B. E. L. R. A.) works in the British Empire, more especially in Africa, and through the medium of a special branch in India, where there are one and a half million lepers. The *Leonard Wood Memorial for the Eradication of Leprosy* (headquarters in New York) concentrated at first on the Philippines, but contemplates extending its action to other tropical regions. The *Mission to Lepers* (London) works in India, China and Africa. The *American Mission to Lepers* (New York) has branches in nearly all leprosy-infected areas, more especially China, Japan and South America; it has even endowed an institution in France, and has been instrumental in the organization of the *Chinese Mission to Lepers* (Shanghai). Italy has the *Opera Francescana internazionale*. Brazil, France, the Netherlands East Indies, the Philippines and Belgium have their (lay) societies for the relief of lepers and defence against leprosy. Several Catholic and Protestant religious orders—the Franciscan Sisters of Mary, St. Paul of Chartres, St.

Vincent de Paul, the Rhineland Mission—there is no space to mention them all—send to every quarter of the globe their missionary brothers and sisters without whom innumerable lepers would be abandoned.

Leprosy being a world-wide disease and a source of anxiety to all governments, whether in their own territory or in dominions, mandated areas and colonies, it is both natural and necessary that the League of Nations should take a prominent part in this international work. The multiplicity of existing organizations is an argument for rather than against such a course.

In 1923 the International Conference at Strasburg voted a resolution appealing to the League of Nations, which was then starting its great health work, to organize international machinery for the anti-leprosy campaign. In 1928, Brazil, greatly concerned by the recrudescence of leprosy in certain foci on its territory, requested the League of Nations to undertake a statistical and epidemiological enquiry on leprosy in the world. In 1926, Brazil proposed the creation of an international centre for the study of leprosy at Rio de Janeiro.

Brazil made to the League of Nations a proposal for the creation of an international study centre at Rio de Janeiro. The Federal Government offered an annual subsidy. Dr. G. Guinle, a philanthropist who has created admirable health institutions at Rio for the campaign against syphilis and cancer, offered a subsidy equal to that paid by the Government. The League of Nations consented to participate by means of research and travelling scholarships. The plan, although delayed by the world crisis, was nevertheless carried into effect in 1934. South America, in its turn, now possesses the centre which was the only leprosy region to lack it, and it is an international centre founded by Brazil under the auspices of the League of Nations.

Like similar institutions—the Institute of International Law, the International Institute of Agriculture, the Educational Cinematographic Institute, the International Institute of Intellectual Co-operation—the International Centre for the Study of Leprosy has one of the League committees as its governing body, in this case the health committee; the committee of management, working on the spot, consists of representatives of Brazil and other leprosy countries of the South American continent, namely, Argentine and Colombia. The director of the centre is a distinguished Brazilian scientist, Dr. Carlos Chagas.

The Rio centre must be a centre of scientific research. It is not qualified to intervene in the administrative organization of prophylaxis and treatment. Its statutes contain nothing which might lead to difficulties for the responsible authorities.

It will find admirable resources for its work in Brazil, comparable to those at the disposal of the Calcutta, Philippines, Japanese and Hawaiian centres. A leprosy hospital has been specially equipped by

Civilization
Has found us
Embarrassed
With thirty feet or so
Of food canal
Well adapted
For prehistoric days
Of irregular meals
With much
Useless material
In the menu.
And so, *constipation*
Became a disease
Of civilization.
But the same civilization
Has provided
The remedy — AGAROL.

Gentle and effective
As only a good
Mineral oil
Emulsion
Can be.
It lubricates
And softens ;
And also stimulates
The intestinal tract.
Palatable
Beyond complaint ;
Suitable
For adult or child,
Agarol is
The modern answer
To the problem
Of constipation.

Agarol is the original mineral oil and
agar-agar emulsion with phenolphthalein.

AGAROL *for Constipation*

the Federal Health Department to serve as a clinic. Five large modern leprosy hospitals, while remaining independent of the centre, will be open to research workers.

The general programme of work is governed by the state of our knowledge of leprosy and by the questions raised by leprosy practice. It is divided into three sections: clinical research and epidemiology; biology (bacteriology, serology, experimental medicine); chemistry, therapeutics and therapeutical chemistry.

THE ANNUAL REPORT FOR 1933 OF THE NATIONAL ASSOCIATION FOR SUPPLYING MEDICAL AID BY WOMEN TO THE WOMEN OF INDIA (COUNTESS OF DUFFERIN'S FUND INCLUDING THE WOMEN'S MEDICAL SERVICE)

This report which has just been published contains a comprehensive survey of medical work by women in India. Only a small excerpt can be taken from this report which covers a large field. The attention of the medical profession should be directed to one important branch namely child-welfare.

Maternity and Child-welfare Department, All-India Institute of Hygiene

Dr. Orkney writes:—Government sanction for holding a diploma course in maternity and child-welfare was obtained on 28th August, 1933, and the classes started on 15th October, with three students in attendance.

The arrangements made with the Presidency General Hospital for instruction in children's diseases has been most satisfactory. The Ante-natal Clinic at the Dufferin Hospital also affords abundant material and excellent teaching but individual instruction has been somewhat difficult because of the large number of patients attending and the limited accommodation in the out-patient department. Next year it is proposed to select 6 to 8 patients each session who will be examined under the direct supervision of the medical superintendent.

The facilities for post-graduate experience in advanced midwifery at the Eden hospital, so far as lectures and bed-side clinics are concerned, are good and practice in the administration of anaesthetics adequate but the opportunities for actual performance of obstetric manipulations are very limited. Practice in midwifery is a most important part of the training; the Eden hospital is the most suitable place in which to gain experience and it will be extremely unfortunate if the necessary changes cannot be made to bring the post-graduate practical work up to a reasonable standard. The period of internship ought to have finished in December, but owing to the late start of the course and the difficulty of getting abnormal midwifery cases, the students will continue to attend until each has conducted the necessary number of obstetric operations.

Accommodation in the Women Students' Hostel is limited and for future courses a possible alternative arrangement in the old Nurses' Quarters has been suggested by the Principal of the medical college.

Lectures and demonstrations in general hygiene, public health chemistry, ante-natal care and the organization of midwifery services have been given throughout the term at the All-India Institute of Hygiene and Public Health.

Part II of the diploma course will commence in January, 1934.

Maternity and child-welfare.—A maternity and child-welfare scheme designed to link up with the school medical service on the one hand and environment hygiene on the other, and to give the students a clear picture of the co-ordination of all the services for the promotion and maintenance of health came into operation in Ward 8, in May 1933. Those interested in the work being done by this service would do well to read this report.

ADMINISTRATIVE REPORT OF THE DIRECTOR OF MEDICAL AND SANITARY SERVICES FOR CEYLON FOR THE YEAR 1933. BY DR. R. BRIERCLIFFE, DIRECTOR OF MEDICAL AND SANITARY SERVICES

This report which contains a considerable amount of material on every branch of medical work in Ceylon should be consulted by those interested. Some of the general remarks should be of general interest.

General remarks.—The year 1933, like its two predecessors, was a healthy year. Although the general death rate (21.2) was a fraction higher than the record low death rate (20.5) of the previous year, the infant mortality rate (157 infant deaths per 1,000 births) was the lowest there has yet been, the birth rate increased from 37 to 38.6 and the excess of births over deaths (94,342) was greater than in any previous year.

Apart from smallpox and plague there were no serious outbreaks of infectious disease, though the typhoid rate still remained comparatively high. Owing to favourable climatic conditions malaria was less prevalent than in any of the past ten years with the possible exception of 1927.

At the end of the year a grant of Rs. 6,000 was kindly given by the International Health Division of the Rockefeller Foundation to enable an epidemiological investigation of typhoid fever to be made in the area of the Kalutara Health Unit. This investigation has since been started. The department is also indebted to the Rockefeller Foundation for a grant of Rs. 5,000 to be used as a 'Revolving Fund' for supplying cement concrete squatting plates of standard design for latrines in rural areas. The plates are sold at cost price to villagers who pay for them in small monthly instalments collected by the headmen or co-operative societies. From the end of March 1933, Rs. 1,800 had been loaned from this fund and 3,362 latrines plates provided. A Rockefeller Fellow was awarded to a government medical officer in October 1933 to allow him to undergo a scientific training in helminthology at the Calcutta School of Tropical Medicine and the Imperial Institute of Veterinary Research, Muktesar.

The leprosy survey of Ceylon, for which two officers had been trained and preparations made in 1932, started in the eastern province. Thanks to a visit of six weeks by Dr. R. G. Cochrane, secretary of the Empire Leprosy Relief Association, the leprosy problem in Ceylon has received a very thorough review and the policy now adopted as the result of his investigations and advice, should in the course of one or two decades bring about a very material diminution in the amount of the disease. The two survey officers are doing much more than merely finding new cases. In each area that they survey they train the department's medical officers, apothecaries and sanitary inspectors to recognize and deal with early cases of the disease, they arrange for the isolation in one of the two leper asylums of infective cases and they leave behind a local organization for the care and treatment of non-infective cases, for the 'follow-up' of old arrested cases and for the periodic examination of contacts. Since completing the survey of the eastern province where 46 new cases were discovered, the two officers have made a survey of Colombo and found there 230 new cases. The reports of Dr. Cochrane and of the leprosy survey officers have been published by Government in the form of a Sessional Paper II of 1934.

Valuable progress has been made in school, medical and health work during the year under review. Reference to section III A (3) will show that a policy for future work has been formulated and the machinery for putting that policy into effect arranged, and though the actual numbers of schools and school children dealt with may be small when compared with the total numbers in Ceylon (8,000 schools and 600,000 school children) an organization has been

provided which is capable of progressive development. In the towns dental trouble is the commonest cause of absenteeism and in Colombo a careful dental survey of school children has been made by the school medical officer who possesses qualifications in dentistry as well as in medicine. He has found that 76 per cent of the children in Colombo schools have dental defects which require attention and through his influence some of the larger schools and colleges have recently arranged excellently equipped dental clinics within their own buildings. Another important investigation started during the year has been the inquiry by the Director, Bacteriological Institute, into the signs of dietary deficiencies in school children (section IX). The department of education working in conjunction with the health education section of the medical department, has established a very practical system of health education in the vernacular schools of the island—the pupil throughout his whole school course is made to practice the health habits which he has been taught.

The Indian population on estates decreased from 741,289 in December 1929, to 609,170 in December 1933, as the result of the depression, but during this period, in spite of lower wages and unsettled conditions of work, the health of the estate population has steadily improved. In 1933, the death rate was 2.3 lower than that of the general population, the birth rate of 39.4 was much above the average of the past few years and the infant death rate of 181 is the lowest yet recorded. In September 1933, however, with improving trade conditions, the recruitment of labour from India began to revive and recently the rate of immigration has been almost 5,000 a week. With this large influx of new labour, health conditions on estates are likely to be adversely affected and higher sickness and death rates are to be anticipated for the next few years.

The infant death rate on the other hand appears to be declining more rapidly and steadily and the improvement must be attributed in some measure to the gradual dissemination of knowledge about infant care and hygiene from the numerous health centres and child-welfare clinics now established in Ceylon.

Definite improvements have continued to take place in teaching arrangements and facilities at the Ceylon Medical College and the hospitals associated with it. The reports and correspondence on the college since Sir Richard Needham's visit of inspection in March 1932, have been published by the Government as a Sessional Paper VI of 1934. The important influence which a good standard of training not only for doctors but for apothecaries, nurses, sanitary inspectors, and midwives will have on the quality of the work and services to be rendered by the medical department in the future cannot be too strongly emphasized. The training given to medical students has undoubtedly improved recently and is likely to improve still further as additional staff and buildings are provided.

REPORT OF THE EUROPEAN MENTAL HOSPITAL, RANCHI, 1933. BY LIEUT.-COLONEL OWEN A. R. BERKELEY-HILL, M.A., D.M. (OXON.), I.M.S., MEDICAL SUPERINTENDENT

THIS report, apart from interesting data about the incidence of the different types of mental disease, discusses the after-care system for discharged patients and the results of some of the more modern methods of treatment.

After-care of discharged patients.—Our 'follow-up-letter' system continues and the reports of the ex-patients received from themselves as well as from their guardians have been satisfactory.

In Calcutta, the Ranchi After-care Home (Bengal Presidency Council of Women), 62, Hazra Road, Ballygunge, and Toc H. Mark I (India), 2-2, Lansdowne Road, have continued to inspect periodically, and report on, the home conditions of the

discharged patients and give them the necessary advice and help. I tender my best thanks to them.

Treatment of mental disorder.—Special method of treatment.—During the year, the following special methods of treatment were carried out:—

(a) *Hydrotherapy.*—This form of treatment as instituted some years ago in this hospital in a manner which was then, I believe, unique, continues to show satisfactory results. During the year fourteen cases were treated of whom seven were subsequently discharged while the maniacal excitement of five others was considerably reduced.

(b) *Induced malarial fever.*—One case of acute mania was treated with blood taken from another person suffering from malaria (benign tertian). The immediate result was a slight improvement which has subsequently been maintained.

(c) *Prolonged narcosis.*—(Somnifen injections).—Three cases were treated in this manner. One was discharged cured. No improvement took place in the other two, one of them being a case of epilepsy with excitement.

(d) *Injections of sulfosin.*—Four patients were treated. Three recovered and were subsequently discharged. This form of therapy has the disadvantage of being extremely painful.

(e) *Somnifen.*—(Oral administration).—Two cases were treated with doses of somnifen by mouth (*m* xx thrice daily). Both cases were suffering from acute maniacal excitement. The treatment produced marked improvement.

(f) *Laudanum.*—(Orally).—One case of acute confusional insanity was treated with *m* xv doses of laudanum thrice daily, but no improvement was observed.

(g) *Glandular therapy.*—Three cases were treated with mixed glands. Two of these cases were suffering from schizophrenia. Of these one improved sufficiently to be discharged home. The other case showed a temporary remission of symptoms sufficient to permit of the patient being sent home on parole for a short time. The remaining case showed no change at all.

(h) *Cocaine following etherization.*—During the year, a report on some recent work of an eminent French woman psychiatrist in Paris came to our knowledge. The *raison d'être* of this form of treatment is the lowering of the strength of the forces of repression and the stimulation of the unconscious during light narcosis with a view to effecting contact with buried complexes and memories. This French observer had published a report on a series of investigations with different drugs known to be capable of stimulating and increasing psychic activity. The drugs she found most efficacious in this respect were cocaine and ether. One patient—a woman—was selected for this form of treatment. The results were eminently satisfactory and she was discharged shortly afterwards. Since her discharge she has written cheerful re-assuring news of herself. Prior to her admission, she had attempted suicide five times.

(i) *Serum therapy.*—Activated horse-serum was thrice injected in doses of 5 c.c. in a case of very severe epilepsy. The results were entirely disappointing.

One case of encephalitis lethargica with a Parkinson syndrome was treated with stramonium in the form of 2½ grs. pills. No effect followed this treatment.

(ii) *Occupational therapy.*—During the year, 43 patients were discharged as recovered or improved, all of whom had undergone occupational therapy. Of the twenty-four male patients, ten were treated in the carpentry section, six in the weaving and rug-making section, four in the cane section and one in the cookery section. The following additional occupations were introduced for women patients during the year:—

(1) Sealing-wax craft on account of the special attraction of the colour-schemes which it presents.

(2) Machine art-embroidery which is both interesting and creative.

(3) Dress-making. The latter appeals strongly to female patients.

IMMEDIATE STIMULATION LASTING INVIGORATION

Bovril not only supplies a safe stimulant in an easily assimilated form; it also builds up lasting strength because it has no lowering reaction.

The invigorating and restorative properties of beef, supplied by Bovril, enable patients to regain and maintain their strength. The value of Bovril as a stimulant-nutrient has been proved for nearly 50 years.

ANNUAL REPORT ON THE HOSPITALS AND DISPENSARIES IN THE CENTRAL PROVINCES AND BERAR FOR THE CALENDAR YEAR 1933. BY COLONEL N. M. WILSON, O.B.E., I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, CENTRAL PROVINCES

Number of hospitals and dispensaries

The number of hospitals and dispensaries at the close of the preceding year was 327. During the year under report, cheap-plan dispensaries were opened at Borakhedi in the Buldana district and at Patunbori and Fulsongi in the Yeotmal district. A dispensary was also opened at the Government Press, Nagpur, in order to give medical relief to the staff working there, and one at the Baraduar limestone quarry in the Bilaspur district. Subsidized dispensaries at Ner Pinglai in the Amriti district and Arni in the Yeotmal district, and one city branch dispensary of the Murr Memorial Mission Hospital at Nagpur, i.e., three in all, were closed during the year. The Mission Dispensary at Panagar in the Jubbulpore district was transferred from class IV (private-aided) to class V (private non-aided). Thus, the number of hospitals and dispensaries open in the province at the close of the year 1933 was 329 of which 164 were rural and 165 urban.

Number of patients

The total number of indoor patients treated in the state-public, local fund and private-aided hospitals and dispensaries increased from 34,035 in 1932 to 35,507 in 1933 and the average daily attendance from 1,312.66 to 1,415.05. The number of beds available rose from 2,112 to 2,163 or an increase of fifty-one, forty-eight of which were on the female side, viz, Victoria Hospital, Jubbulpore (20), Mission Hospital, Seoni (12), Main Hospital, Bhandara (7), Mayo Hospital, Nagpur (8), and Waraseoni dispensary, district Balaghat (1). There were 1,416 deaths during the year against 1,405 in the preceding year, the ratio thereof to the total number treated being 3.99 against 4.13 per cent during the last year. Of the total number treated during the year 5,127 were police cases, 1,221 paupers and 3,033 medico-legal cases against 5,328, 1,176 and 3,280, respectively, in the preceding year.

The number of outdoor patients treated in these hospitals and dispensaries decreased from 2,996,603 in 1932 to 2,871,962 in 1933 and the average daily attendance from 20,281.62 to 19,979.12. This decrease is partly due to the general health of the province being comparatively better than that of the past year and partly to the introduction during the year of the half-anna ticket system which has affected the attendance, especially in the outlying dispensaries in which people who frequently used to seek medical relief for minor complaints have stopped doing so to avoid payment.

Infectious diseases

The infectious diseases show an increase over the past year's figures under the following heads:—Influenza (8,288), leprosy (3,394), cholera (829), gonococcal infection (513) and pneumococcal infection of lung (366). Two hundred and thirty-seven patients were treated for smallpox against 280 during the previous year. Of these 73 were vaccinated, 74 were unprotected, while the vaccinal condition of the remainder was not known.

Venereal diseases

The total number of in- and out-door patients suffering from venereal diseases treated in all classes of hospitals and dispensaries rose from 31,749 in 1932 to 32,328 in 1933.

The treatment of cases of venereal disease in the branch dispensaries is most unsatisfactory owing to lack of drugs and equipment. The Civil Surgeon, Raipur, suggests that the leprosy specialist and leprosy duty assistant medical officers, all of whom are attached to the Public Health Department, should be

turned into venereal specialists as there is much venereal disease. The result of treatment in venereal cases is much better and the attention paid to leprosy by missionary institutions is considerable. The Commissioner, Chattisgarh division, while agreeing with the Civil Surgeon that the question of venereal disease is certainly a very important one in that division, states that it might be possible to have a staff that could deal with both of these scourges instead of only one.

Antirabic treatment

Antirabic treatment was carried out as usual at the five centres, viz, Nagpur, Jubbulpore, Raipur, Hoshangabad and Akola, where 1,655 patients were treated during the year against 1,517 in the past year.

Ticket system

With a view to improving the financial position, the proposal to charge a fee of two pice on each new patient, excepting paupers and those covered by paragraph 341 (4), (5) and (7) of the Central Provinces Medical Manual, at all the main hospitals, including provincialized ones, and the dispensaries managed by the dispensary fund committees, was given effect to during the year and a report on its working submitted to Government. As it has been found that this system has adversely affected the outdoor attendance in outlying dispensaries, the local Government, while sanctioning the continuance of the experiment for another year, has left these dispensaries from its operation.

Correspondence

NORMAL SALINE IN CHOLERA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I wish to draw the attention of your readers to a very simple and efficient method of administering normal saline either in cholera or other conditions of dehydration, after operations, etc.

The method one usually resorted to in cholera is intravenous transfusion which is often not only difficult but sometimes wellnigh impossible in the circumstances in which a medical man or woman has to work in a village or even in the poor hamlet of an ordinary head-quarter town. Further, intravenous transfusion is unnecessary in most cases, for one has to have recourse to it in cases of collapse, or when the pulse is, hardly, or not, perceptible at the wrist.

The method I devised in 1912 when on duty as a plague medical officer in the Central Provinces.

The following are needed:—

(1) A big enamel bowl, an aluminium or a brass *dekchi* or other suitable container (at a pinch) will serve the purpose for boiling water. (2) Water (preferably distilled or rain water) to make normal saline in the proportion of one drachm of sodium chloride (common table salt) to a pint of water. The saline can also be prepared by dissolving three tablets (hypertonic solution tablets made by Parke, Davis and Company or Burroughs Wellcome and Company) in a pint of water.

The saline is injected subcutaneously not by a needle attached to a rubber tubing with a funnel or flask at the other end, but by a 100 c.cm., 40 c.cm., 20 c.cm., 10 c.cm. or 5 c.cm. syringe (the smaller the syringe the more the manipulation required on the part of the medical officer). After washing the skin with soap and water and painting it with tincture of iodine, the whole thickness of the skin with the subcutaneous tissue either in the abdominal flank or other suitable area is pinched up and the needle (preferably a long one

with a thick bore) attached to the syringe is pushed well in almost to the hilt, and the saline injected. The syringe is now detached leaving the needle in position on the patient, refilled from the bowl or *dekchi*, adjusted again to the needle and the fluid injected. This process is repeated until, in the adult, a pint or so of saline is transfused on each side of the flank according to the requirements of each case (which will be indicated by the pulse, general condition, cramps, etc.); in the adolescent half a pint or more on each side, in the child four or five ounces or more on each side according to the age and the needs of the patient. The needle punctures are sealed with cotton-wool dipped in tincture benzoini composita (Friars' balsam) or collodium flexible. The transfused fluid is dissipated by gentle massage, thus expediting absorption from the injected tissues and rapid improvement in the patient's general condition.

In a severe case I administer two pints at a time three or four times in the 24 hours; in a case of moderate severity two pints twice daily usually suffice.

It is my practice to give an initial injection of strychnine and digitalin and subsequently strychnine alone every three or four hours to support the heart. I have found this procedure uniformly very satisfactory. Atropine sulphate—grain 1/100—injections are also useful when purging and vomiting are very frequent. This may be given along with the saline.

When on the subject of cholera one might say a word or two about Tomb's (essential oils) cholera mixture. I have used it almost from the very time that Tomb published his experience with this in Egypt and India and I found that fifteen-minim doses every half an hour give far better and more satisfactory results, in respect of rapid and more cures, than one-drachm doses every hour advocated by its author. The large dose of one drachm is not tolerated by the stomach as well as is a quarter-drachm dose and the results with this smaller quantity are certainly more encouraging than with the larger, while the patient feels decidedly happier. Half-drachm doses may be given after some hours if thought necessary, but I have seldom had occasion to use the larger dose. Tomb's mixture is also beneficial in diarrhoeas.—Yours, etc.,

A. F. W. DE COSTA, F.R.C.S., D.T.M.,
L.M.S., V.D. Major.

MEDICAL COLLEGE CENTENARY CELEBRATIONS

APPEAL

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—The Medical College Centenary celebrations will occur on January 28th to 31st, 1935. In this connection it is very desirable that the members of the staff of the College and former students should come forward with medical papers to be read at the morning sessions on the 29th, 30th and 31st. Such papers should be either (a) papers dealing with the history of the College and its development or (b) brief medical papers of practical interest in such subjects as medicine, surgery, gynaecology, ophthalmology, etc. It would also be desirable to exhibit interesting clinical cases.

May I appeal to you for help and collaboration in this matter? As the time will be limited, papers should be brief, or capable abstracts only being read.

In addition to the reading of papers and showing of clinical cases, it has been decided to have a medical exhibition, which will probably be housed in the pathology and physiology departments.

In this connection I would again appeal for your help and collaboration. Exhibits should be, as far as possible, self-explanatory with clear letter-press, and, as the amount of accommodation is limited, only the very best and most suitable materials should be exhibited.

As the programme has to be prepared well ahead, may I ask for an early reply?—Yours, etc.,

M. N. DE, M.B., M.R.C.P.,
Secretary and Convenor, Scientific
Sub-Committee,
Medical College Centenary.

MEDICAL COLLEGE HOSPITALS,
CALCUTTA,
25th September, 1934.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL M. D. WADIA, Civil Surgeon, is posted to Ambala on return from leave, with effect from 4th September, 1934.

Major A. Y. Dabholkar, M.C., is appointed to officiate as Director of Public Health for the Government of Bombay, with effect from the 14th March, 1934.

Major D. R. Thomas, O.B.E., Officiating Imperial Serologist, Calcutta, is appointed as Chemical Examiner to the Government of Punjab, Lahore, with effect from 6th September, 1934.

Captain W. McAdam is appointed temporarily to officiate as an Agency Surgeon and is posted as Chief Medical Officer in the Western India States Agency, Rajkot, with effect from the forenoon of the 4th August, 1934.

The services of Captain R. M. Lloyd Still are placed temporarily at the disposal of the Government of Burma, with effect from the 10th September, 1934.

Lieutenant C. B. Miller is restored to the establishment, dated 2nd August, 1934.

To be Lieutenants (on probation)

E. C. Rowlette, 1st August, 1934. (Seconded).

W. J. Virgin, 1st August, 1934, with seniority 1st August, 1933.

J. Brebner, 1st August, 1934, with seniority 1st August, 1933.

H. W. G. Staunton, 1st August, 1934, with seniority 1st August, 1933.

J. D. Gray, 15th August, 1934.

LEAVE

Lieutenant-Colonel K. G. Gharpurey is granted leave for five months and seven days, in India, with effect from 5th October, 1934, or subsequent date of relief.

Captain G. B. W. Fisher, Civil Surgeon, Rajshahi, is allowed leave for three months, and furlough under the military rules for five days, with effect from the 24th October, 1934.

PROMOTION

Captain to be Major

C. V. Falvey. Dated 17th April, 1934.

Lieutenant (on probation) to be Captain (on probation)

J. J. Barton. Dated 1st August, 1934.

RETIREMENT

Lieutenant-Colonel T. F. Owens retires 8th October, 1933

Notes

THE WELLCOME RESEARCH INSTITUTION,
LONDON, ENGLAND

Exhibit at the Chicago Exposition, 1934

THE attention which is being devoted to research is typified by the exhibit of the Wellcome Research Institution, founded by Sir Henry Wellcome. The large scale model exhibited of the magnificent building erected in London (Eng.) gives some idea of the founder's devotion to research and his determination that adequate and worthy headquarters should be available for the three research laboratories and the two research museums which bear his name. The corner stone of the Wellcome Research Institution was laid by Lord Moynihan, President of the Royal College of Surgeons of England, in 1931.

The Wellcome Research Institution embraces the Bureau of Scientific Research, the Entomological Field Laboratories, the Physiological Research Laboratories, the Chemical Research Laboratories, the Museum of Medical Science and the Historical Medical Museum, all of which are located in the new research building except the Wellcome Physiological Research Laboratories, which are at Langley Court, Beckenham, Kent (Eng.), with grounds of more than 100 acres of park land; and the Wellcome Entomological Field Laboratories, which are situated in spacious open country at Claremont, Esher, Surrey (Eng.).

Wellcome Research Institution, London (Eng.)
Chicago Exposition, 1934.

Part of the exhibit showing Booths 1 and 12, group H, in the foreground and Booths 13 and 24 in the distance. On the extreme left is a model of the Floating Research Laboratory presented by Sir Henry Wellcome to the Wellcome Tropical Research Laboratories, Khartoum. It is a two-decked vessel and is so fully equipped that it operates as efficiently as any modern scientific research laboratory on land. It is believed to be the first of its kind in the world and enables research work to be carried out on the course of the Nile and its tributaries at places otherwise difficult or impossible of access to the research worker. In the centre is a model of the Wellcome Research Institution founded by Sir Henry Wellcome.

The Wellcome Research Institution exhibits, in addition to the model referred to above, a screen bearing photographs illustrating the Army Medical Motor Field Laboratory presented to the British War Office and attached to the Expeditionary Forces in Palestine, Mesopotamia and Egypt during the Great War. It shows also notable exhibits from the Wellcome Tropical Research Laboratories, Gordon Memorial College, Khartoum, including a model of the Floating Research

Laboratory used on the Nile and its tributaries, and copies of the research reports illustrating the scientific and economic work carried out.

They also have on view some very beautiful enlarged models of disease carriers. Particularly interesting is that showing the tsetse fly—the agent responsible for the transmission of sleeping sickness. Included in this exhibit is a large scale model of the fly's biting apparatus. Amongst other models: *Anopheles costalis*, the mosquito most largely concerned in the transmission of malaria in Africa, and also the plague flea. In each case stages from egg to adult are shown, all upon a greatly enlarged scale so that details may be plainly seen.

Other exhibits depict contributions by the Bureau to the study and research upon diseases, particularly those affecting residents in tropical and subtropical lands. The Museum of Medical Science has exhibits which demonstrate the original system of visual teaching which enables it to give a general survey of human diseases from every aspect and thus makes it of such intense interest to medical men and of such outstanding service to students.

MENSTRUAL DISTURBANCES

MARTIN H. SMITH AND COMPANY have just issued a booklet on this subject which will be read with interest by members of the profession.

The beginning of menstrual troubles lies back somewhere in antiquity. Just when or where these troubles started are matters of little moment in comparison with the immediate needs of the sufferers who to-day are seeking relief.

Evidence is abundant that the unnatural mode of living which civilization has thrust upon us has placed an increasingly heavy burden on womankind. Particularly is this true regarding her most important function, reproduction. The further she departs from the dress, customs and habits of her primitive forebears the greater the penalty.

So common have become menstrual disorders that their diagnosis and treatment almost constitute a specialty in the field of medicine. The general practitioner finds a large proportion of his women patients coming to him with some menstrual complaint.

The forms most frequently presented are amenorrhea, dysmenorrhea, menorrhagia, metrorrhagia and those irregularities incident to the climacteric.

Ergoapiol is the preparation that is recommended in certain of these conditions; this consists of powdered extract of ergot, one grain, aloin, an eighth of a grain, apiol, a special preparation of this company, and Savin oil.

WATSON'S MICROSCOPE RECORD

THIS interesting little publication still maintains its standard, and in No. 32, the last number we received, the usual practical articles on the subject of microscopy will be found.

An article on the application of micrometric scales to photomicrographs will appeal to our scientifically-minded readers, and it certainly appeals to our editorial instincts, as, if the plan of the writer of this article were adopted, one of our main difficulties in the reproduction of photomicrographs would be overcome automatically.

He writes 'What a countless number of photomicrographs there must be whose value would be greatly enhanced if scales of measurement could be easily appended! A mere statement of the magnification of the image is very little use for the visual estimation of the size of microscopic objects. However, the provision of a micrometric scale, correct for that magnification, at the side of, or superimposed on the image, not

only enables visual estimation to be made with certainty, but also allows exact measurement to be made easily when required.

With lantern slides from photomicrographs it is extremely desirable that such scales should be shown, so that, irrespective of the initial or final magnifications, the dimensions of objects can be read off correctly when screened. A statement of the initial magnification alone is obviously inadequate to convey any idea of actual size or dimensions.

He suggests the use of a special micrometric rule (an illustration of which is given in the *Microscope Record*) by means of which a correct microscopic scale can be transcribed on to any photomicrograph or lantern slide.

Amongst the Watson's instruments described is a useful micro-projection apparatus for class work. For lecture-demonstrations of microscopic specimens no method is so satisfactory as projection on a screen. Every detail may be pointed to and it is only necessary to do this once for the whole class.

The most practical micro-projector yet devised is shown in the illustration. As will be seen, it is a strongly built microscope focusing by rack and pinion, with heavy cast-iron foot and large horizontal stage with plate-glass surface. Light is provided by a special sub-stage projection lamp consuming 36 watts and working at 12 volts, the current being obtained from a transformer connected by ordinary lamp flex to any A.C. house supply. A condenser is fitted above the lamp to illuminate a large field evenly and brilliantly. The projection lens is a triple achromatic combination giving a brilliant image magnified 80 diameters on a screen at 15 feet distance. The beam is reflected in a horizontal direction by a large prism which also corrects the transposition which occurs with simple projection on an opaque screen. The horizontal stage is more convenient for mounted objects than a vertical one, and is, of course, the only possible means of exhibiting unmounted objects or objects in fluid and chemicals in suspension or solution.

VITYS

ORIGINALLY the water-soluble vitamin B was considered to be a single substance. Recent work, however (Goldberger *et al.*, U. S. A. Public Health Report, 1926, XLI, 197; Guha, *Biochemical Journal*, 1931, XXV, 960; Reader, *Biochemical Journal*, 1929, XXIII, 689), has shown the existence of several factors, called B₁, B₂, etc., belonging to the water-soluble B group, all of which are necessary for health. Vitamins and specially B-vitamins are not stored in the system for long periods. So, for the maintenance of proper health, they have to be supplied to the system from time to time.

'Vity's', a tablet rich in the various factors of the vitamin-B complex and also in phosphate is manufactured by the Bengal Chemical and Pharmaceutical Works, Limited. It is designed to supplement the ill-balanced dietaries, specially with regard to the B-vitamin content and to make up for the general ill-health, and susceptibility to various ailments consequent to faulty nutrition.

'Vity's' has been biologically assayed by the technique described by Guha and Drummond (*Biochemical Journal*, 1929, XXIII, 880) whereby it has been definitely observed that rats receiving 'Vity's' show optimum growth.

From the clinical standpoint also 'Vity's' tablets have been found to be highly useful in all conditions of avitaminosis B, e.g., beri-beri, epidemic dropsy, pellagra, indifferent growth, neuralgia and other nervous disorders, gastro-intestinal trouble, skin affections, general ill-health and malaise. It is highly recommended for growing children and young people, for expectant and nursing mothers and for those who are easily fatigued after brain or manual work.

MARMITE

A RECENT report on the vitamin-B₁ content of a sample of marmite contained the following details:—

The vitamin-B₁ content of this sample of marmite was estimated by a direct comparison with the international standard for vitamin B₁.

Pigeons were given a diet of polished rice *ad lib.* and tap water; they were caged in a sheltered yard and were exposed to the open air throughout the experiment. The floors were covered with raised wire screens to prevent the pigeons from having access to faeces. Half the pigeons developed retracted neck, the recognized sign of vitamin-B₁ deficiency.

As each bird developed this symptom, it was put into a separate smaller cage and given either a dose of standard B₁ preparation or of marmite, alternate pigeons being given the standard vitamin and marmite, respectively. The results were judged on the number of birds cured and the average duration of cure.

It was evident from both methods of calculation that the dose of 0.1 gramme marmite had the same vitamin-B₁ potency as the dose of 0.03 gramme of the standard vitamin preparation.

The unit of vitamin-B₁ activity is defined as that amount of activity contained in 0.01 gramme of the international standard. Thus, it may be said that 0.1 gramme marmite contains 3 units of vitamin B₁. Therefore this sample of marmite contains 30 international units of vitamin B₁ per gramme, or about 840 units per ounce.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

GENERAL PARALYSIS OF THE INSANE IN BURMA

By G. H. FRASER, M.B., CH.B. (Edm.), D.P.M. (Eng.)
MAJOR, I.M.S.

Superintendent, Mental Hospital, Tada-U, Rangoon

THE following account of the occurrence of general paralysis of the insane in Burma has been prompted by the belief which, so far as one can gather, is common, that parasymphilitic diseases are rare both in India and in tropical and sub-tropical regions generally.

References to this aspect of the subject are few. Power (1930) refers to the relative infrequency of general paralysis among uncivilized countries. Fletcher (Byam and Archibald, 1922) states that 'though syphilis is widespread in most tropical countries, the parenchymatous affections of the central nervous system are comparatively rare among native populations'.

This may be true of countries such as India, where, if this disease does occur, it does not manifest itself in the same way as in other communities. It has been stated by Dhunjibhoy (1930) that 'general paralysis of the insane is extremely rare in India, although syphilis is very common. I have not seen a case of general paralysis of the insane in an Indian, who has not been abroad'. This has been the writer's experience in India, and it is also the experience of many others who are competent to form a reliable opinion.

The relative rarity of general paralysis of the insane in India in association with the high incidence of malaria has led to the suggestion that general paralysis of the insane may occur in India in a modified form and so escape recognition. It may be admitted that aberrant clinical types of general paralysis of the insane may occur in India, but it has yet to be shown that such cases exhibit positive serological reactions. The writer's experience is that these cases invariably exhibit negative serological reactions.

The wide range of the clinical manifestations of general paralysis of the insane, which is a feature of this disease in Burma, renders it difficult to base a diagnosis on the clinical data alone. One must assume that some time during the course of the disease the results of serological tests would become positive. It is, however, conceivable that many cases are missed owing to the fact that they are modified by naturally-acquired malaria. That this may be so is supported by the fact that many cases recover completely or are only slightly reduced mentally as a result of treatment by malaria therapy. It may therefore be presumed that those cases subject to repeated infection of

naturally-acquired malaria exhibit a modified clinical picture. It is also to be expected that the chronicity of the disease will become more marked and the clinical signs modified. Here the usual criteria of diagnosis of general paralysis of the insane does not help us, for, as in the cases successfully treated by malaria, there may be no clinical data and the serological results may be greatly modified. The following serological results of successfully treated patients may serve as examples. These cases have returned to their former occupations and show no clinical signs of the disease.

Case no	Date of specimen taken	Serological results
1	26-4-1933	Wassermann reaction (C.S.F.) ++. Langé's colloidal gold test—555554200.
	2-7-1934	Wassermann reaction (C.S.F.) +—. Langé's test—0123210000.
2	14-8-1933	Wassermann reaction (C.S.F.) ++. Langé's test—555542100.
	2-7-1934	Wassermann reaction (C.S.F.) +. Langé's test—0132000000.
3	2-11-1933	Wassermann reaction (C.S.F.) ++. Langé's test—5555321000.
	7-7-1934	Wassermann reaction (C.S.F.)—negative. Langé's test—0132100000.

Assuming that these patients, instead of being treated by artificially-induced malaria, had been naturally infected and had had frequent attacks of fever while suffering from syphilis, they would not have been found insane, nor would they have shown any clinical signs, but the serological results would be found modified.

In such circumstances it may well be that general paralysis of the insane is more common than is generally supposed in tropical countries, but, whether this premise is correct or not, the facts to be recorded go to show that in Burma, where syphilis is far more prevalent than in most parts of India, the classical form of general paralysis of the insane is relatively common.

In Burma, no race of whatever origin is immune. Indians, who have lived out of India for some years, appear to be as liable to acquire parasymphilitic lesions as the indigenous races.

It would appear that by long residence in a malarious country one acquires an x factor which modifies the course, duration and clinical signs of the parenchymatous affections of syphilis, that, by long residence in a non-malarious country, this x factor is absent so that the reaction of the nervous system to syphilis takes the well-known form, and that, by migration from a malarious to a non-malarious country, one loses this x factor, it will follow that in a large moving population, such as one finds in Burma, many syphilitic individuals will be found in whom this x factor is complete, modified, or entirely absent.

This is a possible explanation of the varied manifestations of parasyphilis in this country. Some parts of Burma are malarious, others are non-malarious. The Rangoon area is non-malarious. More than half the population of Rangoon is non-Burman, consisting chiefly of Indians, some of whom have been residents in Rangoon for long periods; the majority, however, are temporary residents. The large proportion of Rangoon residents who have been born outside Rangoon, namely 510 per mille, is evidence of the fact that the population of Rangoon is largely composed of immigrant races.

In such a mixed population one finds cases of general paralysis which are rapidly progressive, others which take a mild and chronic course, and still others which are diagnosed, not on clinical grounds but as a result of laboratory tests. The following are examples:—

Case 1.—R. C., admitted on the 17th June, 1933; age 35 years, coolie, native of Madras. No history prior to admission obtainable. Sent to this hospital from the Rangoon General Hospital. Physique poor. Health poor, emaciated, neglected. On physical examination there is marked tremor of hands, facial muscles and tongue; pupils react sluggishly to light. Marked slurring of speech, gait stumbling, deep reflexes absent. Mental state:—Constantly restless, habits dirty, naked, speech incoherent. Wassermann reaction report ++ (blood and cerebrospinal fluid); Langé's test—paretic.

23rd September, 1933.—Convulsions resulting in a left-sided hemiplegia.

30th September, 1933.—Died.

Case 2.—Y. N., admitted on the 29th January, 1934; age 30 years, Chinaman, carpenter. Found wandering aimlessly in the streets of Rangoon, getting in the way of traffic; apprehended by the police who sent him to this hospital for observation as he was thought to be insane.

Physique and health good; pupils fixed; reflexes brisk, no tremors, gait normal.

Mental state:—Mildly euphoric; singing and laughing at times, at others threatening, abusive, aggressive.

Wassermann reaction report (blood and cerebrospinal fluid) ++; Langé's test—paretic curve.

Treatment:—Sulphosin, malaria, tryparsamide; great improvement. Discharged to the care of his relatives, 25th May, 1934; no physical signs, mentally sound, conduct and speech normal. Treatment continues.

Case 3.—Z., admitted on the 7th July, 1933; age 27 years; house servant (butler); Indian Christian (Madrassi).

Sent to this hospital from Maymyo by his relatives as he became aggressive and unmanageable at home 20 days prior to admission. No history of previous illness except 'fever'. Gives a history of occasional addiction to alcohol (toddy) and ganja; physique and health good. No physical signs of general paralysis of the insane.

Mentally he is quiet, seclusive, resents interference, occasionally mutters and grimaces, postures; has lucid intervals when he appears normal; occasionally euphoric, whistles, sings quietly to himself or dances gaily.

Blood and cerebrospinal fluid (Wassermann reaction report) ++; Langé's test—luetic curve; cells 18 per c.mm.

Treatment:—Sulphosin, malaria, tryparsamide.

Discharged 23rd February, 1934, cured.

Case 4.—Nga S. L., admitted on the 29th January, 1931; clerk; Burmese Buddhist; age 36 years; sent to this hospital from Rangoon Jail, found insane, acquitted of murder by the High Court of Judicature at Rangoon. It is said that he had killed his father with a *dah*.

He is known to have been insane for four months prior to the crime. The history includes addiction to alcohol, ganja and cocaine.

Prior to the crime he is said to have had delusions of persecution; of people coming to his house to injure him. One night his father wanted to go outside but patient would not let him, fearing that the people threatening him would get in. As his father persisted in going out the patient hit him over the head with a *dah* and killed him. When arrested he did not appear to be insane. When under observation in jail he was reported to be rational at times, but occasionally had outbursts of weeping or laughing. On admission to this hospital was unduly cheerful though conduct and speech were rational. His bodily health and condition were good; reflexes were normal; there were no tremors. He states that he remembers nothing of his crime. On the 5th May, 1932, he became excited, stated that some person was coming to murder him. On the 22nd July, 1933, he showed marked improvement; conduct and speech were rational. On the 16th January, 1934, he was noted to be dull and apathetic, without interest or social tendencies. No physical signs of syphilitic involvement of the nervous system were found. 17th May, 1934—a sample of patient's blood gave a positive reaction to the Wassermann test. A sample of the cerebrospinal fluid was then taken which gave a positive reaction. Cytological count showed 24 cells per c.mm. Langé's gold test gave a paretic curve. He was then given citrated malaria blood, reaction to which was good. Tryparsamide was then given. Marked improvement. Conduct and speech normal.

Case 5.—Mg. H. M., admitted on the 19th October, 1933; clerk; Burmese Buddhist; age 28 years. Was sent to this hospital by his parents who stated that patient had contracted syphilis when 22 years of age and has since had intensive treatment with novarsenobillon and allied arsenical preparations. On admission patient's general bodily health and physique were very poor, very thin and emaciated. Mentally he was dull and stuporose, could be roused but not sufficiently to make an intelligent reply. On physical examination his pupils were fixed, deep reflexes were not elicited.

Laboratory reaction:—Wassermann reaction (blood and cerebrospinal fluid) ++; Langé's test—paretic curve; protein more than normal; cell count 5 per c.mm.

Treatment:—Sulphosin—marked physical improvement. Citrated malaria blood—slight mental improvement. Tryparsamide—physical improvement. Mentally is bright and observant, is rational in speech and conduct.

On 16th March, 1934, discharged cured. Continues treatment.

This patient has been seen by the writer on many occasions since discharge. He has returned to his former occupation as a clerk. He is reported on well by his employer.

During the years 1931, 1932 and 1933 the numbers of admissions of cases of general paralysis have been 14, 28 and 62 respectively. These figures represent an average percentage of direct admissions of 6.25 per cent, 10.29 per cent and 19.447 per cent. During the first quarter of 1934, the number of new admissions of cases of general paralysis was 20, or 21.05 per cent of total admissions.

Diagnosis in each case was, apart from clinical signs, based on a positive result of the Wassermann test on the blood and cerebrospinal fluid, a paretic reaction by Langé's colloidal gold test;

cytological examination, and protein examination of the cerebrospinal fluid.

It may be noted here that it is the rule rather than the exception for these patients to show clinical and verbal evidence of primary infection.

From the year 1933 to the present date each new admission has been examined by the Wassermann test for evidence of syphilis and whether, from clinical examination, the signs of general paralysis were present or absent.

The nationalities of these cases are of speculative interest, keeping in view the fact that, with a few exceptions, all came from the Rangoon area, which, as stated, is a non-malarious area, and that in this area the majority of the population is non-Burman. No reliable information could be obtained regarding the period of residence of each case in this area. The figures are: Burmans (Buddhists) 59; Chinese 8; Indians (Hindus) 11; Indians (Mohammedans) 12; Indian Christians 3; Burmese Christians 1; Anglo-Indians 8; Persian 1; Shan 1.

It is of interest that no case of general paralysis has been admitted to this hospital who is known to have undergone military service.

The large number of Burman Buddhists admitted leads one to speculate as to the cause. The suggestion that first arises is that the permanent resident in the Rangoon area is not exposed to the same factors which render the Indian immune to the course of general paralysis as we know it. There is, however, the sociological aspect of this subject. Compared to the Indian, the Burman is apt to be mentally myopic; he lives for the moment. The Indian, on the other hand, is, generally speaking, more prudent in his outlook, and is ruled by so many religious and caste restrictions that there is a lesser tendency to promiscuity than is the case with the Burman.

The above figures should be compared with the figures given in the last census for the various nationals among the population of Rangoon town from which most of our cases come. The population of Rangoon is 400,415. Of this number, Burmans (Buddhists) represent 32 per cent; Indians, 63 per cent. The proportion of foreign born (out of Burma) is 509 per mille.

Of the above cases of general paralysis admitted during the years 1931, 1932 and 1933, 45 have died, 24 have been discharged and 35 remain in hospital. Of the cases discharged 15 have returned to their former occupations; the remaining, somewhat mentally reduced, are doing well, according to latest reports, and are usefully employed. Of the 35 remaining in hospital the majority show remissions, are employed in minor tasks, and are not discharged because the relatives are not traceable or are

so poor that the requisite amount of care and supervision cannot be provided.

The large proportion of deaths must be accounted for by the advanced state of the disease in which many are admitted. This is to be expected in a large moving population of male persons of the lowest labouring classes. Of the better class of patient whose relatives bring the patient in the early stages of the disease to the proper quarters for expert advice and treatment, the prospect of cure and return to their former occupations is good.

As regards diagnosis, in the majority of cases this is easy. A matter of interest sometimes arises in the early stages of the disease where physical signs may be absent and where the patient shows no sign of mental disorder under prolonged observation. The following is an example :—

Case 6.—M. P. S., age 40 years, Burman, admitted on the 9th June, 1934; under observation as to his mental condition. On the 26th April, 1934, while staying in a monastery (*phongyi Kyauung*) he caused the death of a monk (*phongyi*) by striking him on the head with a mallet. Said to have been insane for five days prior to the crime. After the crime he is reported to have been found laughing and crying alternately. He is said to have had his first attack of insanity 25 years ago. At the first enquiry the first witness stated that on the 22nd April, 1934, the accused felt unwell and began to talk nonsense. He could not be managed well. Next day he went out of his house shouting 'I am afraid' all the time. The witness had to keep him tied with irons. Next day the witness took him to a monk (*phongyi*) to have him cured. Witness no. 2 stated that the accused began to talk nonsense 5 or 6 days before the crime. He was insane at the time of his arrest. The magistrate on his examination observed that the accused looked insane. The civil surgeon had the accused under observation from the 21st May, 1934, to the 28th May, 1934, but found no signs of insanity. The accused behaved well at all times.

Admitted to this hospital for further observation on the 9th June, 1934. His health and physique were good. There were no signs of insanity. Speech and conduct were rational. Social tendencies were normal. He was alert and observant, orderly and active, and employed himself usefully each day. The general opinion of warders and attendants was that the patient was inclined to be solitary, only occasionally initiating conversation, but conversed in a rational manner when spoken to.

On examination the patient stated that he had been under treatment for insanity by two monks (*phongyis*) and a native doctor (*se-saya*) about ten days before the occurrence of the crime. He stated that he did not know about the crime. He only remembers being arrested by his villagers and charged with the murder. He did not know the names of the people who arrested him. He totally denies the crime and accused another person, San Aye, of the same village as the murderer of the monk. He said that San Aye struck the monk with a stick and then ran out shouting that the lunatic (the patient under examination) was attacking the monk. This occurred at the monastery. He did not know anything more about the crime until he found himself in the lock-up prior to this.

He denies having been insane twenty-five years ago or at any other time.

On physical examination no sign of disease or disorder of the nervous system was found.

On examination of the blood and cerebrospinal fluid the following results were obtained:—Wassermann reaction (blood and cerebrospinal fluid) ++; cell count 15 per c.mm.; protein increased; Lange's colloidal gold test—paretic curve. To exclude the possibility of error, further serological examinations were made with similar results.

The treatment adopted in these cases has followed well-known lines. Sulphosin, a 1 per cent emulsion of sulphur in olive oil, as advocated by Schroder, has been used here in debilitated, in elderly and in restless patients, who, it is found, respond badly to malaria. It is administered intramuscularly into the fascia lata of the thigh in increasing doses of 1 c.cm. to 4 or 5 c.cm. at intervals of forty-eight hours. A maximum dose of 10 c.cm. has been recommended but, with these patients, as 4 c.cm. or 5 c.cm. produces the same degree of pyrexia as 10 c.cm. the higher doses have not been given. A temperature of 101°F. to 103.5°F. is produced. A certain amount of local pain follows the injections. In the debilitated and elderly cases malaria pyrexia is not without danger from heart failure. Sulphosin has in our experience produced no undesirable effects, and in the majority of cases delays or arrests the progress of the disease, improves the general health and allows further treatment to be followed.

As many cases are admitted in a highly neglected bodily condition a period of rest with suitable diet and discipline is allowed before active medicinal treatment is begun.

Treatment by malaria pyrexia was given in selected cases with varying results. A patient suffering from malaria is obtained and films of his blood carefully examined to ensure that the infection is one of benign tertian and not malignant or mixed infection. With all reasonable precautions it is sometimes found difficult to exclude the possibility of a mixed infection, for on taking films of blood at hourly intervals between 3 p.m. and 6 p.m. no malignant tertian parasite may be found, and yet when the blood is injected into the patient, a mixed infection is found. This mishap has had unfortunate results in a few cases.

The incubation period in these cases varied from seven days to thirty days. Some patients showed no reaction even on repeated injections of malaria blood. Other cases had only a few pyrexial attacks and no further response. Most cases, however, reacted well and were allowed to have twelve pyrexial attacks. Quinine was administered to stop the pyrexia. Five grains to 10 grains of quinine injected intravenously was found effective to control the pyrexia. In those cases whose pyrexia subsided spontaneously after a few rigors, an injection of 1 c.cm. adrenalin chloride (1 in 1,000) or 5 c.cm. T.A.B. vaccine was found useful in provoking further pyrexia.

The occupation of 25 of these patients prior to admission was unknown; of the rest their occupations were:—

Coolie	15
Clerk	9
Motor driver	7
Bazaar seller	6
Carpenter	4
Farmer	4
Police constable	3
Trader	3
Tailor	2
Assistant to court registrar	2
Foreman electrical engineer	2
Wood-carver	2
Cloth merchant	2

and one each of the following:—township judge, assistant chemical examiner, tax collector, sub-assistant surgeon, school head-master, Burmese physician, railway restaurant manager, store manager, butler, typist, tin-smith, painter, professional gambler, fitter, hat maker, rickshaw puller, sweeper and shoemaker.

These cases represented most of the certifiable stages in the progress of the disease. Many were of the very poorest coolie class, brought in by the police in an advanced stage, having been found wandering or lying about the streets not under proper care or control. A few were of the better classes, and these, brought by their relatives when the patient was in the early stages of the disease, responded well to treatment. In this country, however, where in many circles insanity is still looked on as due to the malign influence of *nats* (evil spirits), the first appeal for treatment of insanity is to the Buddhist monks or unqualified native practitioners. When these fail after long periods of ineffective 'treatment', the patient is brought in a stage of the disease in which prospect of any great improvement is highly problematic. It is significant, however, that, with two exceptions, those who have recovered and have returned to their former occupations have been of the better classes or have received varying degrees of education. It will be seen from the following that, *pari passu* with the mental improvement, there are improved serological reactions. The cerebrospinal fluid of patients who have mentally regained normality was examined on the dates recorded in the table opposite; the first examination in each case being that taken shortly after admission to hospital, and the second examination in each case after treatment and discharge from hospital.

Six of these 'recovered' patients who reside in the Rangoon area or within the neighbouring districts continue to attend this hospital for further treatment. Steps have been taken to

have other 'discharged recovered' or 'remission' cases treated by their respective civil surgeons.

TABLE

Case no.	Date when specimen taken	Laboratory findings
1	26-4-1933	Wassermann reaction (C. S. F.) ++. Total leucocytes—6 per c.mm. Plasma cells not seen. Protein more than normal. Langé's colloidal gold test—555554200.
	2-7-1934	Wassermann reaction (C. S. F.) +±. Total leucocytes—3 per c.mm. Plasma cells not seen. Protein slightly more than normal. Langé's test—0123210000.
2	14-8-1933	Wassermann reaction (C. S. F.) ++. Total leucocytes—21 per c.mm. Plasma cells not seen. Protein more than normal. Langé's test—5555542100.
	2-7-1934	Wassermann reaction (C. S. F.) +. Total leucocytes—1 per c.mm. Plasma cells not seen. Protein slightly more than normal. Langé's test—0132000000.
3	25-9-1933	Wassermann reaction (C. S. F.) ++. Total leucocytes—12 per c.mm. Plasma cells not seen. Protein more than normal. Langé's test—2334310000.
	2-7-1934	Wassermann reaction (C. S. F.) ±. Doubtful. Total leucocytes—1 per c.mm. Plasma cells not seen. Protein normal. Langé's test—0121000000.
4	2-11-1933	Wassermann reaction (C. S. F.) ++. Total leucocytes—7 per c.mm. Plasma cells not seen. Protein more than normal. Langé's test—5555321000.
	7-7-1934	Wassermann reaction (C. S. F.)—negative. Total leucocytes—1 per c.mm. Plasma cells not seen. Protein slightly more than normal. Langé's test—0132100000.
5	20-11-1933	Wassermann reaction (C. S. F.) +. Protein more than normal. Total leucocytes—5 per c.mm. Langé's test—5555432100.
	2-7-1934	Wassermann reaction (C. S. F.)—negative. Total leucocytes—1 per c.mm. Plasma cells not seen.
6	30-11-1933	Wassermann reaction (C. S. F.) ++. Total leucocytes—7 per c.mm. Plasma cells not seen. Protein more than normal. Langé's test—555532100.
	22-5-1934	Wassermann reaction (C. S. F.)—negative. Total leucocytes—1 per c.mm. Plasma cells not seen. Protein more than normal. Langé's test—5555420000.

THE PART PLAYED BY THE FEELING OF GUILT IN THE ÆTIOLOGY OF MENTAL DISORDERS

By OWEN BERKELEY-HILL

LIEUTENANT-COLONEL, I.M.S.

Superintendent, European Mental Hospital, Ranchi

THE study of the ætiological factors of mental disorder is leading to the discovery that the feeling of guilt plays a most important part in the genesis of a number of common disorders of the mind, ranging from feelings of inferiority up to severe psychoses. Hence no serious attempt at prophylaxis against mental illness can afford to disregard this emotional state of the mind. That guilt can be felt by certain animals, e.g., dogs, cats, monkeys, etc., is well known to everyone, but how this feeling arises and why some animals appear to feel it and others do not, is still insufficiently understood. Graham Howe, in his *Motives and Mechanisms of the Mind*, calls attention to the early association in the mind of the child of the moral

(Continued from previous column)

TABLE—concl'd.

Case no.	Date when specimen taken	Laboratory findings
7	12-2-1934	Wassermann reaction (C. S. F.) ++. Total leucocytes—7 per c.mm. Plasma cells not seen. Protein more than normal. Langé's test—5555543100.
	2-7-1934	Wassermann reaction (C. S. F.) ++. Total leucocytes—1 per c.mm. Protein more than normal. Plasma cells not seen. Langé's test—55555321000.
8	20-2-1934	Wassermann reaction (C. S. F.) ++. Total leucocytes—4 per c.mm. Plasma cells not seen. Protein much more than normal. Langé's test—5555310000.
	21-5-1934	Wassermann reaction (C. S. F.) +. Total leucocytes—3 per c.mm. Plasma cells not seen. Protein more than normal. Langé's test—4444210000.

concepts of 'good' and 'evil' with the excretory function. A child is 'good' whose bowels function regularly at the behest of mother or nurse, and the child is 'bad' if it fails to do so. As Graham Howe observes, from the first day the child is born, the ordered exercise of this function is expected and for the most impressionable years of life it is associated with the moral qualities of 'good' and 'bad'. Apart from any psycho-analytical theories on this aspect of human development, the juxtaposition of the genital to the excretory zone must almost inevitably lead to a transference of the guilt-complex from the excretory to the genital area. It seems possible to throw some additional light on this interesting and important problem by applying thereto the theory of the 'conditioned reflex'. As Pavlov could produce the excretion of saliva in dogs who had been regularly fed at the ringing of a bell, by merely ringing the bell in the complete absence of food, are we not at liberty to imagine that our ethical and moral training 'conditions' us to frown or blush when, for example, something obscene or blasphemous is mentioned in our presence? If this be so, and future researches may well show it to be, then we have reached a really important discovery as to the psycho-physiology of the 'moral sense', i.e., it is nothing but a conditioned reflex. This view obtains support from the fact that the feeling of guilt is relative to the standard which authority imposes. In other words the reflex may be 'strongly' or 'weakly' conditioned. For instance, where the parental attitude towards the child is of the conventional 'hush-hush' type as regards excretory and sexual functions, only a measure of guilty feeling springs into existence; where, however, the parental attitude as well as the religious teaching of the child is in terms of sin and punishment, the guilt feeling is liable to become exaggerated to a very dangerous extent and thus becomes a very common source of subsequent neurotic development. It may not be possible to prove that all guilt in adolescence is fundamentally associated with sexual guilt even when it is apparently associated with some other cause, such as stealing or lying. Further, the feeling of 'guilt' is probably operative in the formation of that 'horror' of sexual facts which is so universal among civilized peoples. Whether this 'horror' is or is not a conventional artefact it is not easy to decide. The solution of the problem may lie in the anatomical relationship of the genital and excretory zones to which reference has already been made. Guyon, in his *Sex Life and Sex Ethics*, maintains that this 'horror' of sexual facts is partly the outcome of primitive mystic awe and partly to a sense of supernatural danger. On the other hand, it is just as likely, as Crawley observes in his *Studies of Savages and Sex*, to be a morbid psychosis akin to jealousy on the one hand and

disgust on the other. At any rate, this feeling, while absent among primitive people, is almost beyond dispute a definite mark of neurosis among the so-called civilized races. For example, a short while ago I was asked to see a young lad of sixteen whose intellectual activities were being held, as it were, in a vice composed of shame and guilt; these owed their origin to a habit he had got into of indulging in voluptuous day-dreams. These phantasies were so strongly obsessive in their character as to inhibit him from doing his ordinary school work. He regarded himself as wholly 'wicked' and 'unclean' and as such unfit to mix with his associates, especially with women. His condition was truly pitiful. Again, 'guilt' may have quite another but equally significant function, namely, to establish individual independence through rebellion against the dominance of authority. A boy who is persistently 'naughty' is probably trying to exercise his independence and he feels that one way in which he can do so is by disobeying authority. Authority expects us always to do the right thing, therefore a rebellious independence will show itself by a tendency always to do the wrong thing. Thus 'naughtiness' in young people is often purposive for they may choose to be 'guilty' as a means of exercising their independence. This state of affairs has much bearing on juvenile delinquency. The feeling of 'guilt' naturally evokes the idea of punishment and consequently the fear of it. It may even, somewhat paradoxically, evoke the desire for it. It must not be forgotten that all superstitions can be traced to their origin in a fear of punishment. To be dominated by superstition (and how few of us are not!) is to be dominated by unconscious feelings of anxiety and guilt, a state of mind that borders more closely upon a neurosis than most doctors realize. Since superstitions are based on a fear of punishment their main function is to deflect the impending punishment by an act of propitiation of a symbolical kind, e.g., 'touching wood'. In the full-blown obsessional neurotic this propitiatory mechanism is given the fullest expression to the end and it may develop to such a degree of intensity as to absorb almost the whole energy of life. The apparently ridiculous repetitions of hand-washing, touching objects or counting are not so purposeless as they may seem to be. An obsessional neurosis is therefore nothing more than a defensive propitiatory ritual, expressed symbolically, to avert the (unconscious) dread of punishment that has arisen through the existence in the individual of an intolerable feeling of guilt. The ordinary medical practitioner is invariably irritated through being completely baffled in the presence of an obsessional neurotic. He tries to compensate for his own misunderstanding of his patient's symptoms by telling him to pull himself together, to think of his father and mother

or his wife and children, to take a sea voyage, to interest himself in 'wireless'. After much argument 'about it and about' the patient may be fobbed off with a prescription for 'mixed glands', radio-therapy, or massage. A pail of water thrown over the sufferer would be as effective. Few escape with the extraction of their teeth in attention to the insults hurled at them through ignorance enforced by the unresolved conflicts of the physician himself!

An individual obsessed with a feeling of guilt usually tries to deal with it by resorting to a number of defence mechanisms. Among such mechanisms we may find repression, over-compensation, projection, identification and self-punishment. The commonest form of over-compensation for the ordinary feeling of guilt is moral priggishness, e.g., the 'goody-goody' child. The 'moral prig' is generally happiest when looking out for other people's misdemeanours. The 'nosey Parker', who spends his time in searching the public parks for acts of indecency, is an example of this type of psychological mechanism. Similarly, 'purity leagues', albeit with the best intentions, do a great deal of harm by exaggerating the importance of sexual guilt. For example, the well-meaning pamphlets circulated to adolescents about masturbation are often only examples of the mechanism of projection. Their effect is generally to exaggerate their reader's feelings of fear and guilt and by so doing to do more harm than good. As Dr. Graham Howe observes in his book to which reference has already been made, such pamphlets do more harm than the minor offences which they seek to eradicate. The belief that seminal fluid emanates from the spinal cord is enormously widespread, even among people who lay claim to be educated. Quite recently a patient of mine, holding an important position in a large mercantile firm, told me he had given up sexual relations with his wife so as not to weaken his 'nerves'. I had great difficulty in persuading him that this self-imposed abstinence, so far from doing him any good, was doing him harm, quite apart from the effect it was having on his wife. The frequency with which patients tend to believe masturbation to be the cause of their illness is well known to most doctors. This tendency is not lessened by the fact that they have read that such is the case in 'purity' pamphlets or have been told so by sexually-jealous parents or ignorant school masters.

Perhaps the most terrible of all the defence mechanisms against the feeling of guilt is self-castration. Truly, this does not occur in actuality, except in severe psychoses, but it is by no means uncommon in a symbolical form. The fear of personal injury of any sort is tolerably widespread among boys and youths of

OBSERVATIONS ON THE THICKNESS OF THE FRONTAL AND PARIETAL BONES

By ATINDRA NATH SEN, M.B.

Teacher of Medical Jurisprudence, Campbell Hospital, Calcutta

Two cases of fracture of the skull were transferred to the writer's wards last year, both having been suspected to be cases of cerebro-spinal meningitis.

Case 1.—On the 17th April, 1933, S. A., a Moham-medan male, aged 32, was admitted to the surgical wards for suspected internal injury, but was later transferred, as it was considered to be a purely medical case. Patient at the time was semi-conscious, restless, vomiting often, could not speak at all. Pulse—78, respiration—18 per minute, pupils normal, rigidity of the neck—doubtful, Kernig's sign + on the right side only, Brudzinski's sign—absent, knee jerks + on the right side, Babinski's sign—absent, red blood corpuscles—4,600,000, white blood corpuscles—32,000, polymorphonuclears—92 per cent, lymphocytes—6 per cent, large mononuclears—2 per cent, lungs—normal, lumbar puncture fluid contained neither pus cells nor diplococci.

19-4-33.—Pupils slightly dilated; other conditions same.

20-4-33.—He appeared more stupid and dull with Kernig's sign ++ on the right side; general condition the same as before.

21-4-33.—Patient unconscious with laboured breathing, pulse—90, and respiration—26 per minute.

22-4-33.—He was comatose with pulse—115, respiration—32 per minute. The second lumbar puncture fluid

(Continued from previous column)

neurotic temperament. The analysis of such a fear invariably brings to light that the injury that is dreaded is castration as a punishment for sexual delinquency. Dr. Graham Howe very rightly observes, it is impossible to estimate the price that we pay for the continued existence of our unconscious guilt feelings. As a single source of sorrow it is probably by far the greatest in the world for there is nothing which so intimately touches the lives and happiness of every individual as matters pertaining to sex. We may feel comparatively safe if we attribute to the sexual factor most of the commonest examples of mental ill health besides much that passes for physical ill health. In addition to this we must reckon with much unhappiness that is never confided to the family doctor or to the family lawyer. It is borne in silence. How, it may be asked, may all this misery, or even a portion of it, be prevented? To those who profess an interest in the health of the human mind it must be evident that at least one thing must be done and the sooner the better, namely, to examine ruthlessly the taboos which militate against our happiness and our social efficiency. In short, matters of behaviour should be judged, not in relation to some inherited dogma, but in relation to its probable result. Conduct is good if on the whole it produces good results, and bad if it produces bad results.

contained no pus cells and no cocci. The patient died at 7 p.m.

The post-mortem examination revealed a fissured fracture of the left parietal bone with extra-dural hæmorrhage at the site and softening of the brain matter on the under surface of the right frontal lobe (*contre-coup* injury) with a partially organized clot of blood. The thickness of the parietal bone at the antero-inferior angle was one-tenth of an inch and at the postero-superior angle one-sixth of an inch. It transpired that the man was hit in the stomach with fists and then chased, when he fell down on the stone pavement of the street.

The point at issue was the thickness of the skull and whether fracture of the parietal was possible from a simple fall in the street or from shoe beating on the head.

Case 2.—On the 21st June, 1933, Y. J., a Mohammedan male, aged 30, was admitted to the surgical wards for head injury, but was transferred to my wards on the 24th June, being thought to be a medical case. Patient at the time of transfer was found semi-comatose, did not respond to questions, Kernig's sign +,

serious injuries, nor the blows inflicted repeatedly showing deliberate intention to cause death. In such cases, the accused should not be charged for culpable homicide amounting to murder (I. P. C. section 300). Really the charge should come as simple hurt (section 337) or grievous hurt (section 338) or rash and negligent act (section 304A) or grievous hurt not amounting to voluntarily causing hurt (sections 321 and 322).

I took measurements, in the medico-legal post-mortem examinations of Indians, of the thickness of the frontal bone in the midline at a point 2 inches behind the glabella, in 31 cases, and of the parietal bone at the antero-inferior angle, in 40 cases, and postero-superior angle, in 38 cases, to find out the common average thickness.

The following tables show the different thicknesses, in inches, and their frequency :

TABLE I

All ages from 5 to 60 years

	1"	1 1/8"	1 1/4"	1 1/2"	1 3/4"	2"	2 1/8"	2 1/4"	2 1/2"	2 3/4"	3"	3 1/4"	3 1/2"	Total cases
Frontal	7	3	9	..	7	1	3	1	..	31
Parietal, antero-inferior	3	1	1	1	20	6	5	2	1	40
Parietal, postero-superior	..	1	2	9	..	18	..	5	3	..	38

Brudzinski's sign doubtful, well-marked general rigidity of the body, pupils—dilated, pulse—88 and respiration—24 per minute. Lumbar puncture fluid contained neither pus cells nor cocci.

Blood—red blood corpuscles—4,000,000, white blood corpuscles—12,000, polymorphonuclears—60 per cent, lymphocytes—30 per cent, large mononuclears—8 per cent and eosinophiles—2 per cent. On finding the contra-indications for cerebrospinal meningitis, I decided to have an x-ray examination. In the meantime the patient showed signs of improvement.

On the 29th he became conscious though occasionally violent. He could not remember how he came to hospital but spoke a few sensible and intelligent words. He sat up and was able to walk a few paces with difficulty. By the 3rd July, he remembered how he fell down while alighting from a running train. He was also able to give his name and address. His gait was more spastic on the right side. From this time onwards he made a rapid recovery and complained of nothing beyond giddiness and slight weakness on the right side of the body. He was discharged cured on the 28th July. The x-ray examination showed a tri-radiate fracture (fissured) of the left parietal bone.

A good many people in this country are in the habit of carrying big *lathis* for protection. In direct violence in assaults by *lathis*, the frontal and the parietal bones are most vulnerable to injury, but if the bones are thinner than normal, a slight amount of violence, for instance with fists and shoes, inflicted inadvertently, might cause fracture of the skull terminating in death. The intention might not be to cause death, nor the weapon used of such a nature as to cause

HOOKWORM INFECTION IN THE PUNJAB*

SURVEY OF A RURAL AREA IN AMBALA DISTRICT

By M. YACOB, M.B., B.S., D.F.H., D.B., D.P.H., D.T.M. & H.

Epidemiologist to Government, Punjab

and

J. R. CHAUDHRI, L.R.C.P., M.R.C.S., D.P.H.

Assistant Epidemiologist, Punjab Epidemiological Bureau, Lahore

THE area considered in this paper consists of two villages—Bharatgarh and Bara Pind—in Rupar tehsil of Ambala district. This territory, usually described as submontane, is situated in the vicinity of the Siwalik range and includes a considerable portion of hilly country. The villages are situated on a range of low foot-hills in the close vicinity of the Sutlej river. These foot-hills are very irregular and are traversed by footpaths which lead from the villages situated at the top into the valley below. The soil is a sandy loam and therefore, given the requisite humidity, eminently suitable for the development of hookworm larvæ. The annual rainfall of the area based on an average of the last ten years is about 33 inches, of which over 20 inches are recorded during the months of July and August, when hookworm infection is most likely to take place.

The investigation was instituted under instructions from the Director of Public Health, Punjab, at the request of the District Medical Officer of Health, Ambala, who suspected the prevalence of hookworm infection in this area. One of us (J. R. C.) visited the area in the month of March 1934 and collected 150 stools from the two villages. The method advocated by Maplestone (1929) for collecting and preserving stools was used, namely, a paper capsule with a capacity of 4 c.cm. was filled with each specimen of stool and placed in a

* This is an extension of the work already reported on at length by Dr. R. B. Lal in the publication of the British Medical Association, Lucknow.

(Continued from previous page)

From the above it is evident that in Indians above the age of 20 years, both males and females, it is unusual to find the thickness of the parietal bone at the antero-inferior angle below one-eighth of an inch.

[*Note.*—Dr. Sen's observations on the thickness of the frontal and parietal bones in Indians form an important contribution to forensic medicine in this country; we are not however in entire agreement with his conclusions. In the first place, thickness is not the only quality of the cranial bones on which the cranial contents depend for their protection; there is the question of density.

Again, even if Indians have easily-fractured skulls, presumably they have always had them. The charge should depend on other circumstances in the case, and we do not think that unless the skull is exceptionally thin and brittle that this question of thickness should be taken into account.—Editor, I.M.G.]

bottle containing 20 c.cm. of 2 per cent anti-formin. This strength of antiformin according to Maplestone (1929) is very effective for the preservation of hookworm ova up to 18 days without any appreciable loss due to degeneration, and also for the prevention of larval development. The bottles were already fitted into portable boxes each of which was capable of accommodating 100 bottles. At the same time particulars of each person whose stool was collected, namely, name, age, sex, occupation, religion, etc., were obtained and entered in a special form. The whole material was transported to the laboratory of the Punjab Epidemiological Bureau, Lahore, for examination. Similarly 145 persons, of all ages and both sexes, taken at random, were subjected to a clinical examination for the purpose of detecting any manifestations of hookworm disease. Observations were also made to estimate the percentage of hæmoglobin by means of Tallqvist's scale.

The results obtained are of considerable interest, in view of the fact that very little accurate information about the prevalence of hookworm infection in this part of the Punjab is available with the exception of the solitary observation made by Chandler (1927), who examined the stools of 97 persons in a village near Ambala.

The technique employed

All specimens of stools were examined by Lane's direct centrifugal flotation method with the modification that the cover-slips, instead of being placed on plasticine cones, were placed directly on a microscope slide and examined in the usual manner under the microscope. We found this modification of Lane's technique much more expeditious and convenient to work with than the original technique. In addition 100 specimens of stools were subjected to a modified Stoll's method of counting (1923). The 18 c.cm. of faecal emulsion containing 3 grammes* of the faeces remaining in the collecting bottle, after 6 c.cm. had been withdrawn for diagnosis by Lane's (1922-23) method, were made up to 45 c.cm. by the addition of 27 c.cm. of N/10 sodium hydroxide and thoroughly shaken up with glass beads in a mechanical shaker. Of this emulsion 0.1 c.cm. was measured with a bacteriological pipette and placed on a microscope slide, covered with a $\frac{7}{8}$ inch square cover-slip and the number of eggs counted. This number multiplied by 150 gave us the number of eggs per gramme of faeces.

The incidence and intensity of hookworm infection

Of the stools of 150 persons examined 123 were found positive for hookworm ova, showing

* One c.cm. of faeces very closely corresponds to one gramme.

that 82.0 per cent of the population were infected with hookworm. Of the 100 specimens counted by the modified Stoll's method the average count per gramme of faeces was found to be 422.7. The infection index, which is a measure both of the incidence as well as the intensity of infection, was also calculated according to the formula suggested by Chandler (1926)—

$$\sqrt{\frac{\text{egg per gramme} \times (\text{per cent})^2}{100}}$$

The index was found to be 136.2 for the area under investigation. A comparison of our figures with those of Chandler (1927) in Ambala district is shown in table I :

TABLE I

Hookworm infection in Ambala district

	Chandler's figures	Our figures
Number of persons examined	97	150
Incidence of infection ..	51.5%	82.0%
Average egg count per gramme of faeces.	130	422.7
Infection index ..	67	136.2

It will be noticed that our figures indicate a much more serious state of affairs in Bharatgarh as compared with Chandler's in a village of Ambala district. In Bharatgarh not only is the incidence of hookworm infection higher but the intensity of infection, as indicated by the average egg count per gramme of faeces, is more than three times that of Chandler's in Ambala. Likewise our index of infection (136.2) is more than double that of Chandler's which is 67.

This is further corroborated by the state of affairs revealed by a clinical examination of a certain number of the inhabitants of the area.

Clinical manifestations of hookworm infections

A sample of the population consisting of 145 persons taken at random was examined clinically. Of this number only 20 or 13.8 per cent were regarded as free from symptoms, the rest had some symptom or other indicating hookworm infection. The group of 145 persons was divided into three classes on the basis of their clinical condition as shown in table II. Of this number 119 were found to be harbouring hookworm. Fifteen or 12.7 per cent of the latter had no apparent clinical symptoms; 47 or 39.5 per cent were regarded as showing symptoms of moderate severity, whilst the rest, 57 or 47.8 per cent, exhibited severe symptoms. Table II serves to illustrate the incidence and intensity of hookworm infection in the three clinical groups, and also shows the average hæmoglobin value in each group. It will be noticed that the severity of clinical symptoms increases *pari passu* with the intensity of hookworm infection. The average percentage of hæmoglobin, on the other hand, decreases with the intensity of infection and the severity of clinical symptoms. An important association is thus apparently established between the intensity of infection, the average hæmoglobin value and the clinical effects of the disease. Another point of interest which emerges from a study of this table is the fact that, on an average, an egg count of 192.5 is not of any clinical significance, whereas an egg count of 586.1 is associated with severe symptoms, namely, marked anæmia with indications of cardiac involvement—palpitation and breathlessness on slight exertion.

TABLE II

Clinical effects of hookworm infection

	Number of persons examined	Number found positive for hookworm ova	Percentage infected with hookworm	Average egg count per gramme of faeces per person	Infection index	Average percentage of hæmoglobin
Class I Normal persons with no clinical symptoms.	20	15	75	192.5	89.3	57.7
Class II Persons with signs and symptoms of moderate severity, usually anæmia with or without digestive disturbances.	57	47	82.4	356.5	121.4	56.9
Class III Severe cases with marked anæmia, breathlessness and palpitation.	68	57	83.8	586.1	171.0	52.1

The incidence and intensity of infection according to occupations is shown in table III :

TABLE III

Incidence and intensity of hookworm infection according to occupations

	Number of persons examined	Number found positive	Percentage infected	Average egg count per gramme of faeces per person
Cultivators ..	49	46	93.8	484.1
Labourers ..	23	19	82.6	595.8
Artisans ..	45	33	73.3	396.4
Shopkeepers ..	11	7	63.6	117.8

It will be seen that the incidence of infection is highest amongst the cultivators who work in the fields, and lowest amongst the shopkeepers. The labourers, who take part in the field work at certain seasons of the year when they are hired by the cultivators, come next to cultivators, the artisans occupying an intermediate position between the shopkeepers and the labourers. As regards the intensity of infection indicated by the average egg count, the same order is maintained as in the case of incidence, except that the cultivators show a lower average count than the labourers. The data available, however, are too small to enable us to come to any definite conclusions.

The incidence of hookworm infection according to age groups is shown in table IV :

TABLE IV

Incidence of hookworm infection according to age groups

Age group year	Number of persons examined	Number found positive for hookworm ova	Percentage infected
1-5 ..	6	5	83.4
6-10 ..	13	11	84.6
11-40 ..	114	96	84.2
41 and over ..	17	11	64.7
TOTAL ..	150	123	82.0

The number of persons examined in each age group with the exception of the age group 11 to 40 is too small. It may, however, be permissible to conclude, tentatively, that the incidence of infection tends to remain high up to 40 years, and thereafter it tends to diminish, probably on account of decrease in the amount of work carried out in the fields.

The distribution of hookworm infection according to religion and sex is shown in table V :

TABLE V

Hookworm infection according to religion and sex

Religion and sex	Number examined	Number positive for hookworm ova	Percentage infected	Number counted	Average egg count per gramme of faeces per person
<i>Hindus</i> —					
Male ..	117	96	82	76	471.7
Female ..	20	14	70	12	289.5
<i>Muslims</i> —					
Male ..	13	13	100	12	383.3
Female

The figures are not, strictly speaking, comparable as the number of Muslims examined is very inadequate, namely 13 only, and this does not include any females.

However, the intensity of infection appears to be greater in the Hindu males as compared with Muslim males, as the average egg count per gramme of faeces is 471.7 in the former as compared with a count of 383.3 amongst the latter. This is probably due to the fact that the Hindus include a considerable proportion of low-caste 'Mahashas', or untouchables, who are very insanitary in their habits.

As regards the distribution of infection in Hindu males and females, the latter show an incidence rate of 70 per cent as compared with 82 per cent in the former. The intensity, as shown by the average egg count per gramme of faeces per person, is also considerably higher in the males with a count of 471.7 as compared with a count of 289.5 in the females.

Defaecation habits

With the exception of the few houses belonging to comparatively well-to-do persons, the rest of the houses in the villages are not provided with any latrines. The inhabitants visit the immediate neighbourhood of the villages for purposes of defaecation, the most favourite sites being the numerous footpaths which lead from the top of the hill, where the villages are situated, into the valley below. It seems highly probable that these sites for defaecation, which are subject to intense and concentrated pollution on account of their limited area, serve as much more dangerous and repeated sources of infection than the corresponding sites in the plains where the area is much larger and the sites available for defaecation more scattered. The fields in the valley are often frequented by the males. The females usually do not go far from the houses, while the children freely

and promiscuously use the house yards, the streets, and the old deserted and neglected houses. Favourable conditions of humidity are provided for larval development by the local rainfall during the rainy season, while during the rest of the year the water which is commonly used for ablutions after defæcation serves to keep the defæcation sites sufficiently damp.

No foot-gear is used by the children and the females, the latter using a variety of sandal only on special occasions. Some of the male adults wear Indian shoes which resemble slippers and which are taken off during work in the fields.

Summary

1. A hookworm survey of two villages in Rupar tehsil of Ambala district is described.

2. The collection and preservation of stools in the field was carried out by Maplestone's method.

3. Stools were examined by Lane's direct centrifugal flotation method and the counting of hookworm ova was done by a modified Stoll's method.

4. One hundred and fifty persons were examined giving an incidence rate of 82 per cent, an average egg count per gramme of faeces per person of 422.7 and an infection index of 136.2.

5. One hundred and forty-five persons were subjected to a clinical examination. Of these 119 were found passing hookworm ova in their stools, 12.7 per cent had no symptoms, 39.5 per cent showed symptoms of moderate severity and 47.8 per cent had severe symptoms. There was a direct relationship between the severity of clinical symptoms and the intensity of infection as shown by the average egg count per gramme of faeces. There was an inverse relationship between the severity of clinical symptoms and the intensity of infection on the one hand and the average hæmoglobin value on the other.

6. The incidence of infection was highest amongst the cultivators and lowest in the shopkeepers, the labourers and artisans occupying an intermediate position.

7. The incidence of infection showed a tendency to remain high up to 40 years of age. Thereafter it tended to diminish.

8. The incidence and intensity of infection was greater amongst males than amongst females.

9. The houses in general are not provided with latrines and the chief defæcation sites are the footpaths leading from the village on the crest of the hill into the valley below where the fields are situated.

10. The women and children practically go barefooted. Some of the adult males wear

A STUDY OF TRACHOMA IN BALUCHISTAN

By P. SHANNON

CAPTAIN, I.M.S.

I. Definition of trachoma

At present in different standard textbooks of ophthalmology the terminology varies. Fuchs (1924) refers to typical trachoma granules or granulations, explaining that these should not be confused with granulation tissue as their structure is entirely different. Elliot (1920) also uses the former term while Swanzy (1925) designates them either trachoma bodies or granulations, and Cuenod and Nataf (1930) use the term *granular follicles*.

These multiple terms tend to lead to much clinical confusion, for, depending on the stage of the disease, the appearance of the conjunctiva may present a very varied picture, apart from the trachoma bodies or granules giving the typical frog-spawn or sago-grain appearance.

Where follicles have ruptured and an attempt at healing is taking place, an appearance remarkably like true granulation tissue is given by the combination of papillæ, scar tissue and ulcerated follicles.

This process, however, is much later than that producing the typical sago-grain appearance, so the inexperienced can form no accurate idea of the course of the disease or determine what form of treatment should be adopted.

Strother Smith's (1927) advice 'Do not diagnose a case as trachoma simply because he has granular lids' is valuable, for in India, as in other eastern countries, there is a vast amount of simple chronic conjunctivitis due to the local irritants peculiar to the East—dust, smoke, sand, etc.—together with chronic follicular conjunctivitis and trachoma, but the term 'granular lids' is applied to all of these conditions whether accompanied by the formation of granules or not, with the result that not only are vast

(Continued from previous column)

Indian shoes, but remove them during work in the fields.

numbers of innocent conjunctivitis cases diagnosed as, and wrongly treated for, trachoma, but proper advance in the clinical knowledge of the trachomatous process is greatly impeded.

Since a study of the histopathology of the disease shows that the compound follicle, similar in structure to the lymphoid follicles elsewhere, is the essential lesion in the disease process, I consider that a greater standardization of the terminology according to the two main clinical features of the disease—namely, the follicles and the papillæ—would result in an easier understanding of the character and course of the disease, and, coupled with the adoption of MacCallan's classification, would result in a much more accurate clinical knowledge of what is or is not trachoma.

MacCallan (1931) has classified the disease as follows:—

Stage I or Tr. I. Early stage of 'pin's-head' follicles.

Stage II or Tr. II. Subdivided into—

Tr. II(a) where follicles are large and gelatinous,

Tr. II(b) (i) papillary enlargement as well as follicles,

Tr. II(b) (ii) follicles with the added complication of spring catarrh,

Tr. II(c) trachoma complicated by gonococcal conjunctivitis.

Stage III or Tr. III. Where cicatrization has commenced, often non-contagious.

Stage IV or Tr. IV. Where cicatrization of the conjunctiva is complete. This stage is non-contagious.

The difficulty in separating trachoma from allied conditions, especially those characterized by innocent follicular formations, is shown well by a study of the conflicting views enunciated by present-day workers. Nicolle (1927), for instance, does not regard trachoma as a specific disease of a peculiar type but as the most widely disseminated, most serious and best defined clinically of a very numerous group of diseases—the granular inflammations of the conjunctiva—while Aubaret (1928) regards it as a specific entity. This difficulty is recognized by the Egyptian authorities, and in India Strother-Smith (1927), Coppinger (1927), Wright (1928) and others record that nine-tenths of cases so diagnosed and sent to them for treatment are not trachoma; while the first-named author in quoting his early successes with mercury cyanide subconjunctivally, in 1912 in the treatment of trachoma, has now come to regard the cases showing the marked improvement of which he wrote as cases of simple folliculitis.

Clinically simple folliculitis and trachoma may be differentiated thus:—

<i>Early trachoma</i>	<i>Simple follicular conjunctivitis</i>
1. Follicles embedded in the conjunctiva.	1. Follicles sit on the conjunctiva.
2. Follicles always on an inflamed surface.	2. Follicles on a normal or slightly inflamed surface.
3. Small areas of pinpoint petechial hæmorrhages around follicles.	3. No hæmorrhages visible.
4. Follicles more marked on upper lid than lower.	4. Follicles more marked on lower lid than upper.
5. Follicles definitely encroaching on to tarsal plates of lids—site of election upper margin of tarsal plate and angles.	5. Follicles confined to fornices, lower and upper, showing no tendency to invade the tarsal area of the conjunctiva.

The other points of difference quoted in the standard works are,

(a) ready improvement of follicular conjunctivitis with treatment,

(b) more common occurrence of the innocent condition in children,

(c) lack of lid scarring and corneal involvement, and

(d) lack of spontaneous rupture of follicles on double eversion of the lid,

and are of no value in the diagnosis of the class of case which presents real difficulty in India, namely, the doubtful early (Tr. I) case *versus* the chronic folliculitis case.

For a clear understanding of trachoma as I have seen it in India, both in the North West Frontier Province and Baluchistan, MacCallan's classification is the most practical basis for working on. In a few respects, such as the absence of (a) complicating gonorrhœal ophthalmia and (b) spring catarrh, the disease differs from the Egyptian, (a) is no more common than in the United Kingdom, and (b) is only very occasionally found with trachoma.

I would classify it thus:—

1. *Early trachoma* (Tr. I and Tr. II, MacCallan), confined to the conjunctivæ of the lids as papillæ and follicles situated in and just under the conjunctiva.

2. *Medium trachoma* (Tr. III), consisting of chronic tarsitis and chronic lymphatic infiltration of the conjunctiva together with attempted healing.

3. *Late trachoma* (Tr. IV), completely healed trachoma.

In 'early trachoma' (Tr. I) there are few papillæ and follicles, the former chiefly along the upper border of the upper tarsal plate; the latter, especially in the upper fornix, encroaching on the tarsal conjunctiva centrally and at the angles, but definitely embedded in the conjunctiva and surrounded by little engorged areas or minute hæmorrhages.

In Tr. II the above changes are much more in evidence, but the whole process is still superficial as shown by no true thickening of the

tarsus itself, any thickening being of an oedematous nature.

In 'medium trachoma' (Tr. III) the chief criterion is involvement of the tarsal plate itself, which is more or less grossly thickened and can be so demonstrated clinically by the difficulty experienced in double everting the upper lid with the hook. It is in this stage, after the extrusion of the follicles on the surface,—ulceration—that in between the cicatrices there is the appearance akin to granulation tissue as opposed to the typical sago-grain follicles. The conjunctiva in this stage also often presents the appearance of felt over the whole of the conjunctival surface of the upper tarsus with no evidence of papillæ or follicles, the fornix by now being almost obliterated and no definite cicatricial bands being seen. This stage more or less merges into the next.

In 'late trachoma' (Tr. IV) the tarsal conjunctiva is completely cicatrized with one or two bands of scar tissue such as Arlt's (1881) sulcus. The tarsal plate in this stage is thin again and, if evenly cicatrized, it may be difficult to diagnose the case as healed trachoma. If the cicatrization has occurred unevenly the effects of this, such as entropion, may be visible.

These are the main landmarks in the course of the disease, though sometimes it may be found difficult to separate them in practice, as the change from one to the other is gradual. Of two of the main features of the disease, namely, ptosis and pannus, something further must be said.

Ptosis.—Strother Smith, Bishop Harman (1931) and Galal Aboul Seoud (1927) mention drooping eyelids, trachomatous ptosis as it is called, as the most noticeable point about trachoma which differentiates it from any other conjunctivitis, but I have found that there may be no ptosis in the early cases, and not until stage III is the condition well marked. The only early cases showing marked ptosis have in my experience been those complicated by secondary acute conjunctivitis, when the ptosis appears to be oedematous and inflammatory in origin. The typical ptosis met with in Tr. III is in my opinion the result of the chronic tarsitis which is the essential of this stage and which has caused chronic hypertrophy and thickening with increased weight of the tarsal plate.

In this connection Herbert (1907) has demonstrated 'the sinuous lid border' as an almost exclusive sign of trachoma, his description of the condition being 'the inner portion of the lid margin arches upwards in a normal manner, but the outer half presents a curve with its convexity downwards. It (the distortion) is nearly always bilateral'. He found the condition always associated with marked ptosis and confined to rather severe cases of the disease, but considered that the distortion was not due to cicatricial contraction for he found it was well marked before contraction had

taken place. His explanation, as Elliot (1920) remarks, of its probable cause being blepharospasm remoulding a softened tarsus, is difficult to follow. I consider it is much more probable that this condition is the result of incomplete cicatrization of the hypertrophied and thickened tarsus of Tr. III in severe cases, which is not completely converted into the smooth contracted condition found characteristically in Tr. IV. Instead, the centre of the tarsus has undergone this change, becoming thinned, while the angles remaining thick give this pathognomonic appearance to the lid. This explains Herbert's finding that it is confined to severe cases of the disease in which also the ptosis is most marked, for it is well recognized by MacCallan and others that many cases of healed trachoma show no ptosis and have been so mild that the only evidence of the disease is scanty, horizontal scarring of the surface of the membrane; in others not even this diagnostic sign remains.

Pannus.—The signs originally discovered by Herbert (1904) in this respect, which have since been described under different names by various observers (Bonnet, 1927 and 1928; Millet, 1924) and are now regarded as a true extension of the trachomatous process to the cornea, resulting in follicular ulceration on that surface (Cuenod and Nataf, 1931; Morax, 1929), are certain evidence of active trachoma, but in India large numbers of mild trachoma cases never show corneal involvement and the only evidence in others is a faint haziness of the upper region of the cornea resembling faint arcus senilis but without its sharply demarcated edge. So the corneal signs are of diagnostic value only in active cases of the disease.

II. Details of present work

The work on which my conclusions are based has been carried out in order to appreciate trachoma as it occurs in India.

Quetta, where the examinations were carried out, is the largest military station in British India and has a total population of 60,228 (1931 census—town and suburbs 34,892, cantonments 25,336), with a garrison of over 12,000 (British 3,000, Indian 9,000 approximately). It is situated at a height of between 5,000 to 6,000 feet above sea level. Unlike the greater part of India, it has no monsoon with its sudden break in the hot spell, but a gradual change throughout the year from winter cold with freezing temperatures, rain and snow from December to March, a European spring gradually increasing to summer heat of June, July and August with the temperature reaching above 100°F. (the average weekly temperature during these months is 80 to 85°F.), cooled only for short periods by a few hours' rain.

The rainfall is only four to five inches a year and the humidity is consequently low (weekly relative humidity during the hot months is 50 to 70 per cent). The soil is sandy throughout

the province, Quetta itself being situated on a large sandy plain surrounded by mountains and barren rocks absorbing heat and reflecting light, so that ground glare is particularly troublesome.

In the winter, cold, strong, biting winds from Afghanistan are prevalent, while for four months of the year during the hot weather dust storms occur often two and three times a week. These dust storms sweep throughout the town and district, often continuing throughout the whole day. The dust rises in huge whirlwinds of so-called 'dust devils' reaching 300 to 500 feet high, penetrating everywhere—dwelling houses, work places, parade grounds—collecting in all eyes, and depositing therein dust containing dried infective material from conjunctivitis cases and from the faeces and filth that are deposited anywhere throughout the countryside.

As specialist in ophthalmology for Baluchistan district I have had an opportunity of studying the eye diseases affecting the military population stationed in the province and noting the conditions chiefly responsible for temporary disablement, permanent unfitness for service and permanent damage to sight. It was early found that the majority of Indian troops reporting sick with eye complaints were suffering from external eye diseases—diseases of the lids, conjunctiva and cornea—the numbers in this category being out of all proportion to those amongst the British troops who lead the same type of army life under the same climatic conditions.

Incidence of diseases of lids, conjunctiva and cornea of British and Indian troops in 1931-1932

	1931		1932	
	Number	Per mille	Number	Per mille
British ..	25	0.083	19	0.063
Indian ..	283	0.314	239	0.265

Further it was found that those cases complicated by trachoma proved more serious and were much more slow in responding to treatment than similar cases in British troops. Further, most trachoma cases reporting sick on account of eye symptoms were found almost invariably to be suffering from complicating secondary acute or subacute conjunctivitis. Cases with uncomplicated early (Tr. I and Tr. II) trachoma rarely reported sick on this account. So to study the incidence of the disease throughout the Indian garrison and determine the factors which might influence its occurrence, spread and course, examinations were made of various classes of Indian troops and, for comparison with these, examinations of civilian recruits and school children. The effects of

different forms of treatment were also investigated.

Examinations

An examination of men of the Indian Hospital Corps was carried out in September 1931 and in September 1932—

- (a) to determine the proportion of the uncomplicated disease in the unit,
- (b) to observe and classify the different forms and stages of the disease, and
- (c) to record the findings and re-examine the unit after one year.

The results of this examination show that the unit trachoma incidence was 43 per cent in 1931 and 27 per cent in 1932.

The re-examination after one year was with the intention of forming a check on the original observations, and of noting the changes occurring within this period.

Unfortunately, owing to the retrenchment of the Indian Army since 1931, of the 383 men examined that year only 61 were present for re-examination in September 1932, the whole Gurkha section of the unit having been disbanded and the total unit reduced by two-thirds, so that the figures have not proved as valuable as they otherwise might. There were only minor changes in the classification in 16 cases; ten of the doubtful cases were later regarded as free of trachoma; no case previously regarded as free of trachoma was considered to have shown signs at the second examination; only one case of Tr. III was considered on the second examination to be free of trachoma (this was a mild case which had undergone treatment after the first examination); and no case of early (Tr. I and Tr. II) had become late (Tr. III and Tr. IV).

Bearing in mind the above results the fall in trachoma incidence in the unit from 43 per cent to 27 per cent must be regarded as due to the disbandment of the most heavily trachoma-infected men of the unit.

An examination of a Punjab regiment was carried out. The results show that the unit trachoma percentage is 30.0 while the only marked community variation is found among Sikhs in whom the incidence is twice as great as among others.

Punjabi and North West Frontier Mussulmans in a cavalry unit show an incidence (62 per cent) twice as great as that among the similar classes of infantry.

The necessity for the segregation of the infected into trachomatous units as was carried out during the great war by Lister (1923) and in Indo-China since, and emphasized by Talbot (1929) and others, prompted the examination of a mixed unit (Royal Bombay Sappers and Miners). In this unit two-thirds of the men are Punjabis (Mussulmans and Sikhs) and one-third Mahrattas (natives of Bombay, the Deccan

The results are summarized in the table below :—

protoplasm taking a medium or light blue stain. It was only in these isolated epithelial cells that

(a) = Tr. I and Tr. II cases.

(b) = Tr. III and Tr. IV cases.

It will be noted that the diagnosis of these trachoma cases is based on clinical findings for none of the available laboratory or serological tests were considered more reliable.

Laboratory findings

Scrapings from 10 cases of trachoma grown on ordinary nutrient agar, blood agar and serum agar did not produce very satisfactory results: half the tubes were sterile and in the remainder *Bacillus xerosis*, *Staphylococcus albus* (in one case) and *Staphylococcus aureus* (in four cases) were grown. Very similar results were obtained from 46 cases of acute conjunctival infections.

Conjunctival scrapings (stained by Giemsa's method and examined for cellular contents) showed :—

1. Predominance of large lymphocytes, with large granular nuclei often showing karyokinetic changes.

2. Small lymphocytes and plasma cells considerably less in number than the large variety.

3. Occasional irregular granular cells with deeply-staining intracellular bodies corresponding in appearance to the cells of Leber. These were not prominent and were not very typical in appearance.

4. Epithelial cells in quantity, oftenest in collections together, but here and there as isolated cells with large nuclei and surrounding

faint pink granular bodies, corresponding to those described by Prowazek and Halberstaedter (1907), were seen.

Though such findings were confirmatory of trachoma the clinical evidence was found to be sufficiently reliable. Twelve sections from cases in which tarsectomy was performed showed the classical changes due to the disease. Notable features in these were :—

- (1) In most of the sections the epithelium was missing or only remaining in islands over the surface.
- (2) Typical follicles were present in all. Though in one case of late Tr. III there was only one shrunken degenerated follicle which appeared strangled by the overgrowth of connective tissue.
- (3) The follicle centre in most cases had degenerated into a homogeneous mass with large lymphocytes in it. The outer ring of the follicle consisted of small lymphocytes and plasma cells which also infiltrated the surrounding tissue and especially the layers immediately adjacent to the epithelium itself.
- (4) The formation of new embryonic blood vessels in the vicinity of the follicles was a well-marked feature in all the medium Tr. III cases, with small-celled infiltration in the new vessel walls.

- (5) In the late Tr. III cases, referred to above, the general diffuse small-celled infiltration had given place in one eye to generalized fibrous tissue formation throughout the section.
- (6) In no case could Prowazekia bodies be definitely distinguished in the epithelium in sections, nor was there much small-celled infiltration of the epithelium itself.

Discussion and comparison of results

My experience in India shows that the trachoma problem is one affecting the indigenous population almost exclusively. I have seen no trachoma in British soldiers in four years, and very few cases of doubtful chronic folliculitis suggestive of trachoma. Two British officers presenting suspicious folliculitis, after twelve months' observation, were considered not to have suffered from trachoma. In only one European, the wife of a British sergeant, whose eye trouble had begun in Egypt, did I find definite trachoma (Tr. III).

As far as British troops are concerned there is no appreciable incidence similar to that reported by Eason (1919) and quoted by MacCallan (1932) as occurring among British troops serving in Egypt and Palestine between 1916 to 1918, but undoubtedly occasional instances of Europeans becoming infected do occur, similar to those recorded by MacCallan (1931) and Cuenod and Nataf (1930). As pointed out by the former from his work in Egypt and by Motais (1932) from Cochin China, the chief source of infection is probably the native servants.

Among Indian troops the disease is much more common, the incidence being greatest among the inhabitants of the Punjab. Strother Smith (1927) has mentioned finding 42 cases of trachoma (all old Tr. III) among 700 Punjabi soldiers—a trachoma incidence of 6 per cent. He does not state the community to which they belong, but his figure is much lower than my minimum figure of about 26 to 30 per cent amongst Punjabi Mussulmans. Among Sikhs, the other Punjab community furnishing the majority of army recruits from that province, the disease is much more widespread. My figures for Sikh recruits—75 per cent incidence—and Sikh sepoys—81 per cent incidence—show a constantly very high ratio which is in accord with the generally accepted state of affairs.

Previous to 1930 the attitude of Army Headquarters was to reject all recruits suffering from trachoma. In 1926 a series of lectures and demonstrations to recruiting medical officers was arranged by the authorities; in these Dickson, after describing in detail the manifestations of trachoma, recommended a test treatment 'to distinguish diseases which are not trachoma'. This consisted of hydrargyrum perchloridum 1—5,000 and brushing of the lids with silver

nitrate 2 per cent on alternate days, for three applications, followed by argyrol 10 per cent three times a day until ten days had elapsed. It was explained that this would effect a cure in the majority of cases not due to trachoma. If still doubtful the recruit was to be rejected. Dickson quoting his experience among the labour corps in France (men recruited from China, Egypt and the Cape) mentioned two Chinese companies where, at an initial examination, in the one 12 cases of trachoma were found, in the other 15, while after eight weeks without any precautionary methods or treatment being carried out, the number of infected had increased to 59 in the first and 81 in the second company. By segregation and treatment further spread was controlled. The conclusion to be drawn from this was that, bearing in mind how the disease was intractable and liable to relapse, 'the loss to the State in recruits is of no consequence compared with the danger of spreading the disease amongst the troops' and 'the enlistment of these cases is a bad bargain to the State'.

In October 1930 the experiment of enlisting otherwise suitable recruits who were suffering from 'very mild trachoma' was tried in three recruiting centres. Such recruits were to have three months' constant treatment by their unit medical officers and inspection at the end of that time by the ophthalmic specialist; at the same time instructions regarding segregation and hygiene were issued to the commanders concerned. After three months the condition of the recruits had progressed well though they could not yet be considered clear, and the experiment met with such success that in May, 1931 it was greatly extended. During the nine months from May 1931 to January 1932, 653 cases of trachoma that had enlisted were considered cured, and 65 only discharged as incurable. Investigations carried out about that time in the Jullundur district of the Punjab by the specialist in ophthalmology, Lahore, showed that all the Sikh recruits, who totalled 95 per cent of those offering themselves for enlistment, were infected. Of these 35 per cent belonged to class (a) (corresponding to Tr. I and Tr. II, MacCallan), 52 per cent belonged to class (b) (corresponding to Tr. III, MacCallan, moderately severe), and 13 per cent belonged to class (c) (corresponding to Tr. III, severe, or Tr. IV, with gross lid deformity, corneal involvement).

It was also recorded that skilled examinations in many Indian regiments showed a trachoma percentage of 25 to 30 amongst men who never reported sick. This percentage was higher where Sikhs only were concerned and the great majority of these were first-class shots, and throughout their service never reported sick with eye symptoms. Therefore in June 1932 it was decided that all trachoma cases in classes (a) and (b) above should be enlisted, and only the fact that they were suffering from trachoma

would be noted on their medical history sheets, but that unless they reported sick the eye condition would be ignored. At present this is the position regarding enlistment of recruits for the Indian Army, which occasioned the statement of the D. M. S. (April 1932) that 'It is evident that our difficulties in connection with trachoma have been greatly enhanced by our lack of knowledge of the disease as it occurs in India'.

The results of my independent observations, carried out in an endeavour to obtain a working knowledge of trachoma in the military and civil population, go to confirm these findings and support this change of policy by the military medical authorities in this country.

1. In Punjabi sepoys (excluding Sikhs) the incidence remained at 20 to 30 per cent (with the exception of the cavalry unit examined, where men of the same community showed a trachoma incidence nearly double—52 per cent).

2. In Sikh infantrymen the minimum incidence was 56 per cent with an average figure of 82 per cent. These figures are much higher than a similar average for any other community and confirm the opinion already held by Army Headquarters.

3. In Sikh recruits, excluding 10 per cent classified as doubtful, I regarded 75 per cent as definitely trachomatous, which figure, though less than that found at the Jullundur inspection, is twice as great as the incidence in the recruits of any other community, and furnish the only rejections among all the recruits examined, *viz.*, a rejection incidence of 3.8 per cent in a trachoma incidence of 43 per cent, instead of the 10 per cent rejection mentioned by Army Headquarters, during nine months' observation.

4. During the two years that have elapsed since the enlistment of trachoma-infected recruits has been in force, I have seen no cases of direct contact infection, and my observations confirm the opinion that direct contact infection among sepoys in the Indian Army is not a danger to be greatly feared; no fresh case of trachoma was found in a unit having 43 per cent incidence at initial examination; and only one very doubtful case among a community of Mahrattas from the Deccan, serving as one-third of a mixed unit with one-third Punjabi Mussulmans, with a trachoma incidence of 26 per cent, and one-third Sikhs, whose trachoma incidence though not recorded can be assumed to be at least twice as great as the Mussulmans.

Concerning this problem of the spread of trachoma in armies which has greatly exercised military medical authorities in various countries, De Grosz (1905 and 1929) pointed out that trachoma cases should be treated in the army and not discharged and Angelucci (1917) and Morgan (1917) later emphasized the same point, while Schousboe's (1925) proposals for the classification of those enlisted with trachoma, and the advocacy by Talbot (1929) of the forming of trachoma units in which trachomatous

recruits serve till considered cured, indicate the present position of this problem in armies elsewhere. In this country it does not appear to be of such paramount importance, and this departure by Indian military medical authorities from the measures adopted in the armies of other trachoma-endemic countries would seem to be safe and justified.

Notable points are:—

1. Service in the Indian Army being voluntary there is no question of evasion as there may be in conscripted armies.

2. The decision of Army Headquarters to regard trachoma, even though apparently aggravated by accident during military service, as 'not due to military service' for the purpose of invaliding pensions, obviates the possibilities of self-inoculation with trachoma referred to by De Grosz (1905) and Talbot (1929).

3. The amount of direct contact infection, judging from the results mentioned above, is negligible.

4. The only danger is a loss to the State on account of accident or intercurrent conjunctivitis lighting up a quiescent trachomatous condition, and resulting in severe corneal complications reducing vision below the required standards.

Though the examination of recruits shows an average trachoma incidence of not less than 43 per cent yet of those considered trachomatous only 4.3 per cent were cases of early trachoma (Tr. I and Tr. II), *i.e.*, trachoma in the most infective stages; the vast majority being old-standing cases which, like most trachoma in India, had been present since infancy, with a tendency to progress slowly to a quiescent stage and natural healing—Tr. IV.

Similarly, diseases which had been present since infancy, by the age of enlistment—18 to 20 years—had either developed in a severe fashion with severe corneal involvement reducing vision below army requirements (6/18), resulting in rejection of the recruit, or had in a milder form gradually passed from the infectious stages Tr. I and Tr. II, to become late mild Tr. III or Tr. IV by the time of enlistment. The examinations of Quetta school children does not show a change in the incidence of Tr. I and Tr. II from over 40 per cent to under 10 per cent during school years as MacCallan has demonstrated, but instead appears to point to a fairly constant incidence of the active infective stages among the children in Baluchistan, roughly 20 per cent, with the later stages, Tr. III and Tr. IV, slightly higher up to 26 per cent; while the ratio of early Tr. I and Tr. II to Tr. III and Tr. IV changes from 17:15 at ten years to 15:18 at fifteen years and over. These are in children who have never received any treatment, while MacCallan's figures are influenced by constant school treatment extending over two to three years.

The slowness of this change from Tr. I and Tr. II to late Tr. III and Tr. IV shown by these

school statistics confirms the opinion that the vast majority of the trachoma seen in Indian Army recruits and sepoys has begun in the early years of life and progressed slowly since that age.

This opinion, namely that trachoma infection in most cases begins in early pre-school life even in infancy, is held by many trachoma workers. The emphasis with which Morax and others stressed it in the early part of this century is still recognized by workers in different countries.

MacCallan has demonstrated the certainty with which the infant of a trachomatous mother is bound to develop the disease. Morax (1931) in more recent work has not modified his earlier opinion. Crouch (1929), from his experience among North American Indians, holds the same view, as does Talbot (1932) in Tunis, while Wilson (1931), working in Bahrim, found that, of 140 children under one year old, 25 per cent showed Tr. I (and 38 per cent of the total had acute conjunctivitis) and is of the opinion that most trachoma infection occurs before one year of age.

Also in these school children the percentage of trachoma was considerably higher—57.9 per cent—among those children showing no signs of grossly diseased tonsils and adenoids, than among those showing definite signs of the adenoid syndrome—42.1 per cent. This finding does not accord with the views of Angelucci (1929 and 1930) and Piquero (1932) that adenoidism produces a suitable soil for the infection. It may be that in a trachomatous individual the disease is more prone to develop in a more severe form if the patient also suffers from adenoids. Although Quetta school children, especially Sikhs, show a lower incidence than might be expected, judging from the Jullundur findings and my findings among recruits, this is due in all probability to the fact that the children examined, though children of Punjabi Sikhs, have been born and reared in an environment different from their Punjab villages, and further because the majority are the children of town Sikhs who follow different occupations, e.g., carpenters and shopkeepers, from those of the agricultural class in whom the disease is rampant in the Punjab and who furnish the army recruits.

The varying community incidence which is seen in other countries as shown by Talbot (1930) with an incidence around 30 per cent in the French schools and 53 per cent in Franco-Arabic schools, also by Junes (1931) with 10 per cent incidence in the former, 50 per cent in the latter, and by Kanda and Takizawa (1928) in Formosa (28 per cent among Japanese and 68 per cent Formosan), and that recorded by Fonseca (1932) in Brazil, is easily understood where the indigenous populace is compared with that of the much more highly educated colonizing race; but in India the varying community incidence is among people of the same race (descended from the same stock) living under

similar conditions though differing in habits. It is said that in Indian villages the incidence varies greatly in individual villages of the same community and also probably in individual schools of the one community, just as is reported by Bakker (1928) regarding Java schools, and such variation is undoubtedly influenced by living conditions, individual hygiene, etc.; but the remarkably constant difference in incidence among the agricultural class of Punjabi Mussulmans and Sikhs is more difficult to explain. It will be considered later.

The examination of Gurkhas stationed in Quetta provides the explanation for the cases of early trachoma Tr. I and Tr. II found in soldiers, which though much less common than the cases infected in early life occur even in mild epidemic form. Gurkha recruits (ages 17 to 20) on arrival in British India from Nepal are free from trachoma, yet Gurkha riflemen after five to ten years' service in India show definite evidence of the disease (8.7 per cent). Though the 'line boys' furnish one source of trachoma among these troops the chief factor in my opinion is infection of the men from their families. It is evident why this is a more prominent feature than among Indian units when it is seen that after two or three years' service Gurkhas are allowed 27 per cent to 100 per cent married quarters in the unit lines while Indian units spend most of their service separated from their families.

Also, Gurkha families suffer from acute Koch-Weeks conjunctivitis in epidemic form each summer; I have found this condition in Gurkha families both in Baluchistan and the North West Frontier Province and after it has subsided it leaves behind definite (27 per cent) evidence of fresh early trachoma (Tr. I and Tr. II), which in my opinion forms the source from which the men showing Tr. I and Tr. II become infected. In confirmation of this it was found that the only cases of advanced Tr. III with corneal complications in Gurkhas reporting sick for treatment have been in 'line boys' who were infected with trachoma in a similar manner during their early childhood in the unit family lines.

This rôle played by secondary conjunctival infections, especially Koch-Weeks, in the spread and course of trachoma is widely recognized. Strother Smith (1927) referring to trachoma in the Punjab—the most highly trachoma-infected province in India—states that 50 per cent of the school children there are found suffering from some form of conjunctivitis. De Peyrelongue (1927) in Syria and Zachert (1927) in Tunis record the high proportion of trachoma cases in those countries which are secondarily infected, while the latter author considers such secondary infection the cause of serious corneal complications occurring in trachoma. Similarly MacCallan and Wilson recognize the linking of the diseases. To quote the latter, they consider

'that trachoma is an infectious disease *sui generis* and that preceding infections are not necessary precursors of the disease. At the same time, we believe that the trachoma virus will flourish more readily on an unhealthy conjunctiva and likewise that mixed infections are probably potent causes of the spread of trachoma'.

So those factors influencing the epidemic spread of such acute conjunctival infections likewise influence trachoma, and these authors show their relation to climatic condition (variations in temperature, humidity, etc.), also the part played by flies is considered important. While it is generally recognized that the usual method of spread of trachoma is digital, by infected towels, handkerchiefs, etc., MacCallan (1931) admits that flies do play a part, even though it be a minor one, in the propagation of the disease. Wilson (1931) regards them as important carriers of acute conjunctivitis infection, while Said (1927) correlates the spread of trachoma in Syria with the associated plague of flies, and Cuenod and Nataf (1930), from their experience of trachoma spread in the human being and as the result of their experiments with trachoma transmission by flies in baboons, are of the opinion that flies are largely responsible as a means of spreading the disease.

In judging the results of the treatments carried out in active cases of the disease observed, it is to be noted that the main endeavour was to find some procedure giving a more rapid healing than the older methods. Even bearing in mind the views of such observers as Bishop Harman (1931) who is sceptical of the diagnosis when a case of suspected trachoma reacts speedily to treatment, and Strother Smith (1927) who, in the light of further experience, has come to regard those cases, which he had reported in 1912 as showing rapid response to trachoma treatment, as cases of simple chronic conjunctivitis, I am convinced that certain of the short courses recorded in my series achieved rapid improvement or clinical cures in cases of true trachoma.

Excluding the 8 per cent doubtful Tr. I and Tr. II or chronic folliculitis, which probably were innocent, of the 57 per cent cases Tr. I and Tr. II as resulting in clinical cures, at least three-quarters were undoubtedly early trachoma which had not only resisted treatment measures for ordinary folliculitis but were becoming more severe until trachoma treatment was commenced.

All showing Tr. III signs were unquestionably definite trachoma and of these 6.8 per cent were rendered clinical cures and 34 per cent rapidly healed to Tr. IV after the treatment employed.

In the findings of conjunctival scrapings there was no one special finding typical of trachoma sufficient to be diagnostic, but the combined findings of abundant large lymphocytes, Prowazekia bodies and Leber's cells, from which Cuenod and Nataf (1930) consider an almost

certain diagnosis of trachoma can be made, were seen. As Wilson (1931) says 'there is really very little to distinguish the early stages of trachoma from other follicular conditions of the conjunctiva' though he considers that there is a more marked proportion of large lymphocytes in follicular conjunctivitis; by this means therefore an infallible diagnosis could not be made. Similarly sections of the lining membrane and tarsus are not practicable for diagnostic purposes in the early stages, and in the later stages are unnecessary, so that at present microscopy does not supersede clinical diagnostic methods.

From this study of trachoma in Baluchistan certain features of the disease as it occurs in India are found to correspond to its manifestations in other countries, also local peculiarities, differences and difficulties are found.

1. Though similar in its manifestations to the disease met with in other tropical countries it differs from the Egyptian variety in certain ways:—

(a) The average incidence among the inhabitants of the Punjab, the most highly infected district (as judged by the examination of army recruits), may be no higher than 43 per cent while in Egypt more than 90 per cent of the population are regarded as infected (El-Bakly, 1932).

(b) The severe complicated variety with marked pannus and corneal ulceration is not so common in India as in Egypt, this being at its worst only among the very poor and the lowest castes (sweepers), who besides being undernourished are always employed in the dirtiest of occupations and are rarely other than filthy in person.

(c) The form of the disease seen in town school children and military recruits differs considerably from that met with among the poor cultivator class; in the former, it is mild and shows a tendency to slow change to a quiescent or healed stage, in the latter it more nearly approaches that referred to by Egyptian workers.

(d) Like the Egyptian form it is most often found complicated by secondary conjunctival infections, especially by the Koch-Weeks bacillus and *B. morax*, on account of which the patients demand treatment; but only occasionally—probably only in certain districts—with spring catarrh and very rarely with gonorrhoeal ophthalmia.

2. The incidence of the disease varies greatly in different localities throughout the country. Herbert and Elliot are quoted by Cuenod and Nataf (1930) as estimating a trachoma incidence of 10 to 20 per cent (presumably in Bombay and Madras). Wright (1929) judging from his work in Madras has variously declared it to be from 3.3 per cent to 4.5 per cent in that presidency while my figures for examination of Punjabis show an incidence of 20 to 30 per cent

among Mussulmans and 75 to 80 per cent among Sikhs.

So Wright's figures from Madras, where trachoma is undoubtedly uncommon, give an entirely fallacious idea of the general incidence of the disease throughout the country.

3. The majority of cases show a mixture of follicles and papillæ with one or other type of lesion predominating in different individual cases.

4. The constantly high incidence among Sikhs is difficult to explain, and though no definite reason for it can be determined it throws light on certain points. The mode of life of this sect of purely Punjabi origin does not differ greatly from their neighbours. In their villages they are agriculturists like the majority of Punjabis; in towns they are found chiefly as carpenters, joiners, etc. In habits they are if anything more cleanly than their Mahomedan neighbours, though, on account of their religious custom of never cutting the hair, their head ablutions may not be as easily or frequently performed as among other Punjabis with closely-cropped heads. On the other hand as a community they indulge a lot in communal religious bathing ceremonies performed in sacred tanks at their temples. In my opinion this mistaken religious hygiene is a prominent factor in explaining the constantly high incidence of the disease among them without causing an equal spread to other communities of the same district.

5. The constant community incidence which has been shown among the various classes of soldiers and civilians is kept so by the caste system prevailing in the country. Though Sikhs, Mussulmans and Hindus may mix together at schools, games or in after life at work in the country or towns, or in army service, their intimate relations are confined to their own communities and homes. They will only eat with fellow religionists and their food and utensils are prepared either by their own co-religionists or by themselves, while any common sanitary arrangements such as washing, towels, etc., though they may be common to their family or relations will not be more widely used.

6. Another feature, in connection with the prevalence of the disease among Sikhs and its higher incidence in the Punjab than elsewhere, is that in stature, development and physique the Sikh excels, being robust and muscular, showing no signs of predisposition to deficiency disease, while the Punjabi diet is a good mixed diet of atta (Indian flour), dāl (lentils), meat, ghi (fat), milk and fruit—nutritious and vitamin-containing in comparison with the diet of the southern Indian whose main article of diet is rice.

When it is remembered that such deficiency diseases as beri-beri and keratomalacia are uncommon in the Punjab and frequent in the

south [Wright (1932) regards the latter condition the chief cause of preventible blindness in children in India] where trachoma is rare, it appears to negative the suggestion of Royer (1926) and Kirwan (1927) that the disease is a deficiency one.

7. The examination of a cavalry unit which showed a trachoma incidence twice that of infantrymen of the same community, the greatest intra-community variation I found, together with the lower incidence among town-bred Sikh children born and reared in Quetta instead of in Punjab villages, suggests an environmental influence. The increased incidence and higher proportion of earlier cases seen in the cavalrymen suggests a bigger percentage of recent infections comparatively late in life. I consider this is influenced by their more constant contact with animals and the products of the soil.

The lower incidence among Sikh children living in Quetta, in more urban though no less dusty and dirty surroundings than in their Punjab homes, is due to being less in contact with agricultural pursuits.

The one common feature of the countries where trachoma is endemic is that they are agricultural countries, the majority of the sufferers being of the agricultural class. Egypt, India, Ireland, Russia, Poland all come under this category, and though in these countries the infection is undoubtedly more common among the poor and dirty, the poverty, dirt, undernourishment or lack of hygienic surroundings cannot equal those of the slums of the large European cities of industrial countries, where though trachoma is found it is distinctly less frequent. Is the trachoma virus a soil infection which infects those in contact with the soil and its products, spreading further in unhygienic home surroundings?

8. Most trachoma workers consider that until the causal virus is discovered no great advances in our knowledge of the disease can take place, but it is not certain that even though the microbic cause of the disease is found the main part of our problems will be solved.

9. In the study of trachoma, researches for the microbic causes of the disease must be pursued, though at present there are no immediate prospects of the discovery. The significance of Prowazekia and other inclusion bodies has long been in doubt, and apart from the American observers, Olitsky, Knutti and Tyler (1932), the recent opinion of most investigators elsewhere—Morax (1930 and 1931), Favoloro (1932), Rieger (1932), etc.—is to regard Noguchi's *B. granulosis* as typical of a folliculitis not necessarily trachoma.

Meanwhile the campaign against the disease must be continued, and it would appear that more expert clinical methods, especially by the slit-lamp, will simplify the diagnosis of the disease. Though El-Bakly (1932) is of the opinion that the study of the cornea is not a

great help in the diagnosis of the disease in the doubtful stage, Wilson (1932) considers it of extreme value in the differential diagnosis in doubtful cases especially if mild, while Howard (1933), in his recent review of trachoma-diagnosis literature, conveys the impression that it is in this field that advances in our knowledge are likely to lie.

10. Apart from infection in infancy the main danger of trachoma infection lies in the spread of the disease along with Koch-Weeks or other types of acute conjunctivitis. Whether the disease is latent and only rendered active by the secondary acute conjunctival infection or whether it is spread in epidemic form, a study of the disease among Gurkhas in British India shows a definite spread of fresh trachoma after such epidemics.

To combat this in such a community where laws of hygiene are little understood or practised, a polyvalent vaccine such as recommended by Durand and Lumbroso (1927) should prove of service. From their work in Tunis they found that such a vaccine had no bad effects of any kind and only 9.3 per cent of vaccinated children harboured the Koch-Weeks bacillus as against 30 per cent unvaccinated.

11. From the result of the treatments carried out in this series it is shown that in the majority of cases met with in the army a mild remedy such as sodium chloride in fine powder, massaged into the affected conjunctiva, produces clinical cure very rapidly, while in the more florid type, seen especially among the peasant class, an initial scraping with Volkman's spoon removes the grossly unhealthy follicular masses, often leaving in view a non-infected though œdematous tarsus underneath, so that the cure can be completed by reverting to the sodium chloride massage. I am convinced that if sodium chloride massage were used on a wide scale, especially in children in the pre-school and early school years, instead of the multifarious remedies at present employed by the rank and file of those practising European methods in Indian bazars and villages [*vide* Kewal Ram (1931) who mentions that no fewer than forty-four different remedies varying from native herbs to radium are recommended, without distinction, as useful in the treatment of the disease], marked progress could be made in clearing up the manifestations of the disease.

Conclusions

1. The trachoma problem in India is one which concerns the indigenous population.

2. The incidence of the disease varies greatly in different districts being highest in the Punjab and least in southern India.

3. Among the different communities the disease is present among the different classes of the same community in a fairly constant ratio.

4. Of all the various religions and castes, Sikhs in which the incidence is at least 75 per

cent are those mainly affected, while among southern India Hindus it is practically non-existent.

5. From a study of the disease in the Indian Army most of the cases met with are old, the disease obviously having begun in early life and a large proportion being healed by adult life.

6. On this account we can conclude that the scheme of enlisting recruits suffering from trachoma—which differs from the policy in the armies of other trachoma-endemic countries—is safe and justified, and is unlikely to cause any serious spread to the healthy troops on account of (a) the better hygienic life of the sepoys in comparison with the overcrowding, etc., of Indian village life, (b) the rigid caste system which prevails in army life even when men of different communities are brought together in barrack life, and (c) most of the trachoma being healed or almost healed by the time the age of enlistment is reached.

7. Like Egyptian trachoma most of the infections occur in the homes of the agricultural classes among young children even before school life.

8. Fresh cases in adults are similarly derived from their infected families, especially during epidemics of Koch-Weeks ophthalmia.

9. A treatment measure, such as Saliberry's sodium chloride massage which is cheap, simple, quickly effective and safe in application, is required if the disease is to be effectively treated by any other than a few ophthalmic experts.

10. A national anti-trachoma scheme is necessary, involving wide propaganda on the nature and results of the disease amongst

- (a) Indian practitioners who practise European methods in this country,
- (b) school teachers and educated social workers, and
- (c) the agricultural classes themselves, especially the womenfolk, by means of the two channels above mentioned.

Such a scheme should enlist the co-operation of

(a) the existing research institutions wherein animal and human experiments could be carried out to improve our present knowledge of the disease,

(b) the large military and civil hospitals and institutions where new treatments could be investigated,

(c) the medical colleges and universities where the rank and file might be taught the manifestations of the disease in a practical form to enable them to distinguish the disease and practise its prevention and treatment with safety, and

(d) the village and bazar doctors who alone can carry the treatment campaign to the masses of the people in the form of some standard simple treatment of sufficient prophylactic and curative value, while serious or complicated cases could be treated under the supervision of

a district trachoma authority, or operated on in one of the district centres.

11. If in the beginning such a scheme were confined to the most heavily infected province and limited to children as a child welfare scheme, it would serve as an introduction.

SODIUM EVIPAN ANÆSTHESIA—A STUDY OF 30 CASES

By E. S. CHELLAPPA, M.B., B.S. (Madras)
King Edward Memorial Hospital, Secunderabad

THE only way to assess the true value of a new drug is by the sharing of the experiences of independent workers with that particular drug. No apology is needed, therefore, for a report on 30 operations which were performed under sodium evipan. The following list shows the nature and variety of the operations in which it was used :—

Salpingectomy, excision of broad ligament cyst, laparotomy for peritonitis (3), appendicectomy and appendicular abscess (3), Cæsarean section (2), sub-total hysterectomy (2), ventral hernia (2), strangulated hernia, irreducible

inguinal hernia, bubonocoele, tonsillectomy (2), double hydrocele, dilatation and curetting (6), evisceration of eye for panophthalmitis, cellulitis of neck (temperature 104°F.), and two other operations.

Age limits.—The youngest patient to whom sodium evipan was administered was a girl of 15, for whom tonsillectomy was done, and the oldest was a woman of 68 with a long-standing ventral hernia.

Method of administration.—Sodium evipan is a snowy-white powder put up in ampoules of 1 gramme each. Ampoules containing 10.5 c.cm. of sterile distilled water are also supplied for the preparation of the solution. The manufacturers advise intravenous injection of the freshly-prepared solution at the rate of 1 c.cm. per 15 seconds, while some authors advocate the very slow rate of 1 c.cm. per minute. In my experience, any speed from 15 to 30 seconds per c.cm. is suitable. The patient is asked to count slowly as the injection is given. Most patients lose consciousness after 3 c.cm. or 45 seconds, while some become unconscious only after 3.5 c.cm., and others as early as after 2 c.cm. One educated Anglo-Indian lady, asked as to how she felt during the injection, replied that she felt 'an irresistible desire to go to sleep'. The majority of the patients yawn before they lose consciousness.

Dosage.—The dosage depends chiefly on the relaxation of the jaw. The necessary dose varies very much from case to case. Any quantity from 5 to 10 c.cm. of the solution may be needed. Along with the relaxation of the jaw, the quantity within which the patient loses consciousness and stops counting also helps in determining the dose. Thus, a patient who stops counting early will require a smaller dose than one who counts longer. We have not yet come to any conclusion as to the relationship between the dosage and the duration of anaesthesia. We have observed cases where 2 c.cm. of the solution repeated when the patient was about to come round, would keep him under for a few more minutes. In three cases which received 2, 4 and 6 c.cm. respectively, though the dosage in each case was not sufficient to keep the patient under, the quantity of chloroform subsequently needed was substantially reduced, and the troublesome state of excitation avoided.

Relaxation.—Once the patient gets under, the respiration is slow and steady, and the relaxation of the abdominal wall is extremely satisfactory. The value of this feature in abdominal sections cannot be over-estimated. Another peculiarity we have observed is that even when other muscles, such as those of the limbs, are not fully relaxed, or when the patient is beginning to come round as indicated by the reappearance of the corneal reflex, the abdominal wall still remains flaccid, thus allowing the operation to go on undisturbed. This feature is in contrast

with the stiffening of the abdominal muscles, which is so annoying, when enough chloroform is not administered. An almost constant phenomenon is the spasmodic jerks of the limbs, these are usually weak and few, but were in a few cases strong and frequent. In two cases, tremors of the whole body were observed when the operation was started after injecting 10 c.cm. of evipan, which was not enough to get the patients under.

Duration of anaesthesia.—The effect of evipan is said to last from 15 to 20 minutes but there were in this series more than half a dozen major operations, including two Caesarean sections, and one for ventral hernia, each of which lasted from 20 to 30 minutes. A sub-total hysterectomy and a laparotomy for an appendicular abscess with extensive adhesions were performed, each operation lasting for 45 minutes. No other anaesthetics were administered in these two cases, and the relaxation was splendid throughout. Several operations, up to a maximum duration of one hour, have been carried out with sodium evipan supplemented by chloroform or A.C.E. mixture. The combination of these drugs seems to cause no ill effects. In one case of sub-total hysterectomy for a very large cervical fibroid 11 c.c. of sodium evipan and 4½ drachms of A.C.E. mixture were administered, while one old woman of 68, the oldest of our series, with a very difficult ventral hernia, was given 10 c.cm. of evipan supplemented by 5 drachms of chloroform. The closed method with the Harcourt inhaler was used in both these cases. These two operations lasted for one hour each, and were successfully completed, no bad after effects being noticed.

The corneal reflex.—The corneal reflex disappears immediately after the injection of sodium evipan. In one case of laparotomy for peritonitis and one of appendicectomy, however, lasting 18 and 30 minutes respectively, the corneal reflex was retained throughout, though the patients were well under as shown by good relaxation of the muscles. The reappearance of the corneal reflex does not indicate that the state of anaesthesia has definitely come to an end. It is usually possible to continue the operation from five to ten minutes after its appearance. This is especially so in abdominal operations, as mentioned before.

Post-operative symptoms.—The majority of the patients go quietly to sleep after the operation and wake up three to six hours later, feeling quite refreshed. One man of 25, a case of tuberculous peritonitis, on whom a laparotomy was performed, was in a semi-narcotic stage for 15 hours after the operation, becoming fully conscious of his surroundings only on the morning after. The dose of evipan in this case was 10 c.cm. and the duration of the operation 20 minutes. In ten of the cases, including five of abdominal operations, the patients became very boisterous soon after being

removed to the ward, and had to be given either morphia or eukodal to quieten them. One woman was so violent that two eukodal injections had to be administered to keep her quiet. Only one of these ten cases was ascertained to be a regular arrack drinker. In contrast with chloroform, there is no tendency for the patients to vomit after the operation.

Untoward signs.—So far, untoward signs have neither been frequent nor alarming enough to make us afraid of this new anæsthetic. Three of our patients did not however respond to sodium evipan, though the maximum dose of 10 c.cm. was injected in each case. Chloroform had to be administered subsequently. One of these three patients was strongly addicted to arrack and had also chronic bronchitis. He started coughing violently when the operation was begun after 10 c.cm. of evipan had been injected and much chloroform was used before the cough could be controlled.

We have on record only two cases which caused any anxiety, but both of them were revived easily and speedily. One of them was a young woman whose uterus was being evacuated after an incomplete abortion. After 8 c.cm. of evipan, she became cyanosed, her respiration was shallow, and the pulse weak; but this lasted for less than a minute, and an injection of ether soon set her right. This was the second time that sodium evipan had been administered to her, the same operation having been done on her with the same dose of evipan five days previously with no ill effects.

The second case, a girl of 15, the youngest patient on our list, whose tonsils were removed after an injection of 8 c.cm. of evipan, had a compensated double mitral lesion of the heart, rheumatic in origin. A minute after the injection of the anæsthetic, the pulse became feeble, the respiration stopped, and the patient became deeply cyanosed. She however started breathing very soon after artificial respiration was commenced, and the operation was successfully completed. Her condition after the operation was quite satisfactory, though she was boisterous for some time. We attribute the untoward signs observed to the state of her heart, and we have no doubt that chloroform would have been even more dangerous in her case.

One case of appendicectomy had troublesome hiccough during the first five minutes of the operation, after administering 10 c.cm. of evipan, but it passed off, and the patient had good relaxation of the muscles for 20 minutes afterwards.

The simplicity of the administration of evipan sodium is its most attractive feature. Its greatest sphere of usefulness lies in operations of short duration. The most noticeable shortcoming of evipan is its tendency to cause a boisterous or even a violent condition of the

(Continued at foot of next column)

TREATMENT OF ENLARGED SPLEENS WITH INJECTIONS OF MILK

By A. P. JANA, M.B.

Contai, Midnapore

In the September 1932 number of the *Indian Medical Gazette*, Major B. H. Singh, I.M.S., noted that he had tried injections of milk in enlargement of the spleen due to malaria with amazingly good result. He tried this in enlargement of the spleen due to kala-azar, but the result was not as successful. In the January 1933 number of the *Indian Medical Gazette* D. A. Ganguli stated that these spleens would probably have been cured by the usual treatment without the injection; that the injection of milk has no effect whatsoever on the reduction of the size of chronically-enlarged spleens; and that probably Major Singh used milk in only recent enlargements and that is why he obtained such encouraging results which would not be the case in hard spleens of longer duration.

Being attracted by the results noted by Major Singh I have been trying the injection of milk in all cases of enlargement of spleen with the result noted below. The injection is given twice a week by 2 cubic centimetres at each subsequent injection up to 10 cubic centimetres at the fifth injection. If the spleen does not disappear under the costal arch after the fifth injection, i.e., after one course, another course is repeated after one month. Thus two or three courses are repeated sometimes in obstinate but improving cases. The milk is made fat-free by churning and the fat-free milk sterilized in a water-bath and cooled. The milk for injection is taken into the syringe from below the scum formed after cooling and the injection is given in the gluteal muscle.

I have so far treated 319 cases of which 80 have been discharged as cured. One hundred and forty-six cases received only one injection and did not return, consequently the results could not be noted. The outcome in 173 cases was noted to some extent; of those 173 cases 98 had soft spleens, 54 hard spleens and in 21 cases the consistency of the organ had not been

(Continued from previous column)

patient after the operation. This we have observed in no less than a third of our cases. Its dangers are few while its advantages are many: but fuller clinical research is necessary before the value of sodium evipan can be fully assessed, and its name established as a standard anæsthetic.

I have to thank Lieutenant-Colonel R. F. D. MacGregor, I.M.S., Medical Officer, King Edward Memorial Hospital, who operated on the cases mentioned, for permission to publish this report, and for valuable advice and guidance.

noted. Eighty patients were discharged as cured; of 44 cases no data were recorded, while the remaining 49 cases (24 hard and 25 soft spleen) improved, but ceased to attend before they could be labelled as cured. Of the improved hard-spleen cases two were of ten years, one of six years, three of five years, two of two years, five of one year and others below one year's duration. The size of spleen in these cases ranged from three fingers to nine fingers below the costal arch.

Of the 80 cured cases there were 56 soft spleens, 18 hard spleens and of 6 cases the consistency of spleen had not been noted. Of the hard spleens one was five inches, of ten years' duration and cured in three injections only; one was six inches of six years' duration, cured in 14 injections in three courses; one was eight inches, cured with five injections; two were four inches of four years' duration each cured in four injections. The duration of the others was below one year. One—nine inches of five years' duration—has been slightly reduced and its stone-like hardness considerably softened after one course of five injections. This case is still under treatment and is expected to be cured.

As the patients were all outpatients coming from various distances they did not attend regularly for the injection as advised, consequently the result of the last injection could not be noted. Among the improved cases there must be many cured. In fact we detected on

enquiry three cases cured after the first injection only; all these three were cases of recent origin with small-sized spleens.

The conclusions at which I arrived as a result of my experience were as follows:—

(1) Enlargement of the spleen is reduced by intramuscular injection of fat-free milk.

(2) Milk injection is effective in enlargement of spleen due to malaria.

(3) In enlargement of spleen due to kala-azar, it has very little effect if any. I tried it in one case with four injections regularly but to no effect and the patient was subsequently treated and cured with neostibosan.

(4) Soft spleens are easily reduced in size with this treatment.

(5) The progress of improvement is slow in hard spleens. After the completion of one course of five injections a second or third course is sometimes required, a gap of one month being given between two courses.

(6) The longer the duration of the enlarged spleen the more the number of injections and the longer the time required for its cure.

My thanks are due to my compounders for their hearty co-operation in keeping the records of the injections and noting the results; otherwise it would not be possible for me to have studied the result of this cheap and easily-available medicine in the treatment of an ailment that is so common among the malaria-infected masses.

A Mirror of Hospital Practice

AN ENCOURAGING RESULT OBTAINED BY THE USE OF E. C. C. O.* IN THE EARLY STAGE OF LEPROSY—ANÆSTHETIC TYPE

By NIRMAL CHANDRA DUTTA,

Sub-Assistant Surgeon, Silchar District Jail, Cachar, Assam

Z. N. N. of Hafflong, North Cachar Hills, life-sentence prisoner, aged about 38 years, of indifferent health, weighing 98 pounds, i.e., 8 pounds less than he should have normally weighed, was admitted into the jail hospital on the 18th October, 1932, for the treatment of balanitis, eczema of the scrotum and a superficial erythematous patch on the skin measuring 2 inches in diameter on the left side of the face over the malar prominence, the centre of which was of a brownish colour, shiny and anæsthetic, while the margins were hyperæsthetic. Neighbouring lymph glands were found enlarged to some extent. The patient in addition complained of headache, malaise and anorexia. A specimen of skin from the patch and blood serum were sent to the Shillong Pasteur Institute on the 22nd October. The report, received on the 7th November, was that lepra bacilli were found in masses in the deeper part of the skin and that the Wassermann reaction was negative.

Accordingly the patient was transferred to the leper ward of the jail hospital and was placed on E. C. C. O. and potassium iodide in increasing doses, while the general diet was improved by adding extra milk and fish.

Intramuscular injections of E. C. C. O. was commenced from the 7th November, 1932, at an interval of four days starting from $\frac{1}{2}$ c.cm. and gradually increasing by $\frac{1}{2}$ c.cm. to 5 c.cm. After receiving a total quantity of 113 cubic centimetres of E. C. C. O. the patient was attacked with bacillary dysentery on the 3rd April, 1933, and was treated with salines while the E. C. C. O. injections were stopped during the attack until the 15th April. The injections were again started from the 16th April and continued until the 30th August thereby giving in all 303 cubic centimetres to date. The injections were then stopped until the 5th September as the patient complained of pain all over the body and the site of injection was seen to be inflamed. As this subsided, the injections were again started from the 6th September and continued until the 24th September by which time he had received a total quantity of 328 cubic centimetres. As the patient complained however of vertigo and dizziness the injections were suspended. On the 10th October signs of inflammation were noticed on the right scapular region involving an area of 8 inches diameter which gradually developed into a large carbuncle which was excised on the 24th October, and had healed by the 28th November. The E. C. C. O. injections were again commenced on the 17th December, commencing with $\frac{1}{2}$ c.cm. and increasing the dose by $\frac{1}{2}$ c.cm. each week

* Ethyl ester of hydnocarpus with creosote camphor and olive oil.

until a maximum of 3 c.cm. was being given; the total amount administered up to the 21st January, 1934, was 338.5 cubic centimetres. After the above course of treatment, the patient was found to be totally cured of leprosy as the nasal smear showed no acid-fast bacilli and all other physical signs of leprosy had disappeared. The patient was kept under observation for a period of about two and a half months after the closure of the treatment in the event of a relapse but up to the present there has been none.

After disinfection he was discharged from the leper ward and allowed to mix with the ordinary prisoners of the jail, being given separate accommodation at night.

I am indebted to my Superintendent Captain R. A. Haythornthwaite, I.M.S., for rendering me timely instructions in treating this case and for permission to publish the result.

TWO CASES OF BILATERAL CERVICAL RIBS

By N. MANGESH RAO, M.B., C.M., F.R.C.S.

Surgeon

and

K. MANJUNATH RAO, M.B., B.S.

Assistant Surgeon, General Hospital, Madras

Case 1—A Hindu female, aged 30, was admitted into the General Hospital, Madras, on 21st February, 1934, for neuralgic pains in the right arm of two and a half years' duration.

History—Two and half years ago, while bathing her child, she felt her right arm suddenly benumbed and powerless. With rest and massage she recovered. Some months later she noticed neuralgic pains in the limb after use. Latterly the pains had become worse and extended into the wrist and fingers, but relief was obtained by raising the arm to the side of the head. The pain was of a shooting type with pins-and-needles sensation and numbness. This has recently become persistent.

Condition on admission—A well-nourished young woman, rather fat but sturdy. Both shoulders and arms were of equal proportion with no wasting of muscles. The grips of both hands were equal. On examination a bony resistance could be felt on both sides of the root of the neck. There was no visible pulsation on either side. On the right side neither the brachial nor radial pulse could be felt. The blood pressure in the left arm was 105/70 but none could be made out on the right side. No wasting of the intrinsic muscles of the right hand was seen.

X-ray photographs showed bilateral cervical ribs of the third degree. On the right the cervical rib seemed to join the first rib just lateral to the scapular tubercle without any joint, but on the left a joint could be made out.

Operation—Through a collar incision the tendon of the scalenus anticus was exposed and a tenotomy of this tendon was done as advised by Adson. The pulse in the right brachial returned but was very feeble. After this the cervical rib was exposed by lifting the brachial plexus and the rib was excised subperiosteally as far as the transverse process of the seventh cervical vertebra. The periosteum was then snipped away. The brachial pulse improved but the radial one was not perceptible.

The wound healed by first intention. The radial pulse became perceptible on the third day after operation and steadily improved. All pain and tingling had ceased.

Comment.—The sudden onset was probably due to lifting the child while bathing it. The fact that only arterial pulsation was absent without any atrophy of muscles suggests that the pressure effects were mainly on the sympathetic nerve supply of the artery. The fact that the returned pulse was not as strong as on the opposite side is probably due to some intrinsic narrowing of the arteries from long-standing spasmodic contractions of the vessels. Adson advises simple tenotomy of the scalenus tendon, but in this case it did not improve the

Case 1—X-ray of bilateral cervical rib before operation.

pulse to any great extent until the rib was also removed.

Case 2.—A Hindu male, aged 43, was admitted on 4th April, 1934, for neuralgic pains shooting down the left arm and up into the neck, of two and a half years' duration.

arm to the side of the head was due to the subclavian artery being compressed between the raised clavicle and the cervical rib.

We are obliged to the Government X-ray Institute, Madras, for the roentgenograms.

Case 1.—X-ray of bilateral cervical rib after operation.

History.—The pain was first noticed two and a half years ago in the left side of the neck. Later it became neuralgic, shooting up into the neck and down the left arm. He felt the left arm easily fatigued and benumbed during the attacks.

On admission.—A well-built adult but not stout. A distinct swelling with visible pulsations was seen in the left supra-clavicular fossa. A bony mass could be felt under the subclavian artery. Pressure on these produced the neuralgic pains. There was no muscular wasting and the hand-grip was good. The radial pulse in the left arm was good with the arm hanging down but disappeared on lifting the arm to the side of the head.

The Wassermann reaction was positive. Roentgenograms showed a complete cervical rib on the right and one of third degree on the left. A joint could be made out between the cervical and the first thoracic rib.

After a course of anti-syphilitic treatment the patient was operated on and the left cervical rib was removed as far as the transverse process of the seventh cervical vertebra. The wound healed by first intention. The radial pulse was tested in both positions of the arms (hanging down and abducted to the side of the head) and was as good as on the opposite side. The neuralgic pains had ceased.

The patient was discharged after a full course of anti-syphilitic treatment.

Comment.—The unusual sign of disappearance of the radial pulse on abduction of the

EVIPAN SODIUM FOR SMALL OPERATIONS*

By S. C. GUHA ROY, L.M.F.

Assistant Medical Officer, Pancery Tea Estate, Assam

THE writer's experience with this drug in minor surgery has been encouraging. It appears to be a suitable anæsthetic for use in small hospitals where there is often a lack of assistants. A short note is appended on the application of the drug in a simple case of mammary abscess.

A female coolie suffering from an abscess of the breast was put on the operating table without any preliminary treatment. A total of 5 cubic centimetres of evipan sodium was injected intravenously. After the first 2.5 cubic centimetres had been given the jaw relaxed and complete unconsciousness quickly followed. She regained consciousness nine minutes later by which time the operation had been completed. An hour later the patient felt quite normal.

My thanks are due to my chief Dr. E. Burke for his kind encouragement and permission to publish a note on this case and to Mr. T. Hassain for his able assistance.

Indian Medical Gazette

DECEMBER

THE INDIAN RESEARCH FUND ASSOCIATION

THE Indian Research Fund Association is not only the most important medical research organization in India but it is also the oldest organization of its kind in the British Empire, the Medical Research Council of Great Britain, which was formed during the Great War, being about five years younger. Although this Association will shortly be entering upon its twenty-fifth year of existence, there is still a surprisingly large number of medical men in India who appear to be entirely ignorant of its functions and achievements.

It is the obvious duty of every medical man to maintain an interest in medical research work, even if his routine duties prevent him from taking an active part in it himself; further it is also his duty to interest and to help to educate the general public in this subject, as not only do we rely on the financial support from public funds for the maintenance of the organizations that carry out this work, but the active and intelligent co-operation of the general public is often essential for the successful execution of a research scheme. In these circumstances we feel that it will not be out of place to give a short account of the origin and aims of the Indian Research Fund Association and of the procedure that is adopted in the administration of its funds.

One of the earliest organized investigations into any medical problem in India was the Plague Commission. This Commission was formed in 1903 partly by members of the Indian Medical Service and partly by scientists recruited in Europe. When its main purpose, the demonstration of the transmission cycle of plague, had been fulfilled, the Government of India realized the desirability of having a permanent body of men to continue the work of this Commission and ready to undertake other investigations of this nature when occasion arose; therefore in 1908 they constituted the Bacteriological Department—which has now been more appropriately renamed the Medical Research Department—and three years later they initiated an epoch for medical research in India of almost complete freedom from the governmental system of administration and control. They founded and liberally endowed the Indian Research Fund Association. This Association which was controlled by a Governing Body was permitted to spend its annual income for medical research in whatever way it thought best, and was also permitted to use the Central

Government's existing bacteriological staff and its Central Research Institute for the better organization and conduct of its activities. The defined object of the Government of India in creating this Association was to prosecute and assist researches in tropical diseases and also to carry out experimental work generally in connection with the causation, mode of spread and prevention of sickness and disease in India.

It was anticipated that Government would continue their annual contributions for research and salaries of officers in the Medical Research Department, but on the recommendation of the Incheape Retrenchment Committee their grants were wholly discontinued from 1923 to 1924. The Government grants had enabled the Association not only to finance researches on various problems but to accumulate funds specifically for the purpose of founding an Imperial Medical Research Institute.

The income derived from these accumulated funds helped to tide the Association over the years following the acceptance of the Incheape Committee's recommendations but the annual Government grant was later restored, partially in 1926-27, and fully in 1928-29. As a result of the general economy campaign, from 1932-33 the annual Government grant to the Association has again been discontinued—that is to say it has been reduced to one and a half lakhs, a sum which barely covers the pay and allowances of the permanent members of the Research Department temporarily employed by the Association—and it cannot be said if and when it will be restored. In order to balance the budget, and at the same time to maintain as far as possible all major enquiries in India, and to keep in employment the large body of specially-trained men, many of whom have been working for a number of years, the Association have since that year been drawing from its accumulated funds three to four lakhs a year. The question of establishing the Imperial Medical Research Institute has now been postponed by Government indefinitely, but during 1932-33 and 1933-34 the Association has contributed Rs. 2,11,000 towards the cost of additions and alterations to the buildings of the Central Research Institute, Kasauli, from these accumulated funds.

Besides financing investigations which are being conducted by workers in its direct employment, the Association gives grants-in-aid to outside institutions and also to outside workers. Its expenditure upon various medical research problems has for the last few years approximated to about eight or nine lakhs of rupees per annum. The Association supports the Malaria Survey of India and it contributes substantially towards the cost of the kala-azar enquiry at Calcutta, which has been at work for the last ten years. It also entirely finances the researches on nutritional diseases at the Pasteur Institute of Southern India, Coonoor,

as well as other enquiries on plague, cholera, skin diseases, indigenous drugs, tuberculosis, malaria, cholera bacteriophage, etc., etc., throughout India. The results of these investigations are published in the *Indian Journal of Medical Research* and its *Memoirs*, the *Records of the Malaria Survey of India* and the annual report of the Scientific Advisory Board issued under the authority of the Association. The Association has its own library and stores at Kasauli, and encourages medical research in all possible ways. It is particularly desirous of encouraging junior workers to take up medical research in different branches and it employs a large number of skilled workers of different classes, such as bacteriologists, chemists, biochemists, entomologists, etc.

At present the formation of a junior cadre in order to encourage young scientists to enter the field of medical research is under consideration.

The Governing Body of the Association was until 1927 composed exclusively of officials, but in that year the Raja of Parlakimedi, having made the munificent donation of Rs. 1,00,000 to the Association, was appointed a life member.

The rules of the Association provide for the membership of private individuals who contribute thus to its funds, but up to the present this is the only occasion on which advantage has been taken of this rule. It is to be hoped that this will not long remain an isolated example of the interest of a philanthropist in the activities of the Association.

In 1929, the Government of India took into consideration the question of liberalizing the constitution of the Governing Body and finally decided to enlarge that body by the inclusion of three representatives of the Indian Legislatures, two representatives of Medical Faculties of Universities incorporated by law in India and one eminent non-medical scientist to be nominated by the Governor-General. As a result of further representations from the Universities and the Legislatures, the Governing Body of the Association was again enlarged in 1933 by the addition of one further representative of the Medical Faculties of Indian Universities, making three in all, whilst it was decided that the non-medical scientist should in future be elected by the Indian Science Congress. The Director of the Malaria Survey of India, Kasauli, was replaced by the Director, School of Tropical Medicine, Calcutta.

The Governing Body appoints its own Scientific Advisory Board who examine all proposals in connection with the scientific objects of the Association before submitting them to the Governing Body for approval. The ten members of the Board are appointed for one year but are eligible for re-election. The Scientific Advisory Board consists of scientific men of high standing in India, e.g., the directors of all the chief laboratories in

India; the Director-General, Indian Medical Service, is chairman and the Public Health Commissioner with the Government of India is secretary.

In order to ensure the closest co-operation between workers and to prevent overlapping of effort an annual conference of all medical research workers is convened in Calcutta towards the end of each calendar year and at this conference free discussion is held on the work accomplished and on proposals for future work.

Although this conference has no executive power, it has in the past exerted an important liberalizing influence on the conduct and management of the Association. Individual scientists are enabled to put their cases for the initiation or for the continuation of their enquiries before fellow scientists, and to hear their criticisms or to receive their support. In the past the Scientific Advisory Board, and thus indirectly the Governing Body, have been very largely influenced by the tone of the discussions at this conference.

THE CHRONIC PRIMARY GLAUCOMAS

ONE of the outstanding problems in ophthalmology to-day is the elucidation of aetiological factors in the primary glaucomas, i.e., those not directly resulting from obvious pathological or anatomical defects of the eye. Our knowledge of the mechanisms productive of intraocular hypertension in such cases has been greatly augmented in recent years by the publications of Duke-Elder, Seidel, Magitot, Meesmann, Thiel and others. That increased tension may be due to a disturbance of the physico-chemical equilibrium between the uveal capillary blood on the one hand and the intraocular fluid (largely contained in the vitreous body) on the other, may seem a satisfactory hypothesis in certain types of cases. In others an increase in volume of the intraocular vascular bed may offer a very good reason for hypertension and the displacement of the vitreous body. The action of abnormal intraocular chemical bodies on the physical condition of the vitreous gel may result in an increased volume of the posterior segment, and the safety valve mechanism of the filtration angle which at first copes with this vitreous swelling may be thrown out of action by the encroachment on the anterior chamber. This conception too seems to adapt itself to clinical appearances which are all too familiar to ophthalmologists in India. In the case of glaucoma simplex in relatively young subjects, with an anterior chamber of normal depth, a slight or marked, constant or intermittent, rise in tension, extensive cupping of the disc, and a field depressed towards vanishing point, no very satisfying explanation is available.

However interesting the speculations and proven facts in connection with the intraocular chemical, physical, and electrical conditions may be, and however valuable in helping us to frame rational hypotheses with regard to intraocular hypertension, we are still in almost complete ignorance of the essential origins of such local changes, although it is hardly likely that we can disassociate them from generalized phenomena of a similar nature throughout the body due to the same original causes. In other words it is difficult to think of a chronic primary glaucoma as anything more than a local expression in a peculiar anatomical field of a generalized disorder of unknown origin. If this be so, it may be possible for those who have the opportunity of dealing with primary glaucoma in bulk to throw some light on its ætiology by observing associated signs and symptoms of defective function in other parts of the body which are more accessible to ordinary methods of investigation than the eye. To confine the enquiry into the ætiology of primary glaucoma to the level of the eye is equivalent to limiting the investigation of chronic Bright's disease to the level of the kidney. Clinical observers in India who see large numbers of primary glaucoma cases frequently ask themselves, to what generalized disorders or syndromes does this glaucoma complex belong? What are the noxious influences at work? Are they as insidious in their action and as elusive in their isolation as some of the noxious agents which produce extensive changes in the peripheral arterial tree, e.g., the arterioscleroses? It is quite possible that this is so in some of the chronic primary glaucomas, and that our ætiological search may merely refer us further back to the vague and unsatisfactory region in which we visualize a summation of injuries to the delicate mechanisms of the body which depend on a healthy capillary wall, inflicted by all manner of toxæmias of greater or lesser degree recurring again and again through life.

Fortunately, there is at least one condition which gives us a definite lead in attempting to solve the problem of ætiology, namely, epidemic dropsy. Here we have a generalized disorder associated with the ingestion of a certain type of rice manifesting itself in definite outbreaks, by a toxæmic action on the peripheral vessels productive of dropsy (amongst other pathological changes). One speaks of outbreaks rather than epidemics as the latter term is perhaps a misnomer in this condition. One of the features of this disease is primary glaucoma of a relatively slow non-congestive onset. It stands apart as an isolated example of a clinical combination asking for further investigation; it places primary glaucoma in its proper environment, a symptom-complex of a disease of known ætiology. Calcutta workers have made the study of epidemic dropsy peculiarly their own. They have described it clinically, defined its

toxæmic nature, investigated certain of the associated histopathological changes, and noted the fact—of such vast possibilities to the ophthalmologist—that glaucoma is one of its clinical manifestations. More important still Col. Kirwan has observed during an outbreak that glaucoma may be the first isolated manifestation of this toxæmia. This is surely a significant observation, and Calcutta, so powerfully organized for co-ordinated research, should not let the matter rest here. We feel confident that they will follow up their lead by further investigation which may in time enable us to recognize other provocative agents of this malady so productive of blindness in India amongst the middle-aged and aged, and, armed with this knowledge, forestall it by preventive measures. To quote Col. Kirwan (*Arch. Ophthalmology*, 1934, Vol. XII, p. 1),* 'This subject presents a large field for experimental work and if it is carried out one can look forward to the day when a great part of the problem of glaucoma will be solved by therapeutic measures or methods of prevention'.

TREATMENT OF OPIUM POISONING

By ATINDRA NATH SEN, M.B.

Teacher of Medical Jurisprudence, Campbell Hospital,
Calcutta

OPIUM is very commonly used in Bengal in suicide and the general practitioner has to meet with such cases off and on in his practice. Of all poisoning cases reported, nearly 60 per cent are due to opium. For the purpose of treatment, I divide my cases into three groups:—

(1) Patients conscious, brought immediately after the poison was swallowed, (2) patients brought in a drowsy condition, and (3) those brought in a comatose condition.

In the Campbell Hospital I receive my cases mostly in the comatose state.

The main principles of treatment are based on:—

(1) *Elimination*.—(a) Stomach tube, (b) emetics, (c) purgatives, (d) high colon wash, and (e) diuretics.

(2) *Prevention of action or of absorption*.—(a) emetics and purgatives, (b) permanganate and other oxidizing agents, and (c) substance that will form insoluble compounds.

(3) *Counteraction of effects*.—(a) Stimulate respiration, (b) stimulate heart and circulation, (c) counteract narcosis, (d) reduce the poison in the blood, and (e) preserve the body heat.

I evacuate the contents of the stomach with a stomach tube at once, using plain warm water

and save the washings for chemical analysis. I have observed, in post-mortem examinations, lumps of opium stuck to the wall of the stomach with mucus, though repeated gastric lavage with permanganate lotion has been given. Therefore, as a routine, I now administer a second stomach wash with sodium bicarbonate solution, two teaspoonfuls to a pint of water, allowing sufficient time (three or four minutes) for the mucus to dissolve and the opium to become disentangled. Lastly, I wash out the stomach repeatedly with potassium permanganate solution, not exceeding a pint and a half each time, in strengths of five grains to a pint as long as the return wash comes out decolorized. A grain of morphine (roughly ten grains of opium) is oxidized by a grain of potassium permanganate, but in a poisoning case there are other organic matters which are oxidized also. The permanganate solution wash is repeated at intervals of two hours. If crude opium is taken, dilute acetic, hydrochloric or sulphuric acid is administered with the wash to convert the morphine alkaloid to a salt. After washing out the stomach I always leave behind in it a pint of hot strong coffee, and also give this amount per rectum every two hours, following a colon wash.

If a stomach tube is not available emetics are useful in the first group of cases, they may be so in the second, but when the medullary centres are depressed, as in the third group, they are harmful and useless.

Apomorphine hydrochloride, a tenth of a grain, is injected subcutaneously and with failure may be repeated within 15 minutes; but, whenever emetics of any kind are given, large draughts of water must be administered beforehand to get a really effective wash-out. The next best choice is zinc sulphate, failing which, in an emergency, I use mustard, one tablespoonful, or common salt, a teaspoonful in a cup of warm water, followed by tickling of the throat with the fingers.

As a purgative I always prefer saturated solution of magnesium sulphate, and repeat it, if necessary, after the preliminary stomach wash.

A high colon wash is given in all cases every two hours, but it must be given slowly. Diuretics, such as sodium citrate, potassium citrate, and spiritus etheris nitrosi, are started as soon as the patient is able to swallow them himself. Otherwise, I give caffeine sodium benzoate ($7\frac{1}{2}$ grains), an injection every six hours, and apply hot fomentation or electric bath over the loins.

The next and the most important part of the treatment is to antagonize the action of opium. Atropine is the drug for this and we must know what is the best dose to start with.

(a) Atropine sulphate is injected, an initial dose of $1/20$ th grain which is repeated every half an hour to two hours, watching its effect on the

number and character of the respirations. Small doses are of no value and I am very definite about high doses being well tolerated. On an average for a total cure, I inject $1/8$ th grain during a period of 12 hours; the maximum total dose injected was $1/7$ th grain in about 16 hours. I tried this in seven cases and I lost only one of these.

For asphyxia, oxygen is applied early and artificial respiration is resorted to if necessary.

(b) To keep up the heart and circulation I use strychnine sulphate, $1/30$ th grain, by injection every two hours up to three doses, if required. Caffein, cardiosol, camphor in ether, etc., are regularly given.

(c) To combat narcosis, I use caffeine sodium benzoate injections and flap the nose and face with hot moist towels. I never allow the patient to be exhausted by being made to walk up and down the room. Strong solution of hot coffee by the mouth or rectum is useful in this connection.

(d) To reduce the poison in the circulating blood, I strongly advise venesection, specially when the patient is cyanosed and has a feeble pulse. Fifteen ounces of blood at once, to relieve the congested heart, should be drawn out and the loss should be replenished by normal saline solution given subcutaneously. To guard against the fall of blood pressure adrenalin chloride solution should be given by mouth. I found atropine and strychnine, injected subcutaneously after venesection, increase the immediate good effect. I am so convinced of the efficacy of venesection that I feel that I should probably not have lost my case 4 (*vide infra*) had this been done.

Case 1.—C. C., Anglo-Indian male, aged 28 years, took half a tola of opium on an empty stomach at 2 p.m.; admitted same day at 6 p.m.; drowsy, contracted pupils, pulse—62, and respiration—12 per minute, breathing shallow, and face livid.

Stomach wash, coffee, etc., given. Apomorphine, $1/10$ th grain, acted in two minutes. Total atropine injected in five doses was 16 tablets of $1/150$ th grain each in 14 hours, that is, $1/9$ th grain.

The patient discharged cured after two days.

Case 2.—K. S., Indian Chinese female, aged 32 years, took one tola of opium but vomited. She again took the same amount at 7 a.m. on the 20th May, 1932; admitted at 4.45 p.m. same day—semi-comatose, pupils contracted, pulse—65, respiration—10, cyanosed.

Stomach wash, etc., given. Apomorphine acted after two injections. Total atropine injected was 10 tablets of $1/150$ th grain each, that is, $1/15$ th of a grain in nine hours. Discharged cured on 22nd May.

Case 3.—A. D., Hindu female, aged 24 years, took half a tola of opium with milk in the evening of the 23rd July, 1932. Admitted at 1.30 a.m. on the 24th July; comatose, conjunctival reflex lost, pulse—100, respiration—8, pin-point pupils, face livid, cold clammy skin, and shallow breathing.

The usual stomach wash, etc., given with simultaneous injection of atropine. Total atropine used was 19 tablets of $1/150$ th grain each, that is, $1/8$ th grain in nine hours. Patient was discharged cured on the 25th July.

Case 4.—H., Mahomedan male, aged 27 years, quantity of opium taken was unknown. Took opium at 12 noon and was admitted at 7.20 p.m. on the same

day. Pin-point pupils, deep coma, stertorous shallow breathing, pulse—120, respiration—12, and face, lips and fingers all blue. Half a tola of opium was brought out with stomach wash; atropine and strychnine, oxygen, etc., were given; venesection was not done.

The patient expired at 11-45 p.m.

Total atropine injected was 20 tablets of 1/150th grain each, that is, 1/7th of a grain in three hours but without any effect.

Case 5.—S. G., Hindu male, aged 22 years, took a quarter tola of opium at midnight. Admitted the following day at 11 a.m., drowsy, pulse—84, respiration—12, shallow breathing.

Total atropine injected was 1/12th grain in 20 hours. Discharged cured three days later.

Case 6.—K., Hindu male, aged 40 years, took crude opium, quarter tola, on an empty stomach. Pulse—125, respiration—12.

After stomach wash became cyanosed and comatose in two hours. Strychnine 1/30th grain injected three times every two hours.

Total atropine given was 1/7th grain in 12 hours. Patient improved considerably after venesection was done followed by injection of atropine and strychnine. Discharged cured.

Case 7.—J. S., Hindu male, aged 23 years; quantity of opium taken not known. Admitted at 3 p.m., comatose, pulse—96, respiration—18. Pin-point pupils, cyanosed, breathing shallow.

Total atropine given was 1/10th grain in eight hours; and three injections of strychnine, 1/30th grain each; venesection was not required. Discharged cured three days later.

DEVELOPMENT OF HEALTH EDUCATION WORK IN THE UNITED PROVINCES

By A. HAMID, B.Sc., M.B., B.S., D.P.H., R.C.P.S. (Eng.)
Assistant Director of Public Health, Hygiene Publicity Bureau, U. P., and Honorary Secretary, Provincial Branch, Indian Red Cross Society

THE need of a permanent organization for the improvement of health conditions of the rural masses has assumed considerable importance in all countries of the world. In India the rural masses constitute the bulk of the population and provide the greater part of the revenues of the State. Agriculture being the principal industry of the country and having a close interaction with individual health it is of the utmost importance that the health of the rural masses should be safeguarded. Some of the Indian States, *viz.* Mysore and Travancore, which have realized the importance of this matter and the economic value of keeping the rural population fit, have initiated measures of improvement. Several others are considering proposals for the improvement of the health of their subjects.

Public health work is intimately connected with various other schemes of welfare and in this article an attempt has been made to indicate the lines of development of the health education work in the rural areas of the United Provinces.

Various schemes for the improvement of rural conditions have been formulated and introduced in different parts of India. They have almost all been started with the idea of improving the condition of the masses by providing elaborate establishments from the start. In the United Provinces the aim has been

to improve the conditions by health education. Health, wealth and education go hand in hand and are interdependent and any uplift work will be found to be productive in the long run only if it is based on sound education. 'Uplift' is only a synonym for education. In the opinion of experts 'the health authorities should strive to spread the knowledge of hygiene by every available means as one of the most effective and economic methods of rural sanitation' (Health Organization, League of Nations).

With this principle in view the hygiene publicity bureau was established about twelve years ago and considerable attention has since been paid to *propaganda* among the masses on the occasion of fairs which are numerous in these provinces, *publicity* among selected groups of people like teachers and the education of the school-going population. The evolution of these activities has shown a tendency towards specialization, and the importance of health education has been fully established.

Propaganda work for the masses has done considerable service during the prevalence of the three major epidemics of cholera, plague and smallpox. The older people have their prejudices ingrained and it is not an easy affair to wean them of their ideas. It was therefore found expedient to train the village schoolboy in the simple rules of health as his mind was impressionable. Education in health is really a task of generations and it is not expected to show striking results for the admiration of the superficial observer in a short time. In fact no welfare work should be started which is likely to be short-lived; nor is the work interesting from the doctor's point of view if he has a tendency to limit himself to a routine existence. He must work with the spirit of a missionary, and it is a doctor who is well fitted to live in love and charity with his neighbours and to do good to the people.

One of the peace-time activities of the Red Cross Society is popular health education, and the Indian Red Cross Society found in the public health department of these provinces an agency which could carry out these activities to the best advantage. Funds for material for doing the work have been provided by the Red Cross and a well-trained personnel, distributed in the districts, by the public health department. This is an example of collaboration between health authorities and an unofficial health organization which is of greatest value in the interest of economy and efficiency.

A large number of illustrated posters, booklets and leaflets have been prepared, also light portable models have been made. All medical officers of health in urban and rural areas have been supplied with magic lanterns and slides on various health subjects. Each subject is explained by a story that will appeal to the public. Gradually the equipment has been developed, and now the bureau is in possession

of a number of health cinema films which have been prepared entirely by its own staff of producers, who have written the scenarios, laid out the scenes, photographed them and prepared the positives. There is a motor van in which the models are fitted, and a generator and a projector with films are taken about as a mobile health demonstration unit. Locally in the districts a mobile museum consisting of models has gained access in bullock-carts to those places where the motor van cannot reach. A set of public addresses (loud-speakers) also forms part of the equipment of the hygiene publicity bureau and it is used to amplify lectures with and without the show of films. A recent addition in the motor van is a wireless receiver which has been used at rural fairs to receive health lectures which were broadcasted from the Lucknow University station. It will thus be noticed that the bureau has been well equipped with appliances for imparting health education in all its forms.

Of all these articles the magic lantern has proved to be the strongest weapon in the hands of the district health officers in combating epidemics and in enforcing hygienic measures at all times. The lantern is therefore recommended as a very useful means of *propaganda* in the crude form of a 'tamasha', *delimited publicity* or *health education* in schools, and there is a simple device to work it in broad daylight as well, using the sun as a heliostat. Of course, the success of the lantern lectures will depend on the lecturer's abilities in the work.

With a view to imparting these talents the staff of medical men with public health qualifications, the sanitary inspectors and health visitors are all given a sound grounding in the methods of working so that their angle of vision may be properly adjusted. A public health worker is like an 'emulsion' of many qualities. He must have some medical qualification, he must be conversant with the principles and practice of sanitary laws and laws in general, he must know enough of sanitary engineering to understand common constructional problems, and he must understand enough of politics, without indulging in them, to be able to deal with local bodies. But he becomes like a clear 'mixture' only if he can develop the qualifications of the teacher. The training of these talents of teaching for which the doctor is well fitted has therefore been particularly emphasized by the public health department in these provinces.

The *district health scheme* of these provinces was at first introduced in three districts which were notorious for epidemics, and it has been gradually extended to 30 out of a total of 48. Under the scheme a skeleton organization consisting of one district medical officer of health with an assistant and a sanitary inspector for each tahsil with a gang of six labourers in each

has been posted. The duties consist of inspection of vaccination, inspection of registration of births and deaths, correction of vital statistics, general supervision and inspection of sanitation, inspection of scholars specially in middle and primary schools, supervision of sanitation at religious fairs and other gatherings, supervision and regular inspection of the travelling dispensaries, hygiene propaganda and control of epidemics.

This small staff in a district of at least 2,000 villages is much too meagre to show many results and it is to its credit that it is able at least to suppress the outbreaks of epidemics. It is also to the credit of the workers that the financial stringency did not materially affect the scheme although the public health budget had to be reduced by 33 per cent. The success of the work has been due to the educational work done, specially in the combating of epidemics. Not that all the epidemics have been banished, but it is certain that these outbreaks have not the same devastating results now as they used to have before. All anti-epidemic measures are peacefully enforced and accepted under the influence of that teaching in which the staff has become an adept.

Out of the crude scheme gradually evolved the *village aid scheme* under which each sanitary inspector selected for intensive work groups off half a dozen villages which he could visit frequently. This number was gradually increased and the intensity of the work in them depended upon the conditions of epidemics in each tahsil. It was by persuasion that each family dug its own pit for the daily dumping of rubbish and manure, the labour gang made only demonstration pits in the beginning and it was seen that the cultivator followed the instruction. The practice of keeping all manure in front or inside the homes or close to the wells has entirely been given up in these villages. The use of the pits for calls of nature militated against the æsthetic sense of the cultivator, but he took to the distant fields away from habitations without hesitation. The sympathies of the headman or one or two prominent men of the village were at first enlisted; he became a sort of sanitary scoutmaster in setting an example to others and thus enforcing the unwritten by-laws. Soakage pits for household waste water was another useful device which the cultivators adopted, and they adopted them willingly when they were taught their value as a device for securing drainage and reducing the breeding grounds for mosquitoes. They raised parapets on their wells to prevent the grosser pollution of their drinking water from outside. After all it did not prove an expensive affair, as they were made to understand that the small parapet was more important than the platform and that a *katcha* well could be protected by raising a *katcha* parapet. Bathing and washing over the wells were thus stopped. The sanitary scoutmaster

was given a small village aid dispensary box as an anti-epidemic first-aid appliance in order to be able to render first aid in epidemics, thus popularizing the use of quinine, cinchona, essential oils and potassium permanganate, but to popularize this box a few harmless drugs of the pharmacopœia were added which the villager would in any case take in some form or other from the local grocer in the event of common ailments. This box at once raised the sanitary scoutmaster in the estimation of his compatriots and he readily learnt how to render first aid in common accidents as well. The duty of reporting in the event of epidemics and collection of vital statistics naturally fell upon him. This is another instance of co-operation with unofficials which the public health department secured by establishing a contact with the rural population. Clean midwifery was also introduced by making the village *dai* adopt the simple rules of cleanliness in her practice, but mere lessons for her could not be counted upon, as it was the householder in each case who was taught to demand the clean method.

These were only half measures and most imperfect from the scientific standpoint but they were tolerated in order to raise a sanitary conscience under very adverse financial and social circumstances and they proved successful inasmuch as the villages of the village-aid scheme have seldom been visited by cholera and plague, while these diseases have been raging in the vicinity and while these very villages used to be the starting point of the diseases in previous years. The rat epizootic was checked at its beginning by the exposure to the sun of all household effects. Thus the village aid scheme, delimited in extent though it was, was evolved from the crude district health scheme and was based on education.

Gradually it was found that the school teacher in the village, who was the most literate man, was a more suitable person as a sanitary scoutmaster, and through him the schoolboy could be given all health education. Thus the village school became a centre for village reconstruction work. The school as a whole became a member of the Red Cross, paying a nominal registration fee annually, and formed groups for various health activities which were taken up under the guidance of a teacher who was called the counsellor. In other words the sanitary scoutmaster became the counsellor whose field of vision became broader and activities specialized. He now possessed an internationally recognized title and took pride in guiding the children in the preparation of scrap books which were exchanged with similar Junior Red Cross groups in Europe, America and Japan, as messages of friendliness. The education department encouraged the Junior Red Cross movement and rewarded the teachers by giving certificates of honour. But their energies were

mostly concentrated on organizing the practice of health habits in schools in the shape of tooth cleaning, nail paring, body and clothes washing parades. First aid in sanitation, epidemics and common accidents received a great stimulus and the Mackenzie school course in these subjects, introduced by the Director of Public Instruction and named after him, became popular. Teachers who are holders of the first-aid certificate of the St. John Ambulance Association are permitted to give the training to school children in the Mackenzie school course, but they are tested for certificates by the medical officers of the public health department.

The counsellors exercised their talents by engaging their boys in songs, lectures, debates, dramas, dialogues, poster making, essay writing, model making, competitions and exhibitions on health and hygiene. Vague lessons on hygiene thus took on a concrete shape and the scheme led to the introduction of health education of the right type in villages with the district health staff to direct the energies into the right channel. The value of light and air is now better understood by the village boy and he avoids mouth breathing too. His behaviour is very unlike that of the town schoolboy whose book knowledge of the advantages of sun, light and air once prompted him to open his mouth towards the sun and take deep breaths. Teachers are liable to go astray in health education work either on account of diffidence or excess of zeal and the district health staff is there to direct them. The district health officer is invariably the secretary of the District Red Cross branch and the deputy inspector of schools in the district is often the secretary of the junior section of the district branch. The health department and the education department thus work hand in hand in imparting health education. Incidentally these interesting activities have kept the teachers and the schoolboys engaged during their spare time and thus kept them out of the path of mischiefmongers. The amount of village improvement work which they have done can be judged from the following summary of activities in one place :

'In 1933 the Junior Red Cross groups in one district prepared in all 772 posters and 307 poems on health, and they carried out an immense amount of health propaganda, giving 981 lectures and preparing 305 dramas and 406 dialogues. They filled up 257 depressions on the approach roads and made 72 culverts. They made sanitary improvements in 17 wells and prepared 177 soakage pits. They put up 6 model wells at a cost of Rs. 1,800. They fought fire in 45 cases, saved five persons from drowning and treated 5 cases of snake-bite. They helped the health staff at vaccination against smallpox in 12 villages, at cholera inoculations in 6 villages and at plague inoculation in 8 villages'.

Rural reconstruction or village improvement work is not an isolated subject. Health education has a wide scope and is more interesting as it affects personal welfare directly. Open air exercises and gardening also come on the programme of practical health education. There are two other departments which are closely concerned with village improvement work; they are the agriculture and the co-operative department. Their themes are of a specialized nature and by co-ordinating the activities of the health department interest has been infused in the combined effort at village welfare work so far as agriculture and co-operation are also concerned.

The public health requirements of larger municipalities where funds from taxation are forthcoming are of a definite nature, the village aid scheme is suited for the smaller villages where only limited resources are available and one has to feel contented with the little that can be done. But the amenities enjoyed by larger municipalities can to a great extent be given in a modified form to the larger villages and smaller towns at a moderate cost under what has been termed the *health unit scheme*. One such unit has been introduced into these provinces with the assistance of the International Health Section of the Rockefeller Foundation. This work again is based on health education, and from the evolutionary point of view can well be considered to be the highest type of public health reform in rural areas. Public health is purchasable and it may be taken as an axiom that unless one anna is spent per head per month by the community on public health administration it is not entitled to the commodity. This may restrict the health unit scheme to semi-rural areas, and it is here that the need of such reforms is very great indeed. It is here that the bored-hole latrine of the correct type serves as an inexpensive and inoffensive septic tank which can be installed literally next to the kitchen, as no scavenging or trenching is needed. It must of course be 50 feet from a well and then it is certain that there will be no bacterial pollution of the sub-soil water. There can be no better device for the prevention of intestinal infections, both bacterial and helminthic, in places where bare-footed cultivators have to wade through mud. As regards well improvement the parapet does prevent flood water contamination of a well but the bottom of individual buckets carries much filth inside the well. Small steel hand Persian wheels are fitted on wells which have been completely covered to ensure a safe water supply. But the most important aspect of the health unit work is a trained maternity service to a degree which is sufficient to secure all normal births in the area. This is the hardest part of health education where conservatism is to be 'broken' by house-to-house visits and at clinics. Demonstrations for mothers and 'little

mothers', attention to a few minor ailments only, and the presence of a doctor at the clinic go a long way in popularizing the trained midwife in rural areas. The health education programme in schools is on the same lines as already explained under the activities of the Junior Red Cross.

The health unit is thus an intensive measure of health work which is particularly suited to the rural population and the unit also serves as a training ground for the public health staff, and this is yet another aspect of health education. A well-trained staff who started the work with house-to-house survey is available here for all kinds of experimentation. Conversion of night-soil and rubbish into an inoffensive rich manure, called 'compost', is one in view which promises to be an excellent method of disposal of human and municipal wastes in towns at an expense which is well within their means.

In conclusion it may be said that the success of all health work depends upon how the staff takes to it, and, there being no allurements for private practice, the public health staff can devote its energies in the right spirit to the task of the amelioration of the conditions of their own people. In order to judge the progress made in these provinces a comparison of the districts under the district health scheme with those where there is no health staff will convince even a superficial observer of the amount and quality of uplift work which has been done in the former as a result of the education in health.

Medical News

THE INTERNATIONAL MALARIA COURSES FOR THE FAR EAST

IN India little attention has so far been paid to these international malaria courses organized by the League of Nations, Eastern Bureau. We say 'courses', because, although only one course has so far been held, it is the intention of the organizers to hold them from time to time as long as they remain popular and appear to be fulfilling the object for which they were originated. We are not sure where the responsibility for this lack of attention lies—whether insufficient publicity has been given to them, or whether we in India have been a little slow to appreciate their importance; the fact remains that only one representative from British India attended the course that was held at Singapore last year, this representative being sent by the Madras Government. There were however two representatives from Indian States.

One criticism we heard, namely, that we do not have to go from India to Malaya in order to be taught how to deal with malaria, shows the existence of a misconception regarding the aims and nature of these malaria courses and of a parochial vision, which it is one of their main objects to widen.

Singapore has been chosen as the venue for these courses, for a number of very sound reasons, namely, that it is a central port and most easily accessible to the representatives of all far eastern countries;

that Singapore is a large town with a large medical college, where there are excellent laboratory facilities,

and with plenty of comfortable accommodation for delegates and lecturers from other countries;

that Malaya is a country where the prevention of malaria has been tackled whole-heartedly, so that practical field demonstration can be given almost anywhere in the peninsula. Though there are probably few places in India that present exactly the same problems susceptible to the same solution, as those of Malaya, this is true of any part of the world, malaria being an essentially local problem. It is not by adhering only to methods already in vogue in one's own country, or by imitating slavishly the measures adopted in any one other country, but by studying the methods of all other countries and applying those most suitable to local conditions that the maximum success in malaria control can be achieved;

and, finally, that Singapore is situated in a country where the government is sufficiently broad-minded to appreciate the value of such a course to itself, as well as to other countries, and sufficiently generous to place, at the disposal of the League for the purpose of this course, its medical college laboratories and equipment and the valuable time of its medical officers.

Those mainly responsible for the organization of the first course were Dr. M. Ciuca, Acting Director of the Eastern Bureau of the League of Nations' Health Organization, Dr. R. D. Fitzgerald, Director of the Medical and Health Services, Straits Settlements, and Dr. G. V. Allen, Principal, King Edward VII College of Medicine, Singapore.

Dr. Park, the Director of the Eastern Bureau, has kindly provided us with details of this first course, which we give almost *in extenso* in order that the scope and importance of these malaria courses may be better appreciated in India. We understand that it is his intention to organize a second course next year, much on the same lines as the first but with the few modifications indicated below, which it is hoped will extend its usefulness.

INTERNATIONAL MALARIA COURSE, 1934

THE first International Malaria Course for the Far East was held under the auspices of the League of Nations in April, May and June, 1934. The first part of the course consisted of a theoretical and laboratory study of malaria, combined with demonstrations in the field of certain methods of control, and was held in the King Edward VII College of Medicine, Singapore, and the urban and rural areas of Singapore Island and Johore, commencing on the 30th April, 1934, and extending over a period of five weeks. This was followed by field courses in the Netherlands East Indies and Malaya. These field courses were held simultaneously, the delegates being divided into two groups. The field course in Java commenced on 6th June and extended over a period of three weeks. The Malayan field course also occupied a period of three weeks commencing on the 4th June.

The course was attended by 27 delegates from seven countries; with two exceptions the delegates belonged to one of the medical services of their country of origin.

Australia sent two delegates, one from the Sydney School of Tropical Medicine, and one from the New Guinea Public Health department.

China sent three delegates, two of whom were from the National Health Administration.

Indo-China sent two delegates, Japan two, and Siam two.

Malaya naturally provided the largest number, namely, eleven delegates, all but one members of their medical services.

The Royal Army Medical Corps and the Royal Naval Medical Services each sent one delegate, and, as we have said above, India sent three, one from Madras and one each from the medical services of Baroda and Bhopal.

All the candidates had a knowledge of English and the lectures were given in this language. French was

also spoken in discussion by some of the lecturers and candidates who spoke French had numerous opportunities to read and discuss the work of the course in this language.

The previous knowledge and experience of malaria possessed by the delegates was necessarily not uniform. The majority had had some experience of the control and investigation of malaria before commencing the course and several were experienced malarialogists. This lack of uniformity of previous knowledge was probably less marked than is the case in European courses but it necessitated the inclusion in the course of instruction and practice in the fundamental and elementary aspects of each section of the subject as well as advanced teaching.

THE THEORETICAL AND LABORATORY COURSES AT THE COLLEGE OF MEDICINE, SINGAPORE

The programme of the course was divided into eleven main sections. The first fortnight of the course was devoted to the study of hæmatology, protozoology and entomology; the clinical features, pathology and therapeutics of malaria. With the exception of entomology these studies were completed in this period. The course in entomology extended over the first four weeks and occupied three hours each day. The third and fourth weeks were devoted also to the study of the control and epidemiology of malaria and field demonstrations were given each afternoon. During the last week of the course lectures were given on the malaria problems and methods of control in the Netherlands East Indies and Indo-China, the work of the Malaria Commission of the League of Nations and the history of malaria, and more extended field excursions were organized each day.

The laboratory courses in entomology and protozoology were held in the department of biology in the College of Medicine; an enormous amount of preparation was required for these courses, particularly for the course in entomology. Specimens of adult mosquitoes and larvæ had to be obtained from all parts of the East and the handling and preparation of specimens received from institutions and collectors entailed an enormous amount of work extending over many months. The laboratory was well organized in so far as existing facilities permitted, but we agree with Professor Gater that the courses could have been much improved had sufficient staff, equipment and material been available.

Dr. L. Demeney also gave a lecture and demonstration on the physico-chemical properties of oils in relation to anti-larval oiling in this department.

The clinical and pathology courses were given at the Medical Unit, Tan Tock Seng's Hospital. Systematic lectures were given each morning of the second week on the pathology, clinical aspects and therapeutics of malaria, followed by demonstrations of cases, specimens and autopsies.

The present position with regard to individual treatment, treatment in the field and mass treatment was expounded very thoroughly by the various lecturers, inspired by recent research, the report of the Malaria Commission and their own experience. The contributions to the study of the disease brought about by the study of induced malaria and its treatment were also included.

The course on the epidemiology of malaria was given in the College of Medicine, and consisted of a series of five lectures, illustrated by numerous charts, diagrams and lantern slides. The lectures on epidemiological and statistical methods were completed by an account of the various epidemiological aspects of the disease in certain of the countries of the Far East and particularly in the countries in which the field courses were carried out.

The course on the control of malaria consisted of two parts—systematic lectures and field demonstrations. The lectures were illustrated by lantern slides, charts and diagrams and were given in the College of Medicine. In addition to the field demonstrations included in the

original programme, further demonstrations were arranged at the request of some candidates. They were held in various parts of Singapore Island and Johore and were designed to illustrate the lectures on the various stages and methods of malaria control.

One room in the college was utilized as a malaria museum and many exhibits, including plans, photographs, models, apparatus used in control, and drugs, were on view during the last three weeks of the course. In addition, many of the charts and diagrams used to illustrate lectures were displayed in this room after the lectures for reference by delegates. Exhibitions were also arranged in the Municipal Health Office, Singapore, and the Government Health Office, Kuala Lumpur.

Three cinema demonstrations were given in the College of Medicine and one in the Municipal Health Department, Singapore. These included films showing the bonification methods employed in Italy, control methods used in Malaya and propaganda films.

Field courses

Two field courses were arranged and were held immediately after the theoretical and laboratory courses at the College of Medicine. These field courses were held in Java and Malaya and were attended by 17 delegates. The other delegates were unable to attend as they could not afford the time.

The field course in Java.—This was attended by five delegates and extended from the 5th to the 27th June. The delegates saw the different aspects of malaria work throughout Java and visited many places where anti-malarial work was being carried out.

The methods of control employed in Batavia for dealing with salt-water fish ponds, rice-field malaria in the hilly parts of the country, the growing of cinchona and the physiological action of anti-malarial products were all demonstrated admirably. The vectors in the Dutch East Indies were demonstrated and many examples of species control were shown. The delegates were also given an opportunity to put into practice in the field the methods of survey and spleen measurement which they had studied during the theoretical course. The organization of a propaganda service in a rural district, where films, lantern slides, pamphlets, etc., were used, was demonstrated and the connection between rural hygiene and anti-malaria work was stressed.

The problems associated with the control of *A. ludlowi* in Java and the various methods employed—the biological method applied in brackish fish ponds, the Polder system, filling, etc.—were all demonstrated.

The relation between irrigation work, carried out to dry up rice fields producing a single annual crop, and the control of *A. aconitus* was of the greatest interest to the delegates. The *A. maculatus* problem and the efficacy of the method of providing shade for drains furnished another example of species control. Other practical examples of malaria prevention were found in the methods of crop rotation and of pisciculture applied in a malarial country.

The field course in Malaya.—This course was attended by 12 delegates. The field course was so arranged that delegates were given the opportunity of seeing the methods of control employed under varying conditions in different parts of the country, and the following places were visited:—

Malacca, Kuala Lumpur, Sungei Buloh, Klang, Port Swettenham, Kuala Selangor, Penang, Province Wellesley and Kedah.

The field demonstrations were essentially practical in nature. The value of anti-malarial drainage was demonstrated under varying conditions. Demonstrations of the manufacture of materials used for drainage were given, including concrete mixing, the making of concrete inverts and slabs, Hume pipes and the manufacture of inverts by the process of spun concrete. Various oil sprayers were seen in use and the 'brush oiling' method demonstrated. Other methods of control demonstrated included jungle prophylaxis, fish

control, stream flushing, stone-packing of ravines and drainage schemes associated with water supplies for drinking, washing and agricultural purposes.

Typical breeding places of various species were seen on many occasions and opportunities were also given to collect larvae and adults using various methods. Tidal swamp areas, rice fields and ravines were demonstrated and the methods of control used under particular conditions were shown and explained. The delegates also had the opportunity to study the relation between the health organization and malaria control in urban and rural areas. They saw the working of rural anti-malarial control schemes and visited rural welfare and treatment centres and were given demonstrations of the drainage methods incorporated in the local schemes of village sanitation. Municipal organizations were visited and the methods by which the co-ordination of urban and rural anti-malarial control was assured were shown and explained.

Results

We believe that the object of the course has been attained. The original plan was adhered to, except for a few minor modifications and it appeared to work very satisfactorily on the whole.

The course was, generally speaking, well balanced and co-ordinated. A noticeable feature was the benefit derived by delegates from discussing some problems of their own countries or areas with malariologists from elsewhere. The course was, however, very heavy, the delegates being fully occupied every day until 6-30 p.m. or even later. It is considered that in future the number of hours per diem should be reduced and that more time should be available for the delegates to spend on special examinations and discussions. Certain lecturers issued copies or synopses of their lectures. This proved to be both popular and valuable in that the delegates were able to follow the lectures more closely instead of being occupied in taking notes. The lecturer was also benefited in that he could cover more ground in the time at his disposal. It is hoped that it will be possible to provide copies or abstracts of all lectures for the next course.

It was found that the time devoted to epidemiology was too short and the lack of a special department of epidemiology was very noticeably felt. It is superfluous to emphasize the importance of a department of epidemiology for medical education in general and for post-graduate courses in particular. It was also felt that it would be desirable to provide fuller lists of references to the literature of all aspects of malaria.

FINANCIAL ARRANGEMENTS FOR THE COURSE

The League of Nations provided a sum of \$14,000 for the course. This amount was expended chiefly on six fellowships given to Australia, China, Indo-China, Japan, Malaya, and Siam, on condition that the government of each country sent at least one other candidate at its own expense to attend the course, also on bringing lecturers to Singapore from the Dutch East Indies, Indo-China and different parts of Malaya, on auxiliary staff for collecting the necessary material, and on transport for the field demonstrations held in the Singapore area. Honoraria to certain lecturers participating in the course were paid by the League of Nations from the fees received from the candidates.

SUGGESTIONS FOR THE NEXT COURSE

The maximum number of candidates should be 30 if additional accommodation and equipment are provided. Under the present conditions the number should be limited to 20. The number of candidates this year resulted in overcrowding of the laboratory.

Candidates should be required to have had some previous knowledge of haematology and malaria.

The programme should be fundamentally the same as this year, but if possible it should be so arranged that candidates with considerable previous experience, who are more interested in lectures on special subjects

and field work, could benefit from the course without incurring loss of time.

The course might begin with elementary knowledge and laboratory methods, and the lectures on special epidemiology, malaria control, induced malaria, immunity, new methods, etc., and the field work in Singapore should be arranged to take place during the latter part of the course.

Time should be provided during the course, preferably during the third week, for discussion of malaria problems as a result of information supplied by the candidates regarding their respective countries. Under such circumstances, experienced malarialogists could attend the latter part of the course only and benefit from the field work and lectures on recent research and methods.

The field work alone could be attended by fully-trained malarialogists and the theoretical and laboratory courses could also be taken separately.

A special ward for research in connection with the local malaria would also be useful for competent malarialogists and laboratory facilities should be available for those wishing to investigate special problems.

BOMBAY MEDICAL COUNCIL

The following extracts from the summary of the proceedings of the meeting of the Bombay Medical Council held on the 3rd September, 1934, are published for information:—

The Council proceeded to consider the conduct of Mr. Michael Simon Judas DeSouza, Retired Military Sub-Assistant Surgeon, in giving two incorrect certificates to two passengers, wishing to sail ex-India, to the effect that they had been re-vaccinated by him on 28th April, 1934, whereas they were actually not in Bombay on that date and thus rendering himself liable to be proceeded against for infamous conduct in a professional respect.

The Council held that Mr. DeSouza had been guilty of infamous conduct in a professional respect and the Registrar was directed to remove Mr. DeSouza's name from the Bombay Medical Register.

The Council proceeded to consider the conduct of Mr. Ganpat Subrao Kasyapi, L.M.&S., in completing and submitting on 23rd July, 1933, post-mortem examination reports on three dead bodies received by him for the purpose on the same day from the police and answering every one of the several questions laid down in the form of report regarding the different parts, internal and external, of the bodies, whereas he had actually not opened any of those bodies, so that the detailed information given by him as to the internal organs of the bodies must have been untrue to his knowledge, and thus rendering himself liable to be proceeded against for infamous conduct in a professional respect.

After hearing the counsel by whom the practitioner was represented and after some deliberation, the Council decided to postpone the further consideration of the case to a session of the Council to be held after a year.

The Council resumed consideration of the application made by Mr. B. H. Bhatt, M.B.S., for the restoration of his name to the Bombay Medical Register and, after taking into account the legal opinion obtained as to the exact powers of the Council in dealing with such matters, agreed that the resolution previously adopted by the Council approving the restoration of Mr. Bhatt's name to the Register should stand.

The Council considered the suggestions made by the executive committee regarding the examinations to be visited by the visitors appointed for the purpose by the Council at its last meeting and approved the proposal that two visitors should visit all the examinations to be held next for the L.C.P.S. of the College of Physicians and Surgeons of Bombay.

The Council considered suggestions received from Capt. C. V. Thornton, R.A.M.C. (Retired), Mr. M. N. Talati, L.C.P.S., a Member of the Bombay Medical

Council, and the Chairman of the meeting of the Medical and Dental Professions of Bombay held on 18th March, 1934, regarding prohibition of non-nationals from practising in India, and it was resolved that the question raised by them be referred to Government.

THE DR. B. S. SHROFF MEMORIAL GOLD MEDAL OF THE BOMBAY MEDICAL UNION

The following subject has been selected by the Bombay Medical Union for competitive thesis for the above prize for 1934:—

Old and New Remedies in the Treatment of Malaria

The award will be in the form of a gold medal called the Dr. B. S. SHROFF MEMORIAL GOLD MEDAL OF THE BOMBAY MEDICAL UNION.

The competitor must be (i) a duly qualified member of the medical profession holding a degree or degrees and diplomas from Indian and other universities created by statute, or (ii) a duly qualified member of the medical profession holding the diploma of membership of the College of Physicians and Surgeons of Bombay.

The thesis must be sent in six typed copies so as to reach the honorary secretaries, Bombay Medical Union, Blavatsky Lodge Building, French Bridge, Chowpatty, Bombay, on or before the 2nd January, 1935.

The thesis should be designated by a motto instead of the writer's name, and should be accompanied by a sealed cover containing the name of the writer and his post-office address.

The name of the prize, the year of competition, the subject of the thesis and the writer's motto should be superscribed on the cover.

No study or essay that has been published in the medical press or elsewhere will be considered eligible for the prize, and no contribution offered in one year will be accepted in any subsequent year unless it includes evidence of further work.

The accepted thesis shall be the property of the Bombay Medical Union.

All other theses shall be returned if not accepted provided the return postage expenses are paid in advance by the writer.

In the award of the prize to the successful candidate, the decision of the committee shall be final.

BENGAL COUNCIL OF MEDICAL REGISTRATION

The following is an abstract of the minutes of a meeting of the Bengal Council of Medical Registration No. 68, dated the 16th February, 1934.

1. Minutes of a meeting of the Council, dated the 27th July, 1933, were confirmed.

2. Government of Bengal Notification announcing the election under clause (e) of Section 4 of the Bengal Medical Act, 1914, of the undermentioned gentlemen as members of the Bengal Council of Medical Registration were recorded:—

(1) Lieutenant-Colonel E. H. V. Hodge, M.D., M.R.C.P., I.M.S.

(2) Major B. G. Mallya, M.D., F.R.C.S.E., I.M.S.

(3) Dr. Ramgati Banerjee, M.B.

3. Government of Bengal Notification announcing the appointment of Dr. Taraknath Majumdar, L.M.S., D.P.H., D.T.M., F.C.S., and Dr. T. Ahmed, M.B., D.O.M.S., F.R.C.S., representatives of the Bengal Council of Medical Registration and State Medical Faculty of Bengal, as members of the Sanitary Board, Bengal, for one year was recorded.

4. Reports on the inspection of the undermentioned medical schools were considered:—

(1) Dacca Medical School.

(2) Lytton Medical School, Mymensingh.

(3) Calcutta Medical School.

(4) Jackson Medical School, Jalpaiguri.

5. Report of the Inspection Committee regarding the following items were considered and adopted:—

(a) Dr. A. D. Mukherjee's suggestion regarding the basis of calculation of maximum number of students that may be admitted to recognized medical schools (withdrawn).

(b) Returns submitted by recognized institutions, and

(c) Recognition of the Bengal Medical Institute, Balinghata, Calcutta (not recommended).

6. It was decided that a recommendation be made to Government for sanction to the proposal that 'License in Tropical Medicine' granted by the Calcutta School of Tropical Medicine be recognized as registrable under Section 21 of the Bengal Medical Act, 1914.

7. A Penal and Ethical Cases Committee was appointed for 1934 and Lieutenant-Colonel T. C. Boyd, F.R.C.S., D.P.H., I.M.S., was appointed the Convenor of the Committee.

8. A report of the Penal and Ethical Cases Committee dated the 29th January, 1934, was adopted.

9. Dr. J. C. Chatterjee, I.M.S., was reappointed a representative of the Council on the Managing Committee of the Provident Fund of the office for 1934.

10. It was decided that the undermentioned schools be inspected during the next six months:—

(1) National Medical Institute, Calcutta.

(2) Ronaldshay Medical School, Burdwan.

(3) Bankura Sammilani Medical School.

11. Entries of the qualifications D.T.M. & H. (Eng.) and D.T.M. (J'pool) were sanctioned under Section 21 of the Bengal Medical Act, 1914, against the names of Major Sukumar Nag, I.M.S., and Dr. Jagat Ram Bhatia, M.B., respectively.

12. The budget of the Council for 1932-33 was passed.

THE WILLIAM GIBSON RESEARCH SCHOLARSHIP FOR MEDICAL WOMEN

MISS MAUD MARGARET GIBSON has placed in the hands of the Royal Society of Medicine a sum of money sufficient to provide a Scholarship of the yearly value of £292, in memory of her father, the late Mr. William Gibson, of Melbourne, Australia. The scholarship is awarded from time to time by the society to qualified medical women who are subjects of the British Empire; and is tenable for a period of two years, but may in special circumstances be extended to a third year. The next award will be made in June, 1935.

In choosing a scholar, the society will be guided in its choice 'either by research work already done by her, or by research work which she contemplates. The scholar shall be free to travel at her own will for the purpose of the research she has undertaken'.

There is no competitive examination, nor need a thesis or other work for publication or otherwise be submitted. The society has power at any time to terminate the grant if it has reason to be dissatisfied with the work or conduct of the scholar.

Applications should be accompanied by a statement of professional training, degrees or diplomas, and of appointments, together with a schedule of the proposed research. Applications must be accompanied by testimonials, one as to academical or professional status, and one as to general character. Envelopes containing applications, etc., should be marked on top left-hand corner 'William Gibson Research Scholarship' and should be addressed to Mr. G. R. Edwards, Secretary, Royal Society of Medicine, 1, Wimpole Street, London, W.1, and be received not later than Saturday, 1st June, 1935.

Primary Glaucoma

A Symptom-Complex of Epidemic Dropsy

By E. W. O'G. KIRWAN, M.D., F.R.C.S.I.

(Abstracted from *Archives of Ophthalmology*, July 1934, p. 1)

EPIDEMIC dropsy is a disease which is common in Bengal and which presents the following features:

(1) It always affects rice eaters. The incidences are high when rice is the staple article of diet, low when a little rice is eaten and nil when no rice is consumed. In nearly all cases the disease is caused by rice that has been parboiled, highly polished and stored in hot and damp places for months after milling.

(2) In many outbreaks of the disease it has been possible to trace the source of infection to the same rice store, although the people affected have been widely separated. In early cases, if rice is eliminated from the diet the disease ceases to progress, but in advanced cases in which considerable damage has been done to the tissues the disease often fails to respond quickly and frequently progresses for a considerable time. Outbreaks of epidemic dropsy usually occur during the rainy season and the months immediately following the rains although they have been known to occur during any season.

(3) When the new rice crop is used, the disease quickly disappears. Both sexes are equally affected. Children do not escape the disease, although infants are not affected. The disease occurs most often in people of the middle class who lead a sedentary existence, such as clerks and students, and is uncommon among the labouring class. Servants of the household are often affected, since they eat the same parboiled rice as their masters. The disease occurs principally among Hindus whose staple article of diet is rice, but it is common among Mohammedans, who are also rice

eaters. Cases occur among Anglo-Indians and Europeans, but they are uncommon and are usually in the very poor whose principal article of diet is rice.

(4) The aetiology of the disease is not definitely known, but it is generally agreed that epidemic dropsy is a different disease from beriberi. Both diseases belong to a toxic group in which the three principal signs are oedema, hypertrophy with dilatation of the heart and peripheral neuritis. In epidemic dropsy oedema and peripheral neuritis are usually present, but peripheral neuritis is absent as a rule, while in the dry variety of beriberi there are peripheral neuritis and cardiac lesions, but oedema is never a marked sign. Beriberi is caused by a deficiency of vitamin B in the diet and can be produced by rice, but it occurs in epidemic form and is associated with conditions of famine, while epidemic dropsy is caused by a toxin produced in diseased rice, partly manufactured in the rice itself before ingestion and partly in the alimentary canal of the affected person. The latter origin explains the continuation of symptoms in persons who have ceased to eat infected rice.

Acton, Chopra and their co-workers in the School of Tropical Medicine, at Calcutta, isolated a spore-forming proteolytic bacillus of the *vulgatus* group which is commonly found in diseased rice; this bacillus has been found in the urine and stools of a number of patients. It produces a toxin which is soluble in water, resembles histamine and causes a 'cardio-capillary crisis'. The toxin develops in rice stored in damp, dark places during the hot and rainy seasons and resists destruction by cooking. The infected rice grains are usually found to be spotted or wholly opaque and may float on water. Under the low power microscope, yellowish, oval bodies are sometimes seen.

According to Chopra, the toxins are absorbed through the liver, which shows the typical lesions, and thus get into the general circulation. Symptoms may start

as early as twenty-four hours after the ingestion of infected rice and may continue for many weeks after the patient has ceased to eat infected grain. The toxins may be stored in the cells of the liver and other glands of secretion, and the digestive juices and bile may be the path by which the toxin is poured into the intestine, causing the gastro-intestinal symptoms to persist. Elimination takes place by the feces and urine, and a relapse is known to occur after an initial improvement, which can be explained only on the grounds that a dose of this stored-up toxin is released into the general circulation. The disease is not infectious and is not spread by patients who go to non-endemic areas for a change of climate. The rare cases in which people have been affected after contact with persons suffering from the disease have invariably occurred in endemic localities or following the ingestion of rice imported from these areas.

(5) One attack does not confer immunity, but rather predisposes persons to a relapse in subsequent epidemics if they eat infected rice, and they are the first to contract the disease. They appear to become permanently sensitized to the toxin and should therefore give up eating rice.

(6) The best prophylactic against epidemic dropsy is to expose the rice to the sun properly at regular intervals during the hot and rainy seasons and not to keep it perpetually in dark, damp places.

CLINICAL FEATURES

In most cases there is an initial toxic diarrhoea, which may be mild or severe, associated with nausea or vomiting. Aeton and Chopra found typical Gram-positive bacilli in the stools of these patients early in the disease, while the majority of the organisms in the stools of the controls were Gram-negative bacilli with the ordinary Gram-positive cocci. In severe cases diarrhoea sometimes persists for a long time, but in mild cases it may be absent, or constipation may be present. Gastro-intestinal symptoms vary inversely as cardiac symptoms; diarrhoea brings relief in severe cases, while constipation is often accompanied by cardiac symptoms.

The occurrence of an unexplained dropsy in several members of the same family takes place only in epidemic dropsy or beriberi. Oedema usually appears after the gastro-intestinal symptoms, yet many cases occur in which oedema is the first sign to be noticed. It is more marked in the lower extremities, but may affect the whole body, even the head. Oedema is the most constant sign of epidemic dropsy, and it may be the only sign. The initial oedema of epidemic dropsy is of the solid type and consists of two stages, dilatation of the capillaries and the production of a small amount of lymph. The skin of the affected part is often dark red and is hot and tender. The discoloration of the skin resembles erythema but is darker, though it never reaches the degree of cyanosis. In some cases dilatation of the capillaries in the skin may lead to bleeding ulcers. As the disease progresses, and the symptoms become worse, the oedema increases in extent and the skin pits on pressure.

The cardiac symptoms are characterized by shortness of breath and palpitation on exertion, and cardiac failure is of the acute congestive type. There is enlargement of the heart, with congestion of the veins, but the valves are not diseased. Tachycardia is constant, varying from 110 to 140 beats per minute, and there is usually a fall of both the systolic and diastolic blood pressure. The capillaries are greatly dilated, so that the affected tissue looks angiomatous from a distance. Rupture of blood vessels is very uncommon.

Lesions of the peripheral nerves are extremely variable and are not reliable in diagnosis. The knee jerks may be absent, exaggerated or normal, so that there is undoubted evidence of neuritis in some cases. The sensory nerves are not involved as a rule. Bronchitis

with profuse sanguineous expectoration, epistaxis and signs of oedema are sometimes present.

The blood picture shows a marked diminution of the red cells; the percentage of haemoglobin is diminished, and the anaemia is of the secondary type and is a prominent feature in all cases. In the early stages of the disease the anaemia may be due to widespread capillary dilatation, causing capillary stasis, and later it may be produced by the action of the toxins absorbed from the alimentary canal. In most cases there is a slight leucocytosis. The total nitrogen value is much below normal, this being due mainly to the diminished number of red cells, as the nitrogen value of the serum has been found to be about normal. The non-protein nitrogen content is normal, which is what one would expect to find, as in epidemic dropsy the renal function is normal. The urea and the creatinine content of the blood do not show any deviation from the normal, although the uric acid content is increased. In most cases examination of the blood shows that there is retention of chlorides, which may be one of the causes of the oedema. The oedema is not cardiac in origin, as in many cases in which oedema was marked cardiac symptoms were slight or absent altogether, and many patients without appreciable anaemia have died of cardiac failure. In epidemic dropsy there is hydraemia of the blood, the mottled erythema of the skin and the areas of capillary dilatation, often accompanied by pemphigoid eruptions, show that the oedema is not passive but that there is some active change going on in the capillaries, so much so that they have multiplied, leading to the formation of angiomatous masses. The calcium content of the blood is below normal. In normal serum, the quantity of albumin exceeds that of globulin, the relation being 1.5:1, but in epidemic dropsy the serum albumin is considerably decreased and the globulin content is nearly three times that of the albumin content.

As a rule, the signs and symptoms of epidemic dropsy appear a short time after infection, the period varying according to the severity of the epidemic. It is possible that there may be some variation in the micro-organisms that cause the toxins, as there is a certain amount of difference in the clinical signs of the disease. For example, in some epidemics the skin was harsh and dry, while in others it showed diffuse erythema. In some epidemics there were marked cardiovascular signs and symptoms, while in others the heart and the pulse rate were normal. Again, in some epidemics nervous manifestations such as exaggerated reflexes and paralysis of muscles were present, while in others the nervous system was not involved.

In epidemic dropsy, the pathology of particular interest is the dilatation of the capillaries, which is most marked in the fatty tissue underneath the pericardium and the peritoneum. This dilatation is also found in the alveolar capillaries of the lungs, in the uterus, in the ovaries and in the intestines. It has been observed to occur where the vessels are least supported. There is no inflammatory reaction or wandering cells around the dilated blood vessels, and, as a rule, there is little tendency to haemorrhage, although haemorrhages do occur. Occasionally dilated blood vessels in the skin project forward, forming hemangiomas, and at times these rupture and bleed profusely. Dilated blood vessels were also found in the ciliary body, iris and choroid in cases in which there were no clinical ocular signs or symptoms before death. I have never studied the morbid anatomy of the eye in cases of epidemic dropsy associated with glaucoma, as in the large number of cases in which I have operated I have been fortunate enough never to lose an eye.

with epidemic dropsy was first reported of 100 cases which of epidemic dropsy from 1908

10 1909. Observations on 253 cases in Bengal were reported by Mukerji in 1927.

During the last quarter of 1929 and the first quarter of 1930, a large outbreak of epidemic dropsy occurred in Bengal and Calcutta and, during the last quarter of 1932 and the first quarter of 1933, there was a less severe outbreak in the same areas. During these outbreaks a large number of cases of glaucoma occurred; 325 of the patients came under my care, the affected persons being from Calcutta and from various endemic areas in Bengal.

The glaucoma associated with epidemic dropsy is of the primary non-inflammatory type, and the eye remains quite white even in cases in which the tension is extremely high.

Increased intra-ocular tension usually occurs as a late manifestation of the disease, but in the epidemic of 1932 to 1933 a large number of persons with glaucoma were seen with slight or no other general signs of the disease. Some of those in the latter category gave a history of having contracted the disease in a previous epidemic but, on the other hand, a number gave an irrelevant history, so that in some cases the toxin showed a special predilection for the intra-ocular capillary endothelium, while in the majority of cases this endothelium was involved with the general endothelium system of the body.

The incidence of glaucoma as regards the type of person, age and sex is the same as in the general disease. It is more often seen in persons between the ages of 20 and 35, but I have frequently seen cases of glaucoma associated with epidemic dropsy and a high intra-ocular tension in Indian boys and girls from 8 to 15 years of age.

The first symptoms of glaucoma to be noticed are rainbow colours, haloes around lights and gradual diminution of vision. These haloes are at first transient, but as the disease becomes more marked, they become permanent. Both eyes are usually affected at the same time, although some patients give a history of one eye being affected first. Patients complain also of difficulty in reading, as their sight is blurred. The disease is not accompanied by pain, as a rule, but occasionally there is a sensation of discomfort or heaviness in the eyes. Nausea and vomiting are absent. In almost all cases the conjunctiva and sclera are not affected except for the turgescence of the anterior ciliary veins, which stand out prominently. In the few cases in which congestion of the conjunctiva was observed it was explained by the previous instillation of physostigmine. The corneas may be normal in appearance, or they may have a steamy or ground-glass appearance, depending, as a rule, on the amount of increased tension in the eyes, but in all cases examination with the corneal microscope shows evidence of corneal oedema. The rainbow rings, which are due to oedema of the cornea are always a marked symptom of the disease, and they are an important point in distinguishing the glaucoma of epidemic dropsy from ordinary primary glaucoma, as in the latter variety the rainbow haloes are not always present. The anterior chamber is never shallow as in other types of glaucoma; it is either normal or deeper than normal, and there is never any pushing forward of the lens and iris. The glaucoma is therefore of the anterior segment type, in contradistinction to the posterior segment type in which the anterior chamber is shallow. Swelling of the vitreous body, which usually plays a predominant part in the pathogenesis of glaucoma, is absent, and therefore swelling of this body is not necessarily an essential factor in the causation of glaucoma. The increased intra-ocular pressure is due to the dilatation of the capillaries of the uveal tract followed by an increased permeability of the endothelial walls which leads to an increased output of intra-ocular fluid in the anterior segment of the eye. The pupil is normal in appearance and reacts well to light and in accommodation. Examination with the corneal microscope shows no evidence of inflammation in the aqueous or the iris. In the cases studied, dilatation of the vessels in the iris probably was present, but the vessels

could not be seen owing to the heavy pigmentation of the iris in natives of Bengal. The ciliary body like the iris was not involved, except that weakness of accommodation was nearly always present. The media and lenses were normal. Even in advanced or absolute glaucoma of this type opacities of the lens have never been observed. The fundus cannot always be seen clearly owing to the corneal oedema, but in most cases glaucomatous cupping is not present. In long-standing cases of two or three months' duration, cupping is present with evidence of atrophy of the disc, and the cupping becomes more marked according to the duration of the disease. The fundi were carefully examined in a large number of cases before operation and also after operation when the intra-ocular tension had decreased to normal, and there were no gross changes. The veins either were normal in size or showed some engorgement, and they appeared much darker than normal. Chopra noticed in many of his cases that on venesection the blood was dark chocolate-coloured instead of dark red and that the serum was bile-tinted. His observations can be verified by ophthalmoscopic examination. Retinal exudations do not occur.

The outstanding phenomenon of this variety of glaucoma is the extremely high tension. It is rarely below 50 mm. of mercury (Schiotz) and tensions of from 70 to 100 mm. of mercury are quite common. I have seen some cases in which the intra-ocular tension was over 100 mm. of mercury. The tension, as a rule, remains high constantly, but cases occur in which it varies tremendously, even dropping to normal for a short time. Both eyes are affected, although I have seen a case in which one eye was affected at first and the other was involved a month later. The tension is usually about the same in both eyes. With such high tension, one wonders why blindness from optic atrophy does not result much more quickly. The optic nerves seem to resist the high tension for a number of weeks before any evidence of atrophy is found in the visual fields, but unless the tension is relieved optic atrophy of some degree invariably results, at times progressing to complete blindness. Cases are seen in which the glaucoma disappears spontaneously after the general disease has disappeared, leaving the defects in the visual fields dependent on the duration of the increased intra-ocular tension.

The defects in the visual fields in the glaucoma of epidemic dropsy are much the same as in chronic primary glaucoma. In early cases there is depression of the peripheral field starting in the nasal quadrants. The upper, lower or both quadrants may be affected. In later stages the visual fields show concentric depression. Most cases show Roenne's step. The colour fields react in the same way as the fields for white and shrink as the fields become contracted. In more advanced cases there is a general depression of the peripheral fields; the upper and lower quadrants are more affected than the outer quadrant, and the blind area gradually increases till the field is reduced to an oval or irregular area, leaving the fovea and the blind spot intact. This field may be horizontal on the temporal side, but it may be in one or the other quadrant. In more advanced cases the central vision disappears, leaving only a small eccentric field, and finally this small area also disappears. As in primary glaucoma, various atypical fields are found in the early stages. One quadrant in the nasal field may be affected out of all proportion to the other; the visual fields of the two eyes may be markedly different, and the blind area may be more advanced in one eye than the other, but the nasal fields are always more affected than the temporal fields. Examination of the central field shows a pericæcal depression, and the scotoma, relative or absolute, is continuous with the blind spot to a varying extent. In later stages Seidel's and Bjerrum's signs can be demonstrated according to the duration of the disease. Cases have been seen in which the visual fields improved after operation, Bjerrum's scotoma changing again into Seidel's scotoma; the latter

may diminish in size or may disappear completely, leaving the blind spot normal.

Some observers state that glaucoma does not occur in cases in which there is profuse diarrhoea, but this is not my experience, and I have seen many cases with high intra-ocular tension accompanied by diarrhoea. Purgation produced by the administration of saline solution has no effect in lowering intra-ocular tension in this type of glaucoma.

In the treatment of the general disease the important thing is to eliminate rice completely from the diet and to wash out the alimentary canal by the administration of purgatives and large amounts of fluids. Convalescence is slow, and recovery may take a considerable time, depending on the severity of the attack. In mild cases, the most practical therapeutic measure is to get the patient away from the endemic area, as it is difficult for the average Indian patient to refrain from eating rice, his staple article of diet, for any considerable time. The dietetic and medicinal treatment for this type of glaucoma are most unsatisfactory. Some patients get well without therapy, but invariably a damaged visual field results, depending on the severity and duration of the disease. Purgatives, diuretics and diaphoretics are of little use, even to reduce the tension to a lower level. Intravenous injections of hypertonic saline solutions have been tried without any effect. Miotics, such as pilocarpine and physostigmine, are practically useless, and these have been used so extensively that the pupil becomes pinhole in size. This therapeutic sign is useful in the differential diagnosis from ordinary chronic primary glaucoma, in which the tension usually reacts more or less to miotics. Epinephrine packs placed under the upper lids have also proved useless. I never prescribed physostigmine in cases of epidemic dropsy associated with glaucoma, as it has the added disadvantage of causing hyperemia of the conjunctiva, thus making operative treatment more difficult.

As long as the visual fields show no defect, there is no necessity of carrying out an immediate operation in the hope that the general disease, and with it the glaucoma, will be cured before the optic nerves become permanently damaged by the increased intra-ocular tension. The patient should be kept under observation and should refrain from eating rice, but as soon as defects in the visual fields become evident operation should not be delayed. One would think that this type of glaucoma is, of all known varieties, a primary glaucoma, and that a temporizing operation could be done, as the patient will get well spontaneously when the cause is removed and all that is necessary is to keep the tension down until this end is achieved by repeated anterior sclerectomies. In practice this is not sufficient, as it takes a considerable time to get the disease under control in spite of the withdrawal of rice from the diet and the use of eliminative treatment. I have carried out repeated anterior sclerectomies in a large number of cases, but they only lower the tension for a number of hours. Since I have found the tension to be as high or even higher twelve hours after operation, this type of treatment has been abandoned. A complete iridectomy was also tried in a number of cases and was found to be of little use in keeping the tension down. By far the most successful method is the Elliot operation with a 15 mm. trephine. During this operation, as may be expected, the iris balloons into the trephine hole and the aqueous escapes under great pressure. A small peripheral iridectomy is done. I have never seen intra-ocular hemorrhage at the time of the operation, even when operating on eyes with extremely high tension. The results of trephining are excellent, and the tension seldom rises again once the decompression is carried out. I have found in a small number of cases a moderate increase of tension several days after operation, but this can always be controlled by gentle ocular massage. In the course of time, when the general disease is cured, the trephine

hole closes. I have had to perform a second trephination on some patients in whom glaucoma developed again in a subsequent attack of epidemic dropsy. It is of interest to note that in this type of glaucoma the optic atrophy is caused by the increased intra-ocular pressure alone and cannot be attributed to the toxins that cause epidemic dropsy. Once the increased intra-ocular tension is relieved by operation and the tension of the eye remains normal, optic atrophy ceases to progress. In a number of patients I have observed the fields carefully for a considerable time after operation, and in a few patients up to a maximum period of six years, and invariably the field has remained the same or has slightly improved after operative treatment. Another point of great practical interest is that I have never seen a case of this type of glaucoma in which opacities of the lens have developed after operation which could be attributed to sclerocorneal trephining; neither have I seen a case of late infection after operation.

SUMMARY

Primary glaucoma in association with epidemic dropsy is due to toxins which contain bodies of the histamine group, and the glaucoma is of the chronic primary non-inflammatory type. The toxin circulating in the blood causes a vascular disturbance which upsets in some way the normal function of the intra-ocular capillary endothelium as well as causes dilatation of the general capillary field which leads to an increased output of tissue fluid. As the glaucoma is only part of a generalized disorder, the treatment should be medical if only a speedy method were known to rid the body of the toxins. The operative treatment is symptomatic and is intended to prevent permanent damage being done to the retina by the increased intra-ocular tension till the general disease has been cured by the elimination of the offending toxins. Is the pathologic progress of the other varieties of primary glaucoma somewhat similar to that associated with epidemic dropsy? This subject presents a large field for experimental work, and if it is carried out one can look forward to the day when a great part of the problem of glaucoma will be solved by therapeutic measures or methods of prevention.

Vitamins in Clinical Medicine

By S. J. COWELL, M.A., M.B., M.R.C.P.

(From the *Practitioner*, Vol. CXXXII, January 1934, p. 15)

THE average individual requires of his food that it shall satisfy three or perhaps four conditions. It must satisfy his hunger, it must be appetizing, it must not give him indigestion, and it may have to be attractive to the eye. Observations of the feeding habits of various races of mankind have established the fact that even if these conditions are fulfilled the human species may be content to go on from generation to generation making use of dietaries which are incapable of producing perfect physical development or of maintaining individuals in a state of normal health. When the comparatively recent science of chemistry was first applied to biology it was natural that attempts should be made to analyse the substances used as foods by living animals, and it was equally natural that those components should first be recognized which were present in relatively large amounts. Thus attention soon became drawn to the so-called main constituents of foods, the proteins, fats, carbohydrates and mineral salts, and physiologists set about the investigation of the individual rôles that these constituents played in nutrition. For a time it seemed possible that the secret of good nutrition depended on the supply of the correct proportions of the main constituents, but a series of carefully planned experiments eventually showed that this was not the case. In the first place all proteins were not alike in their capacity for supporting normal

nutrition. It was possible to give animals a plentiful supply of some kinds of protein without their being able to utilize efficiently the nitrogen of that protein. Further, even when an adequate supply of good quality protein was assured, together with a mixture of pure fats, carbohydrates and mineral salts such as occur in foods known to be naturally nutritious, growth and normal nutrition might fail to occur. It was from the results of such experiments that Sir Frederick Gowland Hopkins felt compelled to postulate the presence in naturally occurring foods of 'accessory substances' which were essential components of the diets of animals.

The result of this epoch-making discovery has been an intensive search for the accessory substances—a search which has been so far successful that some seven or eight have already been identified, either by actual separation as pure chemical substances, or by means of more or less specific biological reactions. These substances, which are known to-day as vitamins, are not by any means distributed uniformly in foods, and there is abundant proof that whole races of men, whether living under civilized or uncivilized conditions, are capable of habitually consuming diets which are relatively deficient in one or more vitamins and for that reason allow the development of definite diseases or states of ill-health which would not arise if the deficiencies in the diets were made good. This state of affairs seems to imply that man, by taking a conscious interest in the selection and preparation of his food and pandering to his palate, has lost that instinct for the choice of suitable food which his remote ancestors presumably possessed and which his humbler fellow creatures still appear to possess. Hence man has to be taught that his food must satisfy yet another condition: it must contain an adequate supply of all those essential accessory substances which he is unable to manufacture in his own body from the main food constituents which serve to satisfy his appetite and his energy requirements.

The demonstration, that well-defined symptoms of disease and pathological changes in the tissues result from an insufficient supply of specific food factors which are usually present only in minute quantities in natural foods, has proved of immense practical value in the fields of clinical and preventive medicine. There are, it is true, critics who tend to disparage the importance of these discoveries. A common form of criticism is to deny the applicability of the results of modern nutrition experiments to human beings on the grounds that the metabolism of men differs widely from that of experimental animals. Such criticism would be justified if those who announced their experimental findings put forward categorical claims that their results could be applied to clinical problems without further trials; but this is not the case with honest investigators. These latter certainly do frequently suggest the possibility that some new experimental finding may throw light on the ætiology and treatment of human disease. It is surely then the duty of the medical practitioner to test the point in his clinical work before he condemns it as worthless.

A second form of criticism is to decry the value of the vast amount of labour that is devoted to isolating the specific food constituents. It is sometimes argued that no good can come from any attempt to identify and concentrate these substances; what men require, such critics say, is a mixed diet composed of good natural food produced under the best possible conditions, and then no one need bother about vitamins. Such arguments deny in effect the value of exact knowledge in an important branch of medical science and are therefore scarcely to be listened to with patience. It must be realized that only since the discovery of the vitamins has it been possible to attempt to define good food in a physiological sense. Moreover, although the ideal diet is undoubtedly one

composed of natural foods produced under such conditions that they contain liberal supplies of all the health-promoting constituents, there are times when the treatment of certain diseases is rendered far easier because of the availability of concentrated preparations of some of these constituents.

It is obviously impossible in a short article of this nature to discuss critically the individual properties and physiological effects of the vitamins, but a brief statement of some of their chief sources and clinical uses may indicate the present development of knowledge in this field. The time will shortly come when the individual vitamins will be referred to by names which represent their chemical individualities and not by the letters of the alphabet which at the present time are still their more or less official designations. Vitamin A, the original fat-soluble vitamin, has been prepared in a highly concentrated form, but its chemical constitution has not been ascertained with sufficient certainty for it to have received a name indicating its chemical structure. The vitamins were originally believed to be manufactured only by plants and not by animals, but this view can no longer be accepted. Vitamin A can be made by animals from its precursor carotene, a yellow pigment which is widely distributed in the plant world. Different species of animals apparently vary in the ease with which they can transform carotene into vitamin A, but those animals of which man is probably one, which readily effect this transformation, can obtain their necessary supplies of this vitamin either ready made from food of animal origin or from vegetable foods containing the precursor carotene. The chief sources of vitamin A are the livers of certain fish and mammals, dairy produce from well-fed animals, eggs and animal fats. Carotene is found in yellow root vegetables, green leaves and many coloured fruits and seeds. Vitamin A concentrates are made chiefly from the liver oils of fish and mammals, the liver oil of the halibut being one of the richest sources known.

One of the most characteristic properties of vitamin A is its power of influencing the development of epithelial structures in the body. In the absence of this vitamin from the diet, the cells lining the respiratory, alimentary and genito-urinary passages, as well as those of certain glandular organs, lose their normal structure and arrangement and tend to be changed to layers and nests of keratinized epithelium. The change is of great importance for the reason that the altered epithelial surfaces permit the invasion of bacteria, so that infections are more likely to occur in animals suffering from a deficiency of this vitamin in their diet. Exactly how far a plentiful supply of vitamin A will protect human beings from infections is not known. There is evidence that it reduces, without eliminating, the incidence of certain types of infection, for instance puerperal infections and pneumonia—as a complication of measles. On the other hand, it appears to have no effect on the incidence or course of otitis media as a complication of scarlet fever.

The signs of gross deficiency of vitamin A in human beings most frequently recognized are xerophthalmia and acquired night-blindness, which are not uncommonly associated in the same individual. Such cases are met with in our own country, and it is of importance that this fact should be recognized because they respond very quickly to appropriate treatment in their early stages and can be completely cured. There is also evidence that deprivation of vitamin A leads to a variety of nervous lesions caused by degeneration of peripheral nerves and tracts in the central nervous system. Such degenerations are intensified, at least in experimental animals, by certain common food principles of which one is a substance of unknown composition present in the germ of cereals. How far such observations will be found to shed light on the ætiology of nervous disorders in man remains to be seen. In any case there are indications that vitamin

A has a profound influence on the functioning of the body tissues and that a plentiful supply in the diet produces beneficial effects which are not to be expected when the supply is limited to that minimal quantity which will just prevent the appearance of characteristic symptoms of absolute deficiency.

Vitamin D, the antirachitic vitamin or calciferol, is another of the vitamins which may either be supplied ready made in the diet or be elaborated in the animal body from its precursor ergosterol. But in this case the elaboration within the animal only takes place under the influence of ultra-violet light applied to the surface of the body. Vitamin D differs from most of the other known vitamins in the relative paucity of its distribution in common foods, egg yolk and butter being the only sources which contain it in fair abundance, unless such substances as cod-liver oil are included as common foods. This fact seems to indicate that man is expected to derive his necessary supply of this vitamin from exposure of his body to sunlight. But under present conditions of life in our climate adequate exposure is too often not obtained, especially in the winter months, with the consequence that faulty calcification of the bones and teeth is only too common. It is therefore imperative that growing children should receive some reliable source of vitamin D to ensure their freedom from rickets and to bring about that perfect calcification of their teeth which will enable them better to resist dental caries in later life. This can be done in a variety of ways. The pure vitamin, calciferol, may be given; in this event the dose must be supervised, since large overdoses lead to toxic symptoms. The elaboration of vitamin D may be encouraged by exposure of children to a source of ultra-violet light. The vitamin D content of natural foods, especially milk, may be raised by exposing them to ultra-violet light; such irradiated milk is now produced commercially. Milk used for feeding children may be enriched in vitamin D by an alternative process, namely, feeding irradiated yeast to the cows from which the milk is being produced. Lastly, there is the older but still in many ways very satisfactory method of giving cod-liver oil; this proceeding has the advantage of supplying vitamin A as well as vitamin D, but at least two or three teaspoonfuls of the pure oil, or its equivalent, should be given, except to infants in the first few months of life when the dose is naturally rather smaller.

In connection with vitamin D it should be remembered that the whole problem of perfect bone and tooth formation has not been solved when the supply of the vitamin is ensured. Obviously these structures cannot be effectively produced unless there is a sufficient supply of calcium and phosphorus in the diet to furnish the building material, and the importance of giving milk to children lies in part in the liberal quantities of these elements which milk contains in a readily available form. Again, there are certain common food-stuffs which contain substances which actively interfere with bone and tooth calcification. Of these the cereals are the worst offenders; hence the greater the proportion of the diet that is furnished by cereals, the more important is it that a liberal supply of vitamin D should be given. When circumstances allow, the wisest course is to diminish the cereal intake of children and supply greater proportions of dairy produce and vegetables.

The vitamins we have already considered belong to the group of the fat-soluble vitamins; the second group consists of the water-soluble vitamins, and of these there are recognized a group known as the vitamin B complex and vitamin C, the anti-scorbutic vitamin. The vitamin B complex consists of a number of separate substances of which at least two have already been proved to be of importance in human nutrition. The first, vitamin B₁, is the factor which is lacking in diets capable of causing the disease beri-beri. Its richest sources are the germ of

cereals and yeast, but it is widely distributed in a number of common foods so that symptoms of frank deficiency are not found in those who partake of a mixed diet including such items as eggs, fresh meat, pulses and fresh vegetables and fruit. One of the earliest and most characteristic symptoms of deficiency of this vitamin is loss of appetite, and in experimental animals this is followed by disturbances in the functioning of the alimentary tract generally. This observation has led to the suggestion that partial deficiency of vitamin B₂ is a common cause of constipation and other irregularities of intestinal function. The evidence for this view is conflicting. In the first place it has not yet been definitely settled in the case of the experimental animals how much of the disturbed intestinal function is due to the specific lack of vitamin B₂ and how much is due to the inanition which results from the loss of appetite caused by deprivation of vitamin B₁. In the second place the favourable results which are from time to time reported to follow the giving of preparations of vitamin B to sufferers from chronic constipation have not been proved to be due to vitamin B itself, for as a rule the preparations used take the form of cereal germ which contains many other substances besides the various vitamin B factors.

Vitamin B₂, like vitamin B₁, occurs in yeast and cereal germ, but it is also found in abundance in liver; eggs, milk, meat and green vegetables contain fair quantities. There is a good deal of evidence that the disease pellagra is in some way concerned with a shortage of this vitamin in the diet, although other dietetic faults probably contribute to the production of the disease. Cases of recognizable vitamin B₂ deficiency are seldom met with in this country except, possibly, in those whose absorption of food is seriously interfered with as the result of chronic intestinal diseases.

The last vitamin to be mentioned is vitamin C, the anti-scorbutic vitamin. This vitamin has now been identified with a chemical substance known as ascorbic acid, originally obtained from the suprarenal glands and lately found to be present in the pituitary. Its best known natural sources are the citrus fruits and the green leaves of vegetables. Cases of scurvy are not rarities in this country, and are not very infrequently seen in infants who have been fed exclusively on milk which has been overheated. Vitamin C is very sensitive to heat and even raw milk cannot be regarded as one of its rich sources. When milk which has been pasteurized at the dairy is further subjected in the home to boiling there is a grave risk of sufficient destruction of vitamin C to produce manifest scurvy when milk is the only source of this vitamin in the diet. The simplest method of supplying vitamin C to young children is to give orange-juice; tomato-juice is also a good source, and a still cheaper one is the juice expressed from raw swede turnips. There is some clinical evidence, though this is not yet conclusive, that a sub-optimal supply of vitamin C is by no means uncommon in Western countries, leading comparatively rarely to frank scurvy, but being responsible for ill-defined states of malaise and lack of energy.

This outline of the kind of physiological or pathological effects that have already been traced to the presence or absence of specific food constituents in a dietary may perhaps serve to indicate the recent development of the subject. For certain types of patient and in certain circumstances it may be of paramount importance to ensure the completeness in all known respects of diets which are ordered by the physician. During infancy and early childhood the developing body is particularly susceptible to specific dietary deficiencies, and, even though the deficiencies are not severe enough to cause obvious specific lesions at the time, we have evidence that they may cause imperfections in the structure of various tissues in the body which predispose to definite diseased states in

later life. During pregnancy again it is obvious that the mother should be supplied with liberal amounts of the specific food constituents which are necessary to maintain at a normal level her own stores which are at this time being passed on to the fetus. Finally, during the course of any chronic disease for which a diet is prescribed it is the duty of the prescriber to see that all the known essential food constituents are present. It is not improbable that neglect of this precaution is responsible for not a few failures on the part of confirmed invalids to respond to treatment; it may also be responsible for the appearance of frank deficiency diseases grafted on to the original disease. Such *morbus e medico* should not arise if the importance of accessory factors in the diet were duly recognized.

The Modern Treatment of Burns and Scalds and Other Uses of the Two Per Cent Tannic-Acid Compress

By PHILIP H. MITCHINER, M.D., M.S. (Lond.),
R.N.C.S. (Eng.)

(From the *Medical Press and Circular*, 13th December, 1933, p. 536)

It is, of course, in the treatment of burns and scalds that tannic acid has its greatest use, both as a first-aid dressing and for subsequent routine treatment; and it has been found at St. Thomas's Hospital that a solution of more than 2 per cent. tannic acid has no advantage over greater strengths when used either as a compress or for spraying.

If we consider the severe collapse met with in burns and scalds we must realize that tannic acid is the ideal dressing, applied preferably in compress form, as this is applicable to private practice, at the patient's home, or in the hospital outpatients' department, where the spray method is impracticable. This collapse is due partly to the fright and upset of the accident, but much more largely to the absorption of protein bodies from the damaged tissues and the great loss of fluids which occurs from the burnt area; and the tannic acid, by completely coagulating all these damaged tissues, prevents these latter causes of collapse: it is obvious, therefore, that the earlier the tannic acid is applied, the less collapse will result from the burn. For the shock due to the fright, no drug is better than opium, or its derivative morphia, and this should be administered early and freely, preferably in the form of tincture opii.

FIRST-AID TREATMENT

For convenience in works and other places where burns are likely to occur, tannic acid can be made up into a tablet with 1/2000 perchloride of mercury to act as a mild antiseptic, and enable the solution to be made up safely with warm tap-water. No other antiseptic has proved so satisfactory and painless as the perchloride of mercury, though I have tried many at St. Thomas's Hospital.

Tannic acid	gr. 17½
Perchloride of mercury	gr. ½
Boric acid	gr. 1

This tablet keeps indefinitely; it should be crushed well before adding the water, as otherwise solution is slow. The tablet is dissolved in 2 ounces of warm water, and gives sufficient 2 per cent solution to soak a dressing of lint 8 inches by 4 inches.

The lint should be clapped on quite wet to the burn, and the patient should be left quiet for at least twenty minutes before being moved to an institution for further treatment, being in the meanwhile, of course, kept warm and given fluids to drink; while, if a medical man is present, morphia or tincture opii should be administered in dosage according to the table, after which the patient must be left undisturbed until the drug has taken full effect (usually

about twenty minutes) before proceeding with the cleaning which is a necessary preliminary to the final dressing.

TABLE

Opium dosage for cleansing burns and scalds

I.—In children		
Age	Preparation	Dose
1/12	.. Tinct. camph. co.	min. ii-iii
2/12	.. " " "	min. iv-vi
3/12	.. Tinct. opii	min. ½-¾
6/12	.. " " "	min. ¾-1
1 year	.. Tinct. opii (a)	min. ii-iii
	or	
	Inj. morph.	gr. 1/75
Over 1 year	Tinct. opii	min. ii for each year and min. ii in 15 mins. if necessary.
	or	
	Inj. morph.	gr. 1/75 for each year
II.—In adults		
12-15 years	Tinct. opii	min. xxx
	and	
	Inj. morph.	gr. ½
15-20	Tinct. opii	min. xxx
	and	
	Inj. morph.	gr. ½
Over 20 years.	Tinct. opii	min. xxx
	and	
	Inj. morph. (b)	gr. ½-¾
	or	
	Inj. morph. (c)	gr. ½-¾

Remarks.—(a) Tinct. opii is more satisfactory than morphia. (b) For women. (c) For men according to stamina.

N.B.—Should slow or shallow breathing give rise to anxiety, atropine sulphate, gr. 1/200—1/50, should be administered hypodermically.

ROUTINE TREATMENT

It is essential that this first-aid dressing, even if of tannic acid, should be removed, which it can be most easily, and the area carefully cleaned before the final tannic-acid dressing is applied. By this careful cleansing alone can subsequent sepsis be avoided; and here let me say that, should sepsis supervene during a course of treatment, it is only necessary to remove the tannic-acid dressing, re-clean the area thoroughly, and re-apply a new tannic-acid dressing in order to get a good result.

The cleansing must start with the removal of all dead and charred tissues, the excision of all loose skin raised over blisters, and the removal of grease, especial attention being given to the edges of the damaged area. The whole area should then be gently but thoroughly cleansed with soap and water (applied with a sterile swab and not with a nailbrush), and finally carefully sponged over with ether, to remove all natural or applied grease, in order to get a thorough coagulation. It is obvious that this treatment cannot be carried out unless the patient is rendered insensible to the pain which such a cleansing of the damaged area must entail. We have found at St. Thomas's that it is safer and more satisfactory to procure this insensibility by the administration of large doses of opium rather than the use of general anaesthesia, which tends, even with the greatest care in its administration, to be followed by pulmonary complications, usually of a mild nature, which are detrimental to the rapid recovery of the patient. The table indicates the dosage and drug employed at various ages, and has proved both safe and satisfactory.

A compress consisting of either six layers of sterile gauze or three layers of lint should be thoroughly soaked in a stock solution of 2 per cent tannic acid and 1/2000 perchloride of mercury, and applied closely

and evenly over the entire burnt area without wringing the dressing out. This compress should then be firmly and evenly bandaged in position, the bandage being applied directly to the outer side of the compress. The whole of the outside of the bandage may then be soaked with a spray of 2 per cent tannic acid and 1/2000 perchloride of mercury in order to ensure that the underlying dressing is thoroughly wet. Mackintosh or Jaconet should be placed under the patient until the dressing has dried, in order to save soiling of the sheets by the tannic-acid solution; for though this all washes out excepting for a faint iron mould, the sheet subsequently rots in this area. It is also well to secure the burnt limb temporarily in order to prevent undue movement until the tannic coagulum has formed firmly. This dressing should be left in position and untouched for at least a fortnight in the case of small burns and scalds, and three weeks where large areas are involved. At the end of this time the bandage should be cut, and the dressing lifted, when the scab usually will separate completely from the burnt area. If it does not do so the dressing can be re-bandaged and removed later when separation has occurred. The separation may be rendered quite painless, and assisted by spraying with tannic-acid solution between the coagulum and the skin during this process. May I here say that the escape of a little serous or sanioserous fluid from the edges of the coagulum, or the raising in blisters of its centre with serum is no more an indication for interference or removal of the dressings during the first week after their application than it is with the bare coagulum resulting from the 'spray' method.

Temperature and toxæmia as shown by a rapid pulse, dried and furred tongue, and pain, with possibly the escape of sero-pus in considerable quantities, are the only indications calling for removal of these dressings before the time stated, and these indications in our experience are extremely rare, and usually result from a failure in the thoroughness of the preliminary cleansing. Should removal be necessary, and in my experience it is very seldom called for, the area should be re-cleaned carefully, and another tannic-acid dressing applied.

As indicated, the dressing must be closely and evenly applied to the burnt area; and there are certain areas, therefore, such as the perineum, the groin, axilla, the neck, and also the face, where the absence of bandages is an advantage, and where the spraying method gives better results; but the compress method has been, and can be, used with good effect in these areas.

It should be borne in mind that in burns where destruction of the subcutaneous and muscular tissues has occurred, subsequent scarring and contracture are inevitable and it is, therefore, necessary to apply tannic-acid dressings, either by compresses or spraying, with the part in such a position that subsequent contracture may be counteracted. Equally is it obvious that although full epithelialization will have occurred in those areas where the first, second or third degree burn has occurred, an ulcer must be expected, and will be met with in deeper burns; and this, if extensive, should be treated by subsequent autogenous skin grafting, or, if small, by the application of some lotion, of which, in my experience, the most satisfactory is the following: Purified alum, gr. 20; zinc sulphate, gr. 10; glycerin, 7 fl. oz.; water, to one pint.

MORTALITY

It must be realized that the mortality from burns is very much greater (approximately three to one) than that of scalds, where the hot fluid is only in contact with the tissues for a few seconds, and a more guarded prognosis therefore must be given in the case of burns.

It has been shown that whereas with burns treated with oils, etc., death usually occurs from secondary sepsis rather than immediate collapse, both these

causes are largely eliminated in the tannic-acid treatment, which again is more efficient than pierie acid, where only the surface of the damaged tissue is coagulated, and so collapse from absorption in the deeper parts is not prevented, though sepsis is largely eliminated. The attached mortality table speaks eloquently for the value of tannic acid.

Mortality over five-year periods

Dressing	Burns	Scalds
Oil, etc.	39.0 per cent	18.8 per cent
Pierie 1 per cent	15.5 "	7.0 "
Tannic 2 per cent	4.0 "	1.7 "

OTHER USES OF TANNIC ACID

(1) In chemical burns the tannic-acid treatment is also applicable and very successful, but the burning agent must be neutralized before applying the tannic acid. (2) In any superficial wound, such as grazes or abrasions, or the areas from which skin grafts have been removed, or where extensive curettage has been employed, as in dealing with lupus, the tannic-acid compress makes an excellent and quite painless dressing; and on its removal at the end of approximately three weeks the area will be found completely epithelialized. (3) Another use for the tannic-acid compress is in sunburn, where the results are excellent, and the immediate relief obtained most satisfactory. Unless actual blistering is present it is usually sufficient to retain the compress for two or three days only in these cases. (4) A further use can be found in the treatment of radium and x-ray burns.

It will be seen from the foregoing remarks that the tannic-acid compress has many uses apart from the treatment of burns and scalds, where it has been so successful in removing both the sepsis and reducing the mortality, and it is therefore to be hoped that its uses may become more widely known and the practical method of compress popularized.

Principles of X-ray Therapy of Malignant Diseases

By HENRI COUTARD, M.D.

(Abstracted from the *Lancet*, 7th July, 1934, p. 1)

THE two principal factors in x-ray therapy are the energy and the time. They must be considered in their relation to the cancer cells on the one hand, and on the other hand to the vasculo-connective tissue and the general tissues of the site from which the cancer is developing.

In the course of treatment the principal guides have been, for us, the radioreactions of the vasculo-connective tissue, the radioreactions of the covering epithelium, and the radioreactions of the cancer cells.

When one is irradiating a cancer of very small size and very embryonic in type, the treatment can be completed in a short time, about 20 days; the epithelial radioreactions may be relatively intense, on condition always that their duration never exceeds 15 days.

When one is irradiating a cancer less embryonic in type, the treatment ought to be of longer duration, and the epithelial radioreactions ought to be slight.

When it is a question of a very extensive cancer, irradiated through fields of large dimension, as in the case of cancer of the uterus, the treatments ought to be from 40 days as a minimum; the cutaneous radio-epidermitis ought not to be exudative; and the radio-epithelitis of the vaginal, intestinal, or vesical mucosa ought to be very slight. Symptoms, even temporary, of cystitis, proctitis, or enteritis, ought to be avoided.

The question of energy—i.e., of the cancericidal dose—is essential in the treatment of an undifferentiated embryonic, radiosensitive cancer, and it is more important than the question of time. The energy seems to be directly destructive; the chronology is, above all, protective, since it allows the preservation

of the supporting tissues in order to avoid accidents.

The question of time is more important than the question of energy in the treatment of a differentiated, radioresistant cancer. The energy ought not to provoke a destructive effect. Thanks to a slow chronology and to weak daily doses, the disappearance of the cancer cells seems to follow a cellular evolution resembling the normal evolution. In determining the longer duration of treatment one should aim at the perfect preservation of the supporting tissues so that the evolution effect may become possible.

In conclusion, I would say that it is still absolutely necessary to bear in mind that:

1. The cure of cancer by x-rays is still difficult.
2. The cure of cancer by x-rays is still dangerous.
3. A very small margin exists sometimes between the dose which will determine a cure and the dose which will provoke an injury.
4. The daily examination of the patients is necessary; modification of the normal tissues and of the general condition by x-ray treatment sometimes appears so quickly that it is often necessary to diminish the daily dose or the size of the fields in the course of the treatment.

There exists no fixed method of treatment but a simple clinical treatment for each individual patient and for the special type of tumour.

Reviews

THE ANCESTRY OF THE LONG-LIVED.—By Raymond Pearl and Ruth DeWitt Pearl. The John Hopkins Press, Baltimore. Pp. xiii plus 168. Price, \$3.00

THE problem of long life has intrigued the imagination of man at all times and the tradition of a much longer span of life in the spacious days of the distant past than what the modern man enjoys survives among all nations. Among the Hindus the 'Puranas' set forth that it was a slur on the administration of a ruler if his subjects failed to attain the age of a hundred and twenty. Isaiah states his ideal, 'there shall be no more thence an infant of days nor an old man that hath not filled his days: for the child shall die an hundred years old'.

The investigation of the duration of human life has attained a position of acknowledged importance in every civilized community. There is perhaps nothing so uncertain as a prediction about the probable length of life of an individual but, as Babbage has put it, 'few things are less subject to fluctuation than the duration of life in a multitude of individuals'. The life table, which expresses the community's expectation of life, is however useful mainly from the standpoint of the actuary and the public health worker. The individual is more concerned with knowing those specific factors, if any, which enable a small proportion of his fellow men to attain to very high ages while the great majority fall through, to use the language of the 'Vision of Mirza', the gaps in the bridge of life to be swept away by the great tide beneath.

Professor Raymond Pearl and the biological department of John Hopkins University, Baltimore, have been, for many years, engaged on the investigation of the duration of human life and the latest contribution to the study is 'The Ancestry of the Long-Lived', a book which Professor Pearl has produced in collaboration with Miss Pearl. The biological department has been collecting for over ten years family history records for the purpose of this study and from these collections they selected two groups of individuals, one consisting of nonagenarians and centenarians and the other of shorter-lived persons. These two groups are in no sense random samples and the second group has a mean higher age and less variability in age than in the case of a random sample of the general population. This fact emphasizes that the differences shown between the two groups in this study would have been greater if the sample of longevous persons was compared with a similar one taken from the general population. It is, in consequence, safe to assume that the conclusions reached have been proved as they constitute an underestimate of these differences.

The authors have made a new contribution to the study of the problem by suggesting the total immediate ancestral longevity (tial) as the criterion for investigation. It represents the sum of the number of

years lived by the two parents and the four grandparents of each individual in both groups. They have analysed the contributions to tial from various points of view and have shown the importance of ancestral longevity as a definite factor in determining the length of life of the individual. The average age at death of every ancestor of the longevous group is higher than that of the shorter-lived one. In the case of parents this superiority ranges from 20 to 30 per cent and from 10 to 14 per cent in the case of grandparents. It is, at the same time, interesting to note that, among the nonagenarians and centenarians, about 13.4 per cent came from the matings of parents who were not long-lived (70 years and more). Certain facts relating to the families of longevous persons are equally interesting. The infant and general mortality rates are, in these families, definitely lower than in the case of the population of the country or of the shorter-lived series with which the long-lived persons are compared.

The birth place, race stocks and alcoholic habits of the nonagenarians and centenarians are investigated. The proportion of abstainers among them is significantly greater than in a sample of the general population of Baltimore (by about 11 per cent). But the proportion of moderate drinkers is about 4.1 per cent more than in the general population. About 3.7 per cent survived to extreme old age in spite of being heavy drinkers. On the whole, the evidence points to the moderate use of alcohol as being in no way incompatible with longevity, a position which Professor Pearl has already sustained elsewhere.

Apart from the main theme the book presents a large amount of material of great interest to the student of vital statistics. Thus, at the very beginning, the authors set out a table embodying data for several countries of the world showing the expectation of life at birth, the number of survivors at 92 years of age out of a thousand born alive and the expected mean longevity of survivors at 92. India is one of the countries included. The wastage of life in India, as revealed by these figures, is appalling. The expectation of life at birth is only about 23 years as compared with about 60 years for the most healthy community (Kansas, U. S. A., white population). It is true that the latest actuarial report raises the expectation of life in India to about 27 years but the difference is still enormous. As for the rate of survival till the 92nd year of life, Norway leads and India is again at the bottom, Norway having over one thousand times as many male survivors and over 1,500 times as many female survivors as India.

Again, in another comprehensive table, no. 17, the authors have brought together all the available data relating to the variability in longevity of ancestors.

The book is, on the whole, very stimulating reading though, as has been pointed out in the preface, it is not easy for the general reader. Professor Pearl points out that this is only one stage in the general programme

LIVOGEN

A palatable tonic for the treatment of general debility and lowered vitality and particularly for the malaise following severe illness

CONTRAMINE

For the treatment of chronic infections and chronic complications such as the chronic complications of gonorrhœa

OESTROFORM

A standardised preparation of the crystalline ovarian follicular hormone for use in various conditions arising from metabolic disturbances of ovarian origin

S.U.P. 36

A symmetrical urea for use in the treatment of influenza the common cold tonsillitis pneumonia and similar inflammatory and septic conditions

MANGANESE BUTYRATE B.D.H.

For intramuscular injection in the treatment of boils whitlows carbuncles and similar acute staphylococcal and streptococcal infections

RADIOSTOLEUM

Standardised Vitamins A and D — for sustaining healthy growth and for maintaining the defences of the epithelial linings of the mucous membranes of the

RADIO-MALT

of investigation of longevity and we look forward to the further studies of the problem.

OPERATIVE SURGERY: THE ABDOMEN AND RECTUM.—By Dr. Martin Kirschner. Authorized translation by I. S. Ravdin, B.S., M.D. 1933. J. B. Lippincott Company, Philadelphia and London. Pp. xiv plus 569, with 395 illustrations (mostly coloured). Obtainable from Butterworth and Company (India), Limited, Calcutta. Price, Rs. 37-8

THE first volume of the American edition of Professor Kirschner's *Operative Surgery* was published in 1931. The enthusiastic reception which it received led to impatience for the appearance of the second volume, but the German edition has been delayed by causes which the author explains in his foreword, so that the translator must be congratulated on the speed with which he has completed his heavy task.

The author's foreword is interesting reading, he tells how his transfer from Königsberg to Tübingen, with the consequent replacement of nearly all his assistants, necessitated devoting more time to the practical work of the clinic, to the detriment of his literary work. How a British surgeon envies these continental professors their staff of trained assistants, who work with them for years and carry out all routine without supervision, but how much better for the training of the general practitioner is the British system!

The distinction of attention involved in the planning of a new surgical clinic at Tübingen and the assumption of the university rectorship will be readily understood by many in this country who have to find time for much administrative and academic work in addition to their teaching and clinical duties. German writers cannot keep off politics for long in these days and, accordingly, we find a reference to the (?) struggle of German science and German books for recognition in the world and a pious hope that this book may contribute to the rehabilitation of the German people, sentiments which make one smile in the light of recent events in that country. However that may be, the book will certainly enhance the already high reputation of its author, for it is a fine work worthily produced and the reading of its lucid descriptions is a real pleasure to the surgeon. It represents continental practice at its best, as expounded by one of the masters (the author has since been transferred to Heidelberg), and one is struck, not so much by the differences between British and American practice and that described, by the fact that technique everywhere appears to be standardized and new methods if adopted at all are adopted in all countries.

The present volume deals with the abdomen, including the rectum, but excluding gynaecological, renal and bladder operations. The opening chapter describes methods in general, before, during and after operation. The author's preference for spinal anaesthesia with solutions of low specific gravity for most abdominal operations is in accord with the trend of opinion in England, where the abdominal relaxation thus obtained and the freedom from after-complications is being more and more appreciated. Except that he prefers a mid-line to a paramedian and describes some incisions across the rectus, especially one which he calls the 'fish-hook' for abdomino-thoracic work, his directions are in accord with standard practice. The method given for enlarging the McBurney incision is not the best, to cut across the external oblique greatly weakens the abdominal wall, the translator in a note indicates a better method. In the second chapter all recognized methods of suturing and anastomosing the intestine are minutely described and beautifully illustrated. We learn that the author has had better results and smoother convalescence since he substituted an interrupted Lambert suture for the almost universally-used continuous suture. He uses linen thread for the sero-muscular suture, as catgut, with the exception of the traumatic eyeless needles which are too expensive in

Germany, tears too large holes, as most of us have found. The Petz suture instrument is recommended for passing the through-and-through sutures in all terminal closures and in lateral anastomoses where there is sufficient tissue. There is a description and several figures of this interesting instrument, which enables a practically aseptic intestinal anastomosis to be carried out very rapidly, but we are not told whether the metal clips which the machine inserts ever give trouble afterwards in getting out of the body.

The operations on the various sections of the intestinal canal are then taken up *serialim*, each preceded by a brief résumé of the surgical anatomy of the region, and here is one of the few features calling for adverse criticism, for the arrangement of the lymph glands draining the stomach is most inadequately described in six lines and the same applies to the lymphatics draining the caecum, sigmoid and rectum, all regions which are frequently affected by malignant disease. The usual method of anaesthesia is by a combination of spinal and splanchnic anaesthesia, the solution of novocaine for the latter being injected into the retro-peritoneal tissues by a high pressure apparatus. The operations described are those practised in England, with the decided preference of the Austro-German school for stomach resection in both gastric and duodenal ulcer cases, in order to remove most of the acid-secreting mucous membrane. Actual or anticipated obstruction at the pylorus is the only condition for which gastro-enterostomy is recommended as the operation of choice. There is a most excellent section on post-operative gastro-jejunal ulcer, with full descriptions of these difficult operations. Attention is drawn to the difficulties in which a very short afferent loop will land the surgeon in the event of a gastro-jejunal ulcer subsequently requiring operation. For this and other reasons the author habitually uses a rather longer loop of jejunum in resection or gastro-jejunostomy than is usual in England and America. Perforation of gastric and duodenal ulcer is dealt with in the next chapter and gastro-enterostomy is advised in all cases after suture; alternative methods are given for dealing with cases where suture is impracticable.

The following chapters deal with operations on the small and large intestine and for peritonitis and obstruction on the usual lines, but the author does not advise crushing the stump of the appendix, at any rate in acute cases. In the article on megacolon it is surprising to find no mention of the huge volume of recent work on abdominal sympathectomy in the treatment of this condition, so the translator supplies a description of the operation of resection of the pre-sacral nerve with an illustration. The chapter of sixty pages on the various methods of extirpation of the rectum for carcinoma is one of the most concise and lucid to be found in any book, the clear illustrations in the general discussion of the different types of operation obviate any confusion in following the actual descriptions.

The last section of the book deals with the biliary system and in an otherwise excellent description of the anatomy of the parts it is surprising to find no mention of Hartmann's pouch, which plays such an important part in the symptomatology of gallstone cases by obstructing the outlet of the gallbladder. The author is opposed to drainage of the common bile duct except in severe infectious jaundice, long-standing cases with severe damage to the liver cells, acute pancreatitis and injury cases. After exploration of the common duct he sutures it completely when the passage to the duodenum is patulous, if there is an obstruction he establishes an internal fistula between the bile duct and the duodenum, even in infected cases and claims that the results are superior to those obtained by the usual practice of external drainage. The sections on biliary fistula, injuries to the bile ducts and operations for recurrence of symptoms are particularly good.

The text throughout is written in the most lucid style and high praise is due to the translator for his excellent rendering, though his habit of interpolating

his comments and particulars of his own practice in brackets is irritating, especially when, as on p. 473, we find on turning the page that the author himself deals with the point. After all the book is an exposition of Professor Kirschner's teaching and the reader wishes to learn what his methods are and his reasons. As such the work is the most noteworthy contribution to surgical literature which has appeared in recent years and should be read by all surgeons. Especial mention must be made of the three hundred and ninety-five superb illustrations, mostly in colour.

W. L. H.

THE MANAGEMENT OF FRACTURES, DISLOCATIONS, AND SPRAINS.—By John A. Key, B.S., M.D., and H. E. Conwell, M.D., F.A.C.S. 1934. The C. V. Mosby Company, St. Louis. Pp. 1164, with 1,165 illustrations. Price, \$15.00

The authors state in the preface that 'this book is written for the student, the general practitioner and the surgeon'. It is doubtful whether the medical student of to-day with the crowded curriculum will have the time to give to a book of this size. It is a matter of regret that he cannot.

As a reference book for the general practitioner and more especially for the surgeon this work should prove of great value. Two chapters deserve special mention, each of which has been written by a specialist. In chapter XI there is a masterly description of brain trauma associated with fractures of the skull written by the late Dr. C. E. Dowman.

Fractures of the jaws and related bones of the face is given very fully by Dr. J. B. Brown and contains all the recent methods of treatment. All the recent operative procedures find a place in the book. The work of Boehler is extensively mentioned. British methods of treatment are omitted in certain parts, e.g., Robert Jones' methods of reducing a Colles' fracture and a supra-condylar fracture of the humerus are not mentioned.

In the treatment of compression fractures of the spine Watson Jones' procedure finds no place although it is much simpler to carry out than Davis' method.

In describing the reduction of a dislocated shoulder by Kocher's method, extension is mentioned. Extension was not used by Kocher but is a modification of his method. Manipulation is not mentioned in the treatment of tennis elbow, although practised with much success by manipulative surgeons.

The illustrations are good but several skiagrams are not very clear owing to the reduction in size.

The book is well printed and has heavy-type headings.

We feel sure that this book will be in great demand as it justly deserves.

F. J. A.

AIDS TO OSTEOLOGY.—By P. Turner, B.Sc., M.B., M.S. (Lond.), F.R.C.S., in collaboration with N. L. Eckhoff, M.S. (Lond.), F.R.C.S. Third Edition. 1934. Baillière, Tindall and Cox, London. Pp. vii plus 222. Price 4s. 6d.

THIS small book is one of the well-known *Students' Aids Series*. An attempt has been made to use a standardized nomenclature, and that recommended by the Anatomical Society has been adopted. The well known names which have been changed and which are still in use in surgery might have been placed in brackets after the new names, for example, in a recent book on fractures the following are not found in the index—Talus—Calcaneus. This causes much confusion in the minds of students beginning surgical work.

The necessity of such a book as this is a matter of opinion, that there is a demand for it is shown by a third edition. A master mind only could assimilate the contents of such a book which contains no diagrams nor figures. Teachers of anatomy will certainly not

recommend such a book even as a final 'refresher' before an examination.

F. J. A.

GNOCOCCAL INFECTION: RECENT ADVANCES IN PATHOLOGY, DIAGNOSIS AND TREATMENT.—By R. V. Storer, M.R.C.S. (Eng.), L.R.C.P. (Lond.). 1934. John Bale, Sons and Danielsson, Limited, London. Pp. x plus 91. Price, 7s. 6d.

This is a short monograph which is divided into three parts, biology of the gonococcus; the identification of the gonococcus and the eradication of the gonococcus.

There is a foreword by Kenneth M. Walker.

It is difficult to determine exactly for whom this small book was written. If for the general practitioner, then the sections on cultivation, etc., of the gonococcus could have been omitted. If for the venereologist the space allotted to treatment is too small.

This monograph is however well worth reading by all general medical practitioners for the emphasis that is laid on the tests of cure, and the importance of this being done before marriage.

F. J. A.

MODERN ADVANCES IN DISEASES OF THE THROAT.—By A. Miller, F.R.C.S. (Edin.), D.L.O. 1934. H. K. Lewis and Company Limited, London. Pp. xii plus 120, with 1 coloured plate, 40 illustrations in the text and 2 tables. Price, 10s. 6d.

In this beautifully produced and illustrated book of 115 pages dealing chiefly with the tonsils, the author gives a clear account of the modern methods of removal of the tonsils, and has gathered into this single volume all the recent work on tonsil surgery.

It is well arranged and easy to read. The advice given is sound and practical and the illustrations are excellent. Fourteen pages are devoted to adenoids and a good account is given of the use of the La Force adenotome. Apart from this very little is said about other throat conditions. More might have been written about abnormal forms of peri-tonsillar abscess, and more emphasis laid on the supra-tonsillar fossa method of opening them.

The first part is so well done that one feels disappointed with the latter part and hopes that this may be remedied in later editions.

A full and useful list of references is given. It is a book that should prove of great value to post-graduates and practitioners interested in the tonsil-adenoid problem, and should find a place in every medical library.

A. D.

ALLERGY IN GENERAL PRACTICE.—By S. M. Feinberg, M.D., F.A.C.P. 1934. Henry Kimpton, London. Pp. xv plus 339. Illustrated with 23 engravings and a coloured plate. Price, 21s.

It is a practical book on the subject of allergy for the use of general practitioners. All the technical and controversial points have been carefully avoided. Practically the whole of the book has been taken up by the discussion of asthma and hay fever; the important subject of allergic conditions of the skin has been dismissed within seven pages only. Gastro-intestinal allergy, allergic headaches, and other possible allergic conditions have been very briefly considered. The predisposing causes of allergy have been briefly discussed but no reference has been made to the important work of Barber and Oriel and others which point to the presence of liver dysfunction in the allergic individuals. In the opinion of the author 'allergy is probably relatively uncommon among Indians, Japanese, Chinese, and native South Americans'. The reviewer can corroborate these views as far as the question of allergy amongst the Indians is concerned.

The chapter on the diagnosis of asthma is very well written and should prove useful. The value and importance of a good history in the diagnosis of asthma

is duly emphasized and the subject of history-taking is dealt with in a practical way. An outline of the important points to be elicited in a patient's history is given and the significance of the facts obtained is discussed. A comprehensive list of specific substances (allergens) liable to cause asthma in allergic individuals is given under different headings. The author has not simply mentioned these allergens but has given a list of common foods, preparations and materials in which a particular substance may be found and which may be the cause of allergic symptoms. For example an individual sensitive to wheat will be sensitive to all preparations in which wheat is found and the author has given names of no less than thirty-five such preparations. Similarly a person sensitive to egg may be sensitive to all the preparations of egg and the patent foods such as Ovaltine and Cocomalt which contain egg. This detailed information about the allergens should prove of practical value.

The type of asthma which is most common amongst Indians and which is due primarily to bronchial infection has not been treated at all as the author insists on calling it 'asthmatic bronchitis' and differentiates it from asthma proper. A better plan would have been to divide asthma into allergic and non-allergic types, the latter type including the asthma due to bronchial infection. The author's plan to exclude this non-allergic type of asthma is responsible for such statements in the text as 'tuberculosis is uncommon in this group of individuals', in the sputum 'probably the most constant microscopic finding is the presence of large numbers of eosinophiles', and in the blood 'the most constant finding is an eosinophilia'. Evidences of healed and active tuberculosis are quite commonly found in the non-allergic type of asthma and sputum and blood eosinophilia is to be found only in a minority of cases.

D.

DISEASES OF WOMEN.—By Ten Teachers. Edited by C. Berkeley, J. S. Fairbairn and C. White. Fifth Edition. 1934. Edward Arnold and Company, London. Pp. xii plus 668. Illustrated. Price, 18s.

The fifth edition of the above book makes a welcome appearance.

The ten contributors are representatives of the London schools. Each contributor has written one section and the Editorial Committee has endeavoured with success to co-ordinate the different views into one homogeneous whole. Each section is lucidly written, the illustrations are profuse and easy to follow. Eight very beautiful coloured plates are included.

Thorough revision has brought the book up to date and a new chapter on ovarian hormones gives a clear account of this important subject.

Two valuable chapters on abdomino-pelvic pain and chronic ill health in women from the psychological aspect are also included. Both these chapters deserve special study by students and practitioners.

For clarity of expression, omission of redundant theories and ease in reading, there are very few textbooks on diseases of women comparable to this book. It is specially valuable for students who nowadays are unable to digest the large type of textbook. The book is well printed and indexed.

S. N. H.

HANDBOOK OF THERAPEUTICS.—By D. Campbell, M.C., M.A., B.Sc., M.D., F.R.F.P.S. Second Edition. 1934. E. and S. Livingstone, Edinburgh. Pp. xx plus 444. Illustrated. Available from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 9-6

The progress of medicine has been so rapid that in four years, since the appearance of the first edition, new work has necessitated a considerable degree of revision and affected almost every chapter. The author has added a good deal of new material and brought it

up to date. The opening sections deal with management of patients, various therapeutic measures and physical method of treatment. The arrangement adopted in the subsequent chapters has been in the main to group the diseases anatomically. The sections on cardiac affections and sprue, use of nirvanol in chorea, atabrin in malaria, cortical extracts in Addison's disease, ketogenic diets in septic infections of the urinary passages and in epilepsy, carbon dioxide as a respiratory stimulant in the treatment of asphyxia and whooping cough, deserve to be specially mentioned. The author has dealt with all these subjects in a critical spirit and has left out unnecessary details. Treatment, while less full, is in no case inadequate.

The book is not overburdened with illustrations, which is an advantage, while those given are very helpful. The printing and general get-up is all that can be desired and it should take its place along with others of its kind in the library of the practising physician.

R. N. C.

VEGETABLE DRUGS OF INDIA.—By D. Sanyal, L.M. & S. (Cal.), and R. Ghose, M.B. (Cal.), D.T.M. & H. (Bengal)*. Second Edition. 1934. Published by S. Chatterjee. The Medical Publishers, Calcutta. Pp. 590 plus xxiv. Price, Rs. 4-8

This edition has been an effort to a greater improvement of the original volume. The drugs have been arranged and classified according to their action on different systems of the human body. The authors have tried to describe the action of the indigenous drugs in a method similar to modern books on materia medica. The physical characters, chemical composition and the uses in the indigenous systems have been briefly discussed. Free reference has been made to (1) Watt's *Dictionary of Economic Products of India*, (2) *Indigenous Drugs of India* by K. L. Dey, (3) *Dymock's Pharmacographia indica*, etc., but some of the recent literature appears not to have been so freely consulted.

The book is well got up. It is written in simple and clear English and can be easily understood. In our opinion the book may be of help to the local practitioners and students who wish to make use of indigenous drugs in their clinical practice.

R. N. C.

MANUAL OF DETERMINATIVE BACTERIOLOGY.—By D. H. Bergey. Fourth Edition. 1934. Baillière, Tindall and Cox, London. Pp. xvi plus 664. Price, 27s.

SINCE its first appearance in 1923 this well-known manual has been of great value to bacteriologists and has been a book of constant reference in many laboratories where cultural work is done. This book is now in its fourth edition and has been brought up to date and several material alterations have been introduced in the nomenclature. We are glad to see that *Br. melitensis* and *Br. abortus* have been removed from the genus *Alcaligenes* and placed in the newly recognized genus *Brucella* in the Tribe Bacterica. The genus *Pfeifferella* has been combined with the genus *Actinobacillus* and the description and definition of several genera have been amplified. Descriptions of about 50 new species have been included and what is perhaps more important is that several organisms have been omitted as distinct species and the names recognized as synonyms for other well-known species. Another very valuable feature of this present edition is a brief yet comprehensive discussion on the principles of taxonomic work.

In addition to this book being the only authoritative work on the nomenclature of organisms which obeys the international rules for nomenclature, it contains an

* The degree D.T.M. & H. (Bengal) does not exist: this should presumably be D.T.M. (Bengal).—EDITOR, I. M. G.

enormous mass of information about individual species. It is a book that should be in the hands of every bacteriologist. Workers who are familiar with the previous editions will welcome this new edition while those who have not used this book in their laboratories will find it a most useful encyclopædia of information always handy in the laboratory. It is the best 'key' for the identification of organisms of the class Schizomycetes.

C. L. P.

THE ESSENTIALS OF PHYSICAL DIAGNOSIS.—By R. W. Buck, M.D. 1934. W. B. Saunders Company, Limited, London and Philadelphia. Pp. 259. Illustrated. Price, 12s. 6d.

It would appear to be paradoxical that in an age when we rely less and less on physical diagnosis the number of books which purport to deal only with this subject alone should be increasing so rapidly. However, a little thought will show that the paradox is only apparent; the details of physical examination are perhaps not being omitted from the textbooks of to-day, but they are at least being swamped by other matter, so that, in order to impress on the student that the art of physical diagnosis is the first art for the embryo physician to master, it is necessary to provide him (or her) with a special book on the subject.

This book comes from the United States, the home of most of the books of this kind. It is difficult to criticize it in detail; it enjoys the qualities and suffers the defects of its origin, that is to say, it is very complete, but not always discriminating. Some of the names attached to different 'signs' will be unfamiliar to both British- and Indian-qualified medical men.

On the whole the book fulfils admirably the purpose for which it was written, and we can recommend it to the student.

A TEXTBOOK OF NEUROPATHOLOGY.—By Arthur Well, M.D. 1934. Henry Kimpton, London. Pp. viii plus 335, with 260 illustrations. Price, 25s.

In this book the author has made an effort to treat his subject as a pure science. He has not only confined himself to the discussion of microscopic and naked-eye pathology, but has also dealt fully with the chemical and physical aspects of disease of the nervous system. Useful sections are appended dealing with preparation and staining methods, and a comprehensive bibliography is given.

Although the descriptions and excellent reproductions will recommend the book to the specialist and research student, it is doubtful whether it will appeal to the general practitioner. Few clinicians will turn to a work on pure pathology when in difficulty. Its value would perhaps be enhanced if some attention were paid to the interrelation of the pathological findings with the symptoms observed at the bedside.

J. C. D.

A HANDBOOK OF MODERN PHYSIOLOGY.—By R. K. Pal, M.Sc., M.B. (Cal.), D.Sc., M.R.C.P. (Edn.), F.R.S.E., and A. Chakravarti, B.Sc., M.B. (Cal.), M.R.C.P. (Edn.). 1934. The Book Company, Limited, Calcutta. Pp. xiv plus 596. Illustrated. Price, Rs. 7-8

THIS is a summary on the ever-advancing subject of physiology and it is not intended to replace the bigger textbooks. In some places the description is too concise and requires a little elaboration. Yet it contains much useful and up-to-date information and will assist students in preparing for examinations in physiology. The inclusion of brief notes on applied physiology enhances its value. The treatment of chemical aspects are comprehensible and not laborious. Some printing mistakes have been admitted. The paper and printing are satisfactory.

P. D.

A SYNOPSIS OF REGIONAL ANATOMY.—By T. B. Johnston, M.B., Ch.B. Third Edition. 1934. J. and A. Churchill Limited, London. Pp. xxiii plus 460, with 11 illustrations. Price, 12s. 6d.

THE usefulness of this edition of the book has been increased by the addition of the section on osteology, so that the book is now complete in itself. The author in dealing with all the sections has avoided unnecessary anatomical details which tax the memory of students of anatomy, but at the same time by printing them in italics has given prominence to the facts which have a surgical bearing and should be carefully studied. In the description of the muscles the main attachments and actions have been concisely mentioned so that they can be more easily remembered by the student. The relations of the important blood vessels have been carefully given. The section on the nervous system has been revised to include all up-to-date information on the subject. The revised British nomenclature of anatomy, as approved by the Anatomical Society of Great Britain and Ireland, has been used throughout the book with advantage and will be much appreciated on account of its simplicity. A glossary showing the approved changes in the British nomenclature of anatomy has been appended for reference. The book is admirably suited for revision work for which it is intended.

N. P.

MEDICAL ELECTRICITY FOR MASSAGE STUDENTS.—By Hugh Morris, M.D., D.M.R.E. 1934. J. and A. Churchill, Limited, London. Pp. x plus 387, with 103 illustrations. Price, 15s.

THIS work is intended for students doing the course in medical electricity for the examination of the Chartered Society of Massage and Medical Gymnastics.

The author is to be commended for the simple and lucid manner in which he has set forth his facts.

The first portion of the book deals with the elementary principles of electricity. This is followed by the application of these principles in electro-diagnosis and treatment.

The section on treatment is particularly good. The book has an added interest in a series of brief biographies of people prominently connected with the science. It also has an excellent glossary of terms commonly used and an adequate index.

It seems a pity not to have included any section on diathermy even though this subject is only included in the second part of the examination. Also in further editions the author could with advantage include some larger scale drawings of motor points and make these more complete.

We warmly commend the book to nurses and technicians who have to deal with this branch of medicine. Budding electro-therapists will also find much of interest and value to them.

Abstracts from Reports

BENGAL PUBLIC HEALTH REPORT FOR THE YEAR 1932. BY R. B. KHAMBATA, D.P.H., DIRECTOR OF PUBLIC HEALTH, BENGAL

THIS report although somewhat late in making its appearance must be of interest to a large section of the medical profession. The report covering some 200 pages contains valuable matter on all aspects of public health in the broadest sense of the term. Below is an excerpt of some of the salient points of interest.

SOLGANAL-B oleosum

*The safest and most efficient form
of Chrysotherapy in Tuberculosis. •*

Advantages:

Ease of Administration (intramuscular).
Gradual Absorption. Prolonged Action.
Secondary Effects Eliminated.

Highly recommended at the International Tuberculosis Congress
at The Hague by Dumarest and Mollard (France) and Schroeder
(Germany).

The great psychologist,
William James,
Sized man up rightly
As a creature of habit.
His habits once formed,
Man holds on to them
Tenaciously.
Any attempt at change meets
With great resistance.
Regular bowel movement
Is also the result
Of the formation
Of regular habits.
This is possible
When A G A R O L
Is employed
In *constipation*.
For Agarol,

Agarol is the original
mineral oil and agar-agar
emulsion with phenol-
phthalein . . . Palatable,
easily mixed with other
liquids, Agarol is suit-
able for every age period.

The original emulsion
Of mineral oil and
Agar-agar
With phenolphthalein,
Not only softens
The intestinal contents,
But also gently
Stimulates
The peristaltic function
This makes evacuation
Not only easy
But also certain
When a dose,
A tablespoonful,
Is taken
At bedtime.
Soon after breakfast
Next morning
Evacuation
Takes place.
Repeated daily
This soon will grow
Into constant habit.
Regularity
Makes for habit ;
And habit
For regularity.
And Agarol
Promotes both.

VITAL STATISTICS

Estimated population.—The estimated population of Bengal for the year 1932 and the birth and death rates calculated thereon are given below :—

The population of Bengal according to the census of 1931 is 49,901,080. The estimated mid-year population for the year 1931 is calculated to be 50,046,202 (excluding migration) according to the 'natural increase' method. By the same method, the mid-year population for 1932 is estimated to be 50,243,355, and the birth and the death rates per mille are to be 26.4 and 20.3, respectively, as against 26.6 and 20.5 calculated on the census population of 1931.

It will be seen that the birth rate in Bengal is the lowest compared with that of other provinces. The death rate on the other hand is, as in 1931, higher than that of Burma, Assam and North-West Frontier Province, but lower than that of the remaining provinces. The rate of natural increase was 6.1 com-

1932 was 691,737 males and 636,597 females, or a total of 1,328,334 against 722,094, 666,125 and 1,388,219, respectively, in 1931. The birth rate is 26.6 per mille of population in 1932 against 27.8 per mille in 1931. Thus during 1932 the birth rate shows a decrease of 1.2 per mille of population as compared with the corresponding figures for 1931. The birth rate is 26.6 per mille in the previous quinquennium and is the same in 1932. The number of males born to every 100 females in 1932 was 108 and in 1931 the corresponding figure was also 108.

DEATHS AND DEATH RATES

Provincial deaths and death rates.—During the year 1932, 1,022,219 deaths were registered in the province, representing a death rate of 20.5 per mille from all causes. The corresponding figure for the year 1931 is 1,113,312 or 22.3 per mille and 22.6 during the previous quinquennium. The death rate of 1932 was reduced

Comparison of Bengal vital statistics with those of the other provinces

Provinces	Birth rate per mille of population for the year 1932	Death rate per mille of population for the year 1932	Rates of natural increase + or decrease — per mille, 1932	INFANT MORTALITY RATES PER MILLE CALCULATED ON THE NUMBER OF BIRTHS REGISTERED DURING THE YEAR 1932		
				Male	Female	Total
Bengal Presidency ..	26.6	20.5	+ 6.1	184.8	172.4	178.9
Madras Presidency ..	36.03	21.96	+ 14.07	193.62	171.78	182.58
Bombay Presidency ..	35.89	23.04	+ 12.85	164.01	148.12	156.39
United Provinces ..	34.66	22.23	+ 12.43	169.16	155.49	162.72
Punjab ..	41.36	24.70	+ 16.66	182.80	173.72	178.52
Central Provinces ..	45.20	26.89	+ 18.31	215.16	186.40	201.12
Bihar and Orissa ..	33.8	20.6	+ 13.2	138.2	119.0	128.8
North-West Frontier Province.	28.89	20.00	+ 8.89	129.93	128.57	129.34
Burma	27.75	17.30	+ 10.45	196.64	171.85	184.50
Assam	30.06	18.96	+ 11.10	166.05	146.51	156.58

pared with 5.5 per mille in 1931. The infant mortality rate was lower than that in Madras Presidency, Central Provinces and Burma, but higher than that in the others.

BIRTHS AND BIRTH RATES

Provincial births and birth rates.—Excluding still-births, the number of children born during the year

by 8.1 per cent as compared with 1931. It was reduced by 9.3 per cent when compared with the quinquennial figure. It was lowest on record since 1892. 527,968 males and 494,251 females died during the year 1932 while 572,800 males and 540,512 females died during the year 1931. A hundred and six males died to every 100 females. The death rate from various causes is shown below:—

Causes of deaths : death rates per mille

Years	Cholera	Smallpox	Fevers	Dysentery and diarrhoea	Respiratory diseases	Injuries	All other causes	All causes
1932 ..	0.7	0.2	13.8	0.8	1.2	0.4	3.3	20.5
1931 ..	1.6	0.2	14.7	0.9	1.2	0.4	3.3	22.3
Percentage of difference	— 56.3	±	— 6.1	— 11.1	±	±	±	— 8.1

Mortality according to class.—Classified according to class, 551,690 Mussalmans, 439,495 Hindus, 2,327 Christians, 3,114 Buddhists and 25,593 other classes died during 1932, the death rate for Hindus being 20.4 per mille and for Mussalmans being 20.1 per mille. During 1931 the death rates of 21.8 and 22.3 per mille, respectively, were returned against Hindus and Mussalmans. It will thus be seen that the death rates in 1932 both for Hindus as well as for Mussalmans are the lowest on record since 1911.

Mortality according to age.—The death rate for every age period was reduced in 1932 compared with that during the previous year except in the case of the periods under one year. In the age periods 10 to 15 and 15 to 20 years the decrease amounted to 13.0 and 14.1 per cent, respectively.

STATE OF PUBLIC HEALTH IN THE PROVINCE AND THE HISTORY OF CHIEF DISEASES

Cholera.—Cholera claimed 33,910 deaths in 1932, giving a death rate of 0.7 per mille against 79,073 deaths and a rate of 1.6 per mille in 1931, thus showing a decrease of 56.3 per cent.

SMALLPOX

Smallpox claimed 7,910 victims in the province in 1932 against 9,207 in 1931. The death rate was 0.2 per mille in 1932 being the same as in 1931, and 0.5 the mean of the previous five years, showing a reduction of 60.0 per cent against the latter, being stationary in the former. Smallpox was responsible for 0.77 per cent of the total provincial mortality against 0.83 in 1931. One thousand nine hundred and ninety-five villages out of 86,360 were affected with smallpox in 1932 compared with 2,332 in 1931.

FEVERS

Deaths from fever numbered 691,513 in 1932 against 731,784 in 1931. The death rates from fever were 13.8 per mille in 1932, 14.7 in 1931 and 14.7 during the last quinquennium. The fever death rate in this year was thus reduced by 6.1 per cent compared with the previous year as well as the last quinquennium. Excepting kala-azar in which the death rate was a little higher than that of the previous year, there was a general reduction in all other kinds of fever in 1932. Fevers accounted for 67.6 per cent of the total provincial mortality against 65.7 per cent in the previous year.

Kala-azar.—Ten thousand seven hundred and twenty deaths were registered from kala-azar in 1932 with a death rate of 0.21 per mille. Six hundred and forty-six deaths were returned from towns, of which 241 occurred in Calcutta, and 10,074 from the rural areas. Compared with 1931, the death rate in all Bengal towns decreased by 10 per cent and in Calcutta by 16.7 per cent. In rural areas the number of deaths increased by 571, the death rate having increased by 5 per cent. Twenty-five towns returned rates above the provincial urban average (0.18), the highest mortality from kala-azar with 1.0 per mille each having been registered in the Kalna (Burdwan district) and Chandrakona (Midnapur district) municipalities. Out of 118 towns 46 did not record any death from kala-azar. Kala-azar accounted for 1.55 per cent of fever deaths and 1.04 per cent of the total provincial mortality against 1.39 and 0.92 per cent, respectively, in 1931.

Enteric fever.—Compared with the previous year, the death rates from enteric fever in 1932 showed a decrease of 20 per cent in the whole province with a decrease of 25 per cent in the rural areas. But an increase of 14.3 and 10.2 was recorded, respectively, for Calcutta and the urban areas.

Measles.—The provincial death rate from measles in 1932 was 0.01 against 0.06 in 1931. It was stationary in towns, but decreased in the rural areas by 33.3 per cent and increased in Calcutta by 25 per cent. Only five towns returned rates above the provincial urban average (0.7 per mille). No death from measles was reported from 87 out of 118 towns in the province. Measles accounted for 0.3 per cent of fever deaths and 0.2 of the total provincial mortality against 0.4 and 0.3 per cent, respectively, during 1931.

DYSENTERY AND DIARRHŒA

The total number of deaths reported from dysentery and diarrhœa in 1932 was 39,562 with a death rate of 0.80 against 42,764 deaths with a death rate of 0.86 in 1931. The death rate thus decreased by 7 per cent against the previous year rate and increased by 14.3 per cent against the last quinquennium average (0.7). Twenty thousand seven hundred and forty-six males and 18,816 females died from this disease. Taken separately, dysentery accounted for 21,539 and diarrhœa 18,023 deaths in 1932 against 24,014 and 18,750, respectively, in 1931, the corresponding ratios being 0.4

Analysis of fever deaths in 1931 and 1932.

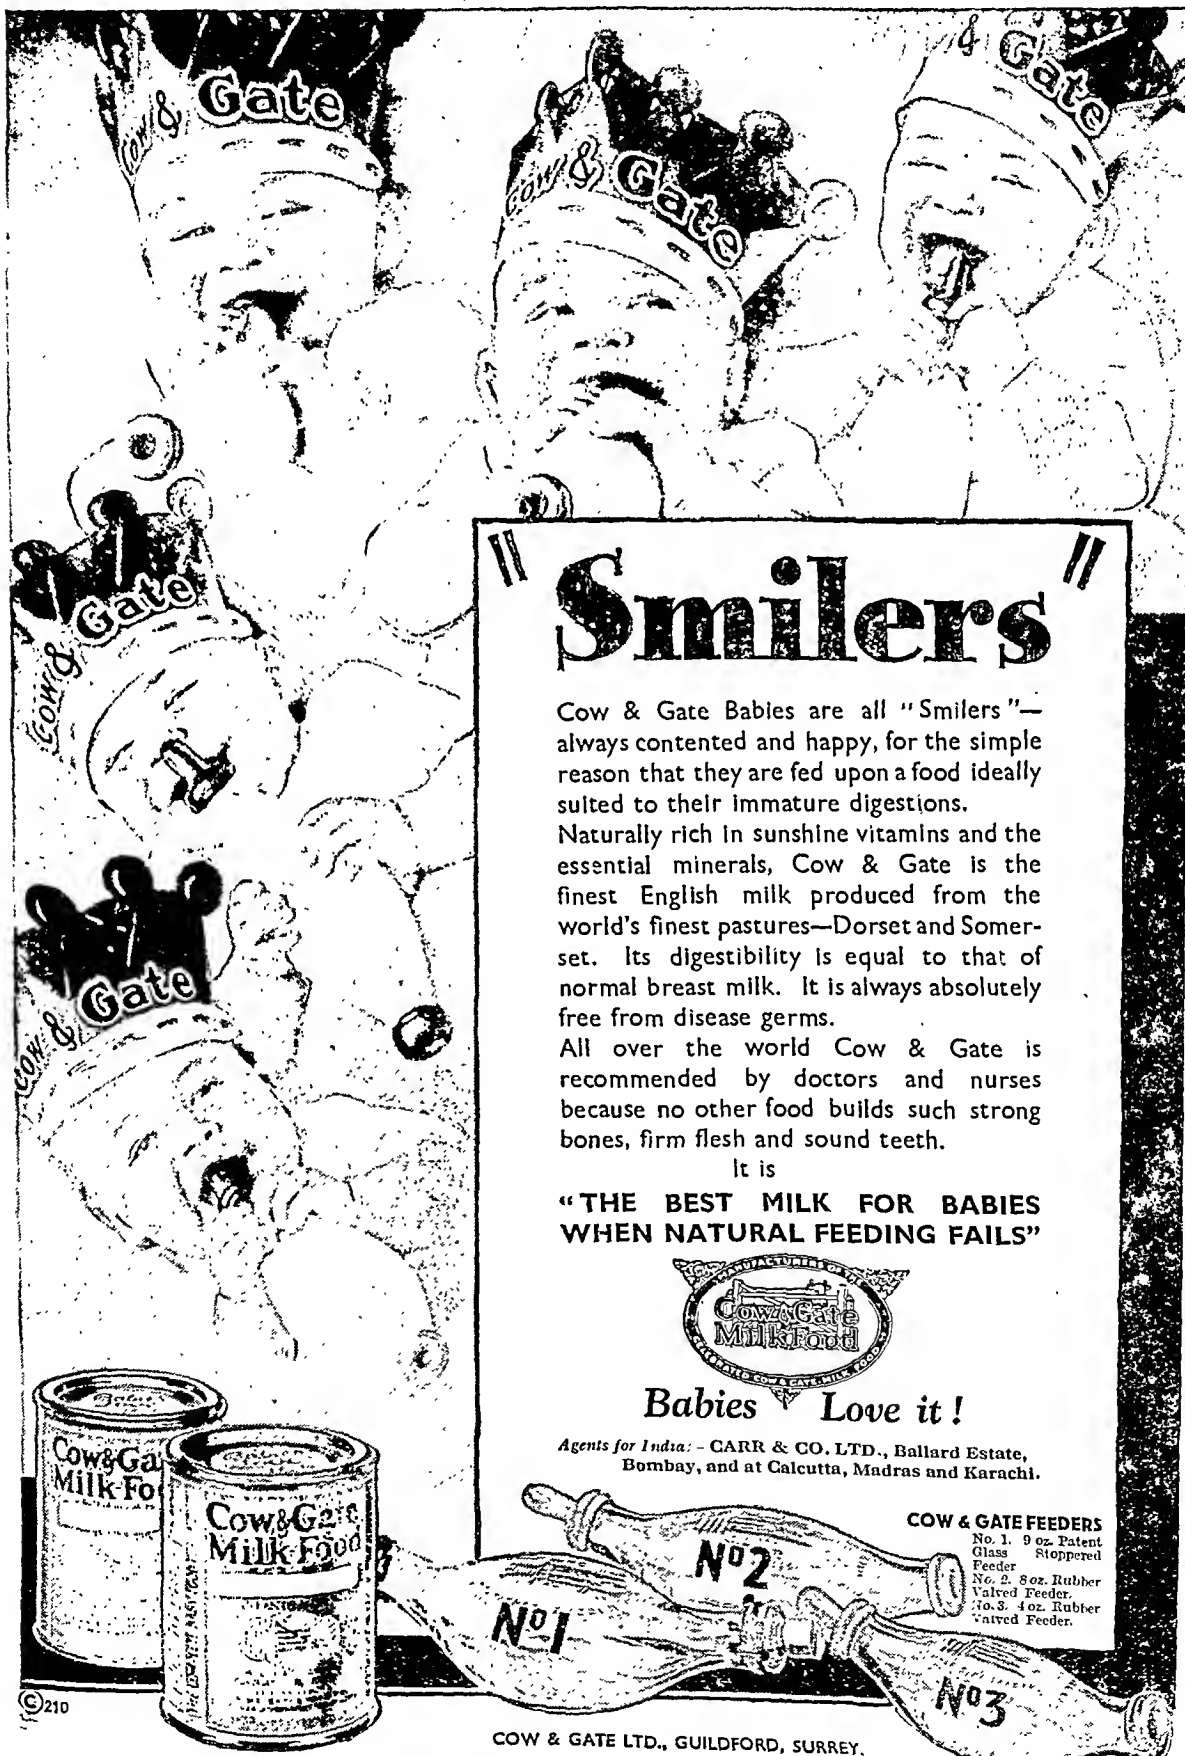

Causes	Number		Death rates per mille		Percentage of increase + or decrease — in 1932	Percentage of total fever mortality	
	1931	1932	1931	1932		1931	1932
Malaria fever ..	349,111	327,386	7.0	6.6	— 5.7	47.7	47.3
Enteric fever ..	12,608	10,176	0.25	0.20	— 20.0	1.7	1.5
Relapsing fever	5,705	4,357	0.11	0.08	— 27.3	0.8	0.6
Measles ..	2,954	2,442	0.06	0.04	— 33.3	0.4	0.3
Kala-azar ..	10,199	10,720	0.20	0.21	+ 5.0	1.4	1.6
Other fevers ..	351,207	336,432	7.0	6.7	— 4.3	48.0	48.7

Quinine consumption.—9,031.3 pounds of quinine were consumed in 1932 against 7,835.5 pounds in 1931. Burdwan, Bankura, Hooghly, Howrah, Calcutta, Khulna, Jalpaiguri, Darjeeling, Rangpur, Dacca, Mymensingh, Bakarganj, Chittagong, Noakhali and Tippera showed increased quinine consumption, although in the Dacca and the Burdwan district the fever indices had fallen in the year under report. Quinine consumption was less than that in the preceding year in the districts of Nadia, Jessore, Dinajpur and Malda, although the fever indices had risen in them during the year. The average consumption per head of population was highest in Chittagong.

and 0.4 against 0.5 and 0.4, respectively, in 1931. Dysentery and diarrhœa accounted for 3.37 per cent of total deaths against 3.84 in 1931.

RESPIRATORY DISEASES

Respiratory diseases were responsible for 62,249 deaths in 1932 with a death rate of 1.2 per mille against 62,351 and 1.24 per mille, respectively, in 1931 showing a decrease of 102 deaths only, i.e., a decrease of 0.16 per cent. The death rate was higher by 24.0 per cent than the provincial quinquennium average. The death rate from pneumonia rose from 0.55 in 1931 to 0.56 in 1932 and those from phthisis and influenza fell from 0.21

Smilers

Cow & Gate Babies are all "Smilers"—always contented and happy, for the simple reason that they are fed upon a food ideally suited to their immature digestions. Naturally rich in sunshine vitamins and the essential minerals, Cow & Gate is the finest English milk produced from the world's finest pastures—Dorset and Somerset. Its digestibility is equal to that of normal breast milk. It is always absolutely free from disease germs.

All over the world Cow & Gate is recommended by doctors and nurses because no other food builds such strong bones, firm flesh and sound teeth.

It is

"THE BEST MILK FOR BABIES WHEN NATURAL FEEDING FAILS"

Babies Love it!

'BYNIN' AMARA

TRADE MARK

A Powerful Tonic and Hæmatinic

'BYNIN' AMARA is of special value in neurasthenia, particularly when associated with low blood pressure, anæmia and atonic dyspepsia ; in convalescence it gives that impetus which often enables the system to overcome the aftermath of disease and to recover completely

'Bynin' Amara has important advantages over Easton's Syrup on account of its basis being 'Bynin' Liquid Malt in the place of syrup. The 'Bynin' Liquid Malt, besides having valuable digestive and nutritive qualities is an efficient solvent for the other ingredients and helps to mask their unpleasant taste.

COMPOSITION :

Quinine Phosphate	-	1½ gr.
Iron Phosphate	-	2 "
Nux Vomica Alkaloids	-	equal to Strychnine ⅛ "
'Bynin' Liquid Malt	-	1 oz.

In bottles containing 10 oz.,
20 oz. and 40 oz.

DOSE : 2 to 4 fluid drachms in water twice or
thrice daily after meals.

Further particulars will be sent
on request.

Allen & Hanburys
Ltd,
LONDON

(Incorporated in England)
Clive Buildings, CALCUTTA

and 0.09 in 1931 to 0.23 and 0.07 per mille, respectively, in 1932. The death rate from other respiratory diseases also rose from 0.35 to 0.38 per mille in 1932. 6.09 per cent of total deaths was due to respiratory diseases against 5.60 per cent in 1931.

INFLUENZA

A reduction of 1,249 deaths from influenza against those in the previous year was reported in 1932. The mortality decreased by 1,295 in the rural areas but it increased in all towns by 46, of which Calcutta alone was responsible for 45. In the province the reduction in the death rate was 22.2 per cent, but there was an increase in all towns of 6.2 per cent. There was an increase in the death rate from influenza in Calcutta also by 7.3 per cent, but the reduction in the rural areas was by 33.3 per cent. Influenza deaths were reported from 35 out of 118 towns, in six of which the death rate was above the provincial urban average (0.2).

PNEUMONIA

The total number of provincial deaths from pneumonia in 1932 was 28,153 with a death rate of 0.56 against 0.55 per mille in 1931. There was an excess of 559 deaths from this cause in 1932 over that of 1931. The death rate increased by 9.1 per cent in the rural areas and decreased in towns by 15.1 per cent, of which Calcutta alone had a reduction by 39.7 per cent. The larger mortality from this cause in 1932 was wholly due to rural areas, although there was a reduction in towns including Calcutta. The death incidence from pneumonia having been on a steady rise since the last ten years, nearly three times what occurred in 1923 (10,767), demands special notice and investigation. Only four towns (Jaynagar, Netrokona, Bajitpur and Patuakhali) did not return any death from this cause.

PHTHISIS

General prevalence.—Deaths reported from this cause numbered 11,801 in the province in 1932 showing a decrease of 437 against the previous year. The decrease was wholly due to towns and numbered 472, although there was an increase in the rural areas by 35. The death rates, however, were lower than those in the previous year by 13.2 per cent in all towns and 14.4 per cent in Calcutta. The provincial death rate from phthisis was reduced by 4.2, while the rates in the rural areas remained unchanged. 70.0 per cent of the deaths in all towns occurred in Calcutta alone.

MALARIA

A. ludlowii menace to Calcutta.—There was an epidemic of malaria in the jute mill areas at Budge-Budge in 1930. An investigation was carried out by the Department of Public Health, Bengal, and it was found that *Anopheles ludlowii* were at the root of this epidemic. The mosquitoes were subsequently found to be creating similar havoc on the other side of the river Hooghly at Chengail in the beginning of 1931. As the discovery of the species so close to Calcutta, Budge-Budge being only 12 miles from Calcutta, was a serious threat to the port of Calcutta and the health of the city in general, Government convened a special conference in March 1931 to consider the desirability of carrying on a proper investigation into the *ludlowii* position in the vicinity of Calcutta. A survey party with an entomologist at the head was sanctioned and a further investigation was started in May 1931. This survey revealed the breeding of *A. ludlowii* mosquitoes in other areas as well, for instance in Uluberia on the Bengal Nagpur Railway, the tract along the river Bidyadhari from Port Canning to Champahati, Taki, Basirhat, Hasnabad, Falta, and the neighbouring villages. In April 1932, the village Nabasan about five miles from the Salt Lake area was also found infested. Then, the Salt Lake itself to the east of the city was actually found to be involved in *ludlowii* breeding. In December 1932, *A. ludlowii* were discovered at Nawapati, Mahishbathan and Kristopur, all

situated within 4 to 5 miles from the municipal limits of Calcutta. During this period the transportation of *A. ludlowii* mosquitoes to the city by trains and country boats was also established. Adult mosquitoes of this species were frequently caught from trains at Howrah, Majherhat and Shambazar stations belonging to the different railways. Adults were similarly found to be carried by country boats at Kristopur.

ANNUAL REPORT OF THE BERRY WHITE MEDICAL SCHOOL, DIBRUGARH, ASSAM, FOR THE YEAR 1933-34. BY COLONEL J. P. CAMERON, C.S.I., C.I.E., V.H.S., I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, ASSAM

The following are a few excerpts from the report which will give one an idea of the general progress and condition of the school:—

The lack of funds continued to handicap seriously the expansion of the school in many directions, but various minor improvements were carried out.

The arrangement proposed last year to treat Police sick in the Civil Hospital and utilize the Police Hospital buildings for hostel purposes was not brought into operation. The Police insist upon having self-contained hospital accommodation provided apart from the general wards, and if funds can be made available, this is to be done. The scheme as previously suggested will then be carried out, and the additional hostel accommodation required will be available.

The only building improvements undertaken during the year were annual repairs to existing buildings, a few minor alterations and additions in the wards of the Civil Hospital and the linking up of one of the students' dining halls with the kitchen by a covered passage.

The Superintendent has brought to notice various requirements necessary for adding to the efficiency of the school. These will be met in order of urgency as funds permit.

A considerable sum was spent last year in providing instruments and appliances which were found necessary. Additional expenditure will have to be incurred this year in purchasing equipment for the physiological department.

Sanction was accorded during the year to the appointment of additional demonstrators in pathology and anatomy to take effect from the current financial year. These appointments will enable practical instruction in these subjects to be carried out more efficiently.

The question of improving practical instruction in public health and hygiene, by arranging for the Assistant Director of Public Health (Assam Valley) to attend the school for a specified period each year to train the students, is under consideration.

The desirability of deputing assistant surgeons and sub-assistant surgeons selected for teaching appointments for special courses of instruction in their respective subjects to the Calcutta Medical College and Campbell Medical School, respectively, prior to joining their appointments, is also under consideration. This, it is thought, would go a long way to raising the standard of medical education in the school.

Twenty-two labour cases were attended by the senior students during the year, against 17 in the previous year. No headway has been made in the matter of providing a properly equipped female hospital at Dibrugarh, owing to financial stringency. There is some hope, however, of this project going forward this year, as funds are likely to be forthcoming from a private source. The training of students in midwifery and gynaecology is greatly handicapped for want of a properly equipped women's hospital, as patients will not come forward freely for treatment under existing conditions.

The x-ray plant has been thoroughly overhauled by Lieut.-Colonel Sen, who is an expert radiologist, and very shortly this section will be quite up to date.

In no cases were vaccines or any other treatment necessary. Generally three sittings were enough, one every second or third day and, what is more noteworthy, no patients were off work; the pain lasted for about fifteen minutes to half an hour and the patient went back to work with the needle-rack closed up by means of collodion or tincture of benzoin.—Yours, etc.,

CALCUTTA MEDICAL COLLEGE CENTENARY
For all past students of the Calcutta Medical College
To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In connection with the centenary of the Calcutta Medical College to be commemorated early next year, it is proposed to compile a volume giving a history of the origin and growth of this institution which has played such a large part in offering modern medical education and medical relief during the last 100 years. The compilers have tried their best to get together a connected link of history and progress. Thinking that some old student or their descendants might enlighten us with old records, certificates of merit, or photographs connected with the institution, we take the liberty of appealing to all such gentlemen or ladies to communicate with me indicating the nature of such records.—Yours, etc.,

A. C. UKIL,

Secretary and Convenor,
Centenary Volume Sub-Committee,
Medical College Centenary.

MEDICAL COLLEGE HOSPITALS,
CALCUTTA,
30th September, 1934.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL F. R. THORNTON, Civil Surgeon, Ahmedabad, on relief by Lieutenant-Colonel A. H. Harty, to be Civil Surgeon, Dharwar, *vice* Lieutenant-Colonel Shah

Lieutenant-Colonel B. Z. Shah, Civil Surgeon, Dharwar, to be Superintendent of Mahabaleshwar.

Lieutenant-Colonel A. H. Harty, on relief by Lieutenant-Colonel Candy, to be Civil Surgeon and Superintendent, B. J. Medical School and Mental Hospital, Ahmedabad.

Lieutenant-Colonel R. H. Candy to be Civil Surgeon and Superintendent, B. J. Medical School, Poona, on return from leave *ex-India*.

Lieutenant-Colonel C. E. Palmer, Inspector-General of Prisons, United Provinces, is appointed to officiate as Inspector-General of Civil Hospitals and Prisons, Assam, with effect from the afternoon of the 7th January, 1934, until further orders, *vice* Colonel J. P. Cameron, granted leave.

The services of the undermentioned officers of the Indian Medical Service are placed permanently at the disposal of the Government of Madras, with effect from the date mentioned against each:—

1. Lieutenant-Colonel M. M. Cruickshank, 25th February, 1931.

2. Major A. I. Cox, 1st February, 1932.

3. Major J. A. W. Ebdon, 1st February, 1932.

The services of Major R. S. Aspinall are placed at the disposal of the Chief Commissioner, Delhi, for appointment as Civil Surgeon, New Delhi, with effect from the 16th October, 1934.

Captain H. S. Smithwick to be Civil Surgeon, Sholapur.

LEAVE

Colonel J. P. Cameron, C.S.I., C.I.E., V.H.S., Inspector-General of Civil Hospitals and Prisons, Assam, is granted leave on average pay for 1 month and 7 days, with effect from the afternoon of the 7th January, 1935, preparatory to retirement.

PROMOTIONS

Major to be Lieutenant-Colonel

W. J. S. Ingram, M.C. Dated 30th September, 1934.

To be Lieutenant (on probation)

V. M. Albuquerque. Dated 5th June, 1933, with seniority from 5th June, 1932.

Lieutenant (on probation) to be Captain

V. M. Albuquerque. Dated 1st May, 1934.

Notes

ACRIFLAVINE B.D.

Of the flavines, by far the most generally known and widely used is Acriflavine.

Properties.—Acriflavine is a yellowish-red crystalline powder, extremely soluble in water, forming a clear solution which remains bright on the addition of normal saline. Isotonic solutions of Acriflavine can be prepared readily and quickly, and they may be used for injection without filtration.

Solutions of Acriflavine are slightly acid in reaction. For this reason, unless it be at greater dilution than 1 in 1,000, its use is not recommended for intravenous injections, its neutral form, Eusflavine, being preferred.

Solutions of Acriflavine are perfectly stable up to 130°C.; hence, although they are aseptic in the ordinary way, they may be sterilized by heat, if required, without risk of decomposition. They should be stored in amber-coloured bottles, as, under the influence of light, a deposit is gradually formed.

Acriflavine has been tested for bactericidal action against well-known organisms in comparison with other antiseptics, such as mercuric chloride, iodine, silver nitrate and phenol, and it has been proved that unlike other disinfectants the high antiseptic power of Acriflavine is not only undiminished in the presence of serum, but is actually enhanced. In the presence of serum, Acriflavine is 800 times more powerful than phenol, and more than 20 times more powerful than mercuric chloride.

Acriflavine owes its value largely to the fact that it is absolutely non-toxic to the tissues and to phagocytes: thus, when used in the treatment of wounds, Acriflavine does not inhibit the natural healing processes; on the contrary, by creating a powerful antiseptic zone, it actually increases considerably the rate of healing.

At the strength at which it is generally used (1 in 1,000), Acriflavine is only very slightly acid, and it is practically non-irritant even to mucous surfaces.

In the treatment of wounds.—Acriflavine 'B.D.' has become the standard antiseptic for use in wound dressing; for this purpose a 1 in 1,000 solution (in saline or in water) is usually employed, but a much weaker solution is often found to be sufficiently active, a 1 in 100,000 solution being strong enough to kill organisms suspended in serum. On the other hand, a 1 in 500 solution may be applied to injured tissues with perfect safety and without risk of causing pain or any injury to the tissues.

SUCKING DISSECTORS FOR TONSIL ENUCLEATION

By R. R. WOODS, F.R.C.S.I.

THE idea of a tonsil enucleator which also removes the blood from the field of operation is so simple and such a good one in practice that one wonders that it
